Appendix K

Meat, Milk, and Egg Transfer Coefficients

K.1 Chemical Transfer Coefficient (Tco) Derivation Methodology

Meat, cow's milk and eggs can become contaminated when food-producing animals inhale or ingest contaminated materials that then transfer into these food products. The transfer coefficients (Tco) presented in Tables K.1 and K.2 were derived from published studies investigating chemical concentrations in food products resulting from animal intake of the chemical. In most studies, the chemicals were mixed into the animal's feed, although some studies investigated the bioaccumulation of chemicals from contaminated soil in poultry feed. The Tcos, expressed in day/kilogram (d/kg), represent the ratio of contaminant concentration in fresh weight animal product (in mg/kg, for example) to the daily intake of contaminant by the animal (in mg/day). Tcos were determined only for the main food-producing animal sources, including cow's milk, eggs, and meat from cattle, pigs and chickens.

The studies selected to estimate Tcos were usually of long enough duration to allow steady-state concentrations to be reached in milk-, meat- and egg-producing animals. Steady-state concentrations in the tissues are a function of the tissue elimination half-lives (MacLachlan and Bhula, 2008). Assuming a first-order process, an exposure duration that is five times greater than the tissue elimination half-life has been used to represent time to steady-state conditions (i.e., the ratio of the measured concentration at five half-lives to steady-state concentration is 0.968).

Realistically, fast-growing animals used for food may never attain a true tissue steady-state for persistent organic chemicals due to the competing factors of growth, fattening and lactation (Fries, 1996; Hoogenboom, 2005). A steady-state concentration in food-producing animals will likely be reached more quickly than in humans due to these factors and may even show declining levels in fat during the fattening phase of the animals' prior to slaughter (Fries, 1996). The most practical approach is to base the Tco on exposure studies that expose the animal for a majority of the animals' life span up to or near marketable weight. The studies that followed tissue and milk contaminant levels during exposures over most of the animals' productive lifespan have shown that a sufficient semblance of steady-state is reached during the productive life of lactating dairy cattle and laying hens, and in meat animals prior to slaughter.

Default consumption rates of contaminated feed were used for estimating Tcos if no consumption data were provided in the primary studies. Usually, the food-producing animals in biotransfer studies were caged or treated similar to commercial farming practices. However, this exposure assessment document is primarily concerned with small farm or family farm situations in which the food-producing animals may be allowed to roam more freely than in commercial operations. This is particularly relevant for pigs and chickens. Free-range and organic farming will result in greater feed intake, slower

growth, and potentially greater contaminant exposure from range forage and soil ingestion (MacLachlan, 2010).

Specifically regarding poultry food products, the term “poultry” refers to a number of avian species that are food sources for humans. Due to the substantial human consumption of eggs and meat from chickens, the Tcos described here were exclusively based on data from chickens, laying hens (usually Leghorns) for the egg Tcos and usually meat chickens (broilers) for the meat Tcos. However, these values could also be reasonably applied to other home-raised avian species, such as turkeys and quail.

Compared to chickens and dairy cattle, fewer swine and beef cattle exposure studies could be found to estimate the biotransfer of ingested contaminants to muscle tissue. Rather than simply adopting the same cattle Tco values for swine when biotransfer data are lacking, contaminant transfer models are employed by OEHHA to estimate differences in chemical accumulation among livestock. For transfer of organic lipophilic chemicals, MacLachlan (2009) developed Physiologically Based Pharmacokinetic (PBPK) models to derive scaling factors that are used to assist the extrapolation of transfer studies, carried out most often on lactating dairy cows, to beef cattle and pigs. Given the estimated half-life (or extraction ratio for liver) of the chemical in the animal and the ratio of the chemical concentration in milk fat to body fat of dairy cows, the appropriate scaling factor can be selected and combined with the Tco derived from lactating dairy cattle to improve estimates of residues in beef cattle and pigs.

For metal Tcos, a metabolic weight adjustment can be made that accounts for differences in tissue transfer of chemicals in animals of different weight (i.e., a lower metabolic rate is expected in larger animals such as cattle compared to smaller animals such as swine, resulting in slower rates of transfer into tissues). A similar metabolic weight approach has been used to estimate the transfer of metals to dairy cattle from data in sheep (Crout et al., 2004). This adjustment is reasonable considering most of the metal compounds of interest have passive uptake and elimination processes and are subject to little or no metabolism.

The effect of metabolic weight is apparent when comparing the meat Tco values between chicken and cattle in Tables K-1 and K-2. Where published data were used to directly estimate individual chemical Tco values, the chicken Tcos were greater than cattle Tcos. For chemicals in which biotransfer could not be estimated from published reports in pigs, a default meat Tco was estimated with the following formula:

$$\text{Pig } Tco_i = (W^{0.75}_{cow}) / (W^{0.75}_{pig}) \times \text{cow } Tco_i \qquad \text{Eq. K-1}$$

Where: $W^{0.75}_{cow}$ = live-weight in kg of a cow to the 0.75 power

$W^{0.75}_{pig}$ = live weight in kg of a pig to the 0.75 power

Pig Tco_i = pig meat Tco for chemical i

Cattle Tco_i = cow meat Tco for chemical i

Using average live weights of 500 kg for cattle and 60 kg for swine, the metabolic weight ratio adjustment is 4.8.

Table K.1 Meat, Milk and Egg Transfer Coefficients for Persistent Organic Chemicals

Organic Chemical	Tcos (d/kg)[a]				
	Cow's Milk	**Chicken Egg**	**Chicken Meat**	**Cattle Meat**	**Pig Meat**

[a] All Tco values were rounded to the nearest whole number.
[b] The meat Tco was estimated using the metabolic weight adjustment ratio of 4.8 from cattle to pig
[c] NA – no data available or were not applicable

Speciated data existed that allowed the derivation of individual Tcos for polychlorinated biphenyls (PCBs) and polychlorinated dibenzo-p-dioxins and furans (PCDD/F), shown in Table K.1, that are of toxicological concern under the "Hot Spots" program. Tcos for unspeciated mixtures of PCBs and PCDD/Fs have also been calculated by OEHHA from literature sources and are shown in Table K.1. In risk assessments in which only the unspeciated mixture is determined, OEHHA recommends using the Tcos for PCB126 to represent the PCBs, and the Tcos for 2,3,7,8-TCDD to represent the PCDD/F's. These compounds are one of the most persistent and toxic congeners within their respective classes. The unspeciated Tco values in K.1 are for only comparison to the other Tco values. Different emissions sources of these chemicals may result in different mixtures of PCBs and PCDD/Fs, and thus influence the unspeciated Tco value.

K.2 Tco Derivations for Milk, Meat and Eggs

K.2.1 Semi- and Non-Volatile Organic Chemicals

The exposure studies used to derive organic compound Tcos often normalized the muscle tissue, egg and cow's milk contaminant concentrations to their respective fat content. The Tcos presented here are based on fresh, whole meat, egg and milk concentrations of the contaminants. If necessary, the fat concentration of a chemical was adjusted to the average fresh weight concentration using fat content default factors derived from reference sources: 0.11 for egg, 0.07 for chicken meat, 0.19 for beef cattle meat, 0.23 for pig meat, and 0.04 for cow's milk (Malisch et al., 1996; Pirard and De Pauw, 2005; U.S. EPA, 2005). If only the fat concentration of the organic chemical in egg yolk was provided in the key study, the fresh weight whole egg concentration was derived based on a fat content default value of 0.30 for yolk, and a yolk volume of 0.32

for the whole egg. If the study determined the fat content in food products, these were used for adjustment to fresh weight concentration in lieu of the default values.

For chicken meat, organic chemical content in skin was usually not included by the studies, although skin has a higher fat content and is often consumed with the meat. This would suggest that the skin could have a higher contaminant content than the muscle tissue. Due to lack of skin chemical concentration data and potential loss or destruction of organic chemicals in skin when the meat is cooked, the concentration of chemical in skin was considered similar to the concentration of a chemical in muscle for Tco derivation.

In general, extensive bioaccumulation of persistent, organic chemicals is not as great in either beef or dairy cattle as might be expected, even though beef cattle have no major fat excretion pathway as dairy cattle do with milk production (McLachlan, 1996). This finding is a result of the short life spans and rapid growth dilution that is characteristic of modern animal husbandry. A beef cow develops 100-150 kg of fat in which to deposit the chemical that it absorbs over its 1.5-year life. While a milk cow might excrete its absorbed contaminant in 300 kg of milk fat over the same period, it consumes more feed (and contaminant) in this time. Hence, the chemical concentrations in milk fat were not always much lower compared to beef fat (McLachlan, 1996; RTI, 2005).

Interestingly, the lower-than-expected bioaccumulation of persistent, hydrophobic chemicals in cow's milk does not translate to human milk (McLachlan, 1996). Persistent, organic chemicals tend to bioaccumulate in human milk by an order of magnitude greater than in cow's milk, presuming similar chemical concentrations in the diet on a mg/kg basis. This pronounced difference in bioaccumulation is due to a more limited capability of humans to excrete these chemicals. In addition, the extent of contaminant absorption from food in the human digestive tract may be greater. For example, nursing human infants absorb over 95% of PCBs and most PCDD/Fs while absorption in cows for these same compounds averages closer to 80%.

K.2.1.1 Diethylhexylphthalate (DEHP)

At high concentrations (1% DEHP in feed), Tcos for chicken eggs and breast muscle were estimated by OEHHA to be 0.04 and 0.002 d/kg (Ishida et al., 1981; Ishida, 1993). The low transfer values for DEHP relative to other organic chemicals are likely due to rapid metabolism and excretion of DEHP in the chicken.

In dairy cattle, DEHP was observed to be extensively metabolized prior to secretion into the milk (Bluthgen and Ruoff, 1998). OEHHA surmised that much of the metabolism begins in the rumen, where DEHP ester-bond cleavage would occur. Consequently, steady-state is reached in about 7 days and a low milk Tco of 9×10^{-5} d/kg was calculated by OEHHA. Cessation of DEHP administration resulted in nearly undetectable milk levels within 3 days post-exposure. No data could be found regarding residue levels of DEHP in cattle muscle, so a Tco of 4×10^{-4} d/kg was estimated after adjusting for the average fat content difference between cow's milk and cattle muscle. PBPK modeling by MacLachlan (2009) observed a ratio of about 1.5 for residues of

highly metabolized lipophilic compounds, such as DEHP, in body fat of non-lactating cows and steers to the same compound in body fat of lactating dairy cows. Thus, the Tco of 4×10^{-4} d/kg was increased by a factor of 1.5 to arrive at a Tco of 6×10^{-4} d/kg for DEHP in meat of beef cattle.

Bioaccumulation data are lacking for DEHP in pigs. Thus, a scaling factor by MacLachlan (2009) was applied for the transfer of lipophilic xenobiotics from lactating cattle to other livestock species. For chemicals such as DEHP that are extensively metabolized in the animal and have a short half-life ($t_{1/2}$ <5.8 d in lactating cows), the ratio of simulated residues in the body fat of pigs to the body fat of lactating dairy cows was essentially equal to 1. Therefore, the dairy cattle muscle Tco determined above (4×10^{-4} d/kg) was only adjusted for the difference in muscle fat content in pig to beef cattle (ratio = 1.2) to arrive at a default Tco of 5×10^{-4} d/kg for pig meat.

K.2.1.2 Hexachlorobenzene (HCB)

HCB in the atmosphere is predicted to be predominantly in the vapor phase (Lane et al., 1992). However, due to the extreme persistence of HCB and other chlorinated organic compounds in the environment, deposition and accumulation of non-volatile forms of these organics onto crops, soil and sediment are significant pathways of exposure (Eisenreich et al., 1981; Kelly et al., 1991; Douben et al., 1997; Horstmann and McLachlan, 1998).

In dairy cattle, two studies recorded nearly identical cow's milk HCB Tcos of 0.015-0.016 d/kg with 60-70 days of exposure (Fries and Marrow, 1976; Firestone et al., 1979). The data suggested near steady-state levels in milk were attained with this duration of exposure. A higher Tco of 0.030 d/kg was recorded in pregnant dairy cattle after about 8 months of exposure (Vreman et al., 1980). Steady-state was reached in milk of the pregnant dairy cattle after about 5 months. The average HCB Tco from these three studies is 0.02 d/kg.

In his review, Kan (1978) provided bioaccumulation data from which to calculate Tcos for HCB. The Tco for egg and chicken muscle were estimated at 16 and 13 d/kg, respectively.

In beef cattle, steady-state levels of HCB were at or near attainment in subcutaneous fat following ten weeks of exposure in the feed (Dingle and Palmer, 1977; RTI, 2005). A muscle Tco estimated from this study was 0.090 d/kg. Exposure to HCB in dairy cattle provided similar Tco values. A muscle Tco of 0.070 d/kg was calculated from HCB concentrations in body fat of lactating dairy cattle following 60 day exposure in the feed (Fries and Marrow, 1976). An eight-month HCB exposure in dairy cattle resulted in a muscle Tco of 0.16 d/kg (Vreman et al., 1980). Because the Vreman study provided a considerably longer exposure overall for cattle, the Tco was based on this study. The PBPK-based scaling factor data by MacLachlan (2009) was applied to estimate the transfer of HCB from lactating cattle to body fat of steers. Using data supplied by Fries and Marrow (1976), a slow elimination half-life of HCB in lactating dairy cattle (average: 50 days) and a small ratio for milk fat concentration over body fat concentration at

steady state (0.04) suggests that the PBPK-generated ratio of simulated HCB level in body fat of steers to body fat of lactating dairy cows would be about 1.5. The final default beef Tco is 0.24 d/kg (0.16 d/kg x 1.5)

No data for HCB accumulation in pig muscle tissue could be found. Therefore, a PBPK-based scaling factor was also applied to estimate the transfer of HCB from lactating cattle to pigs (MacLachlan, 2009). The PBPK model results generated a ratio of 0.5 for the simulated HCB level in body fat of pigs to body fat of lactating dairy cows. The final default pig Tco is 0.08 d/kg (0.16 d/kg x 0.5)

K.2.1.3 Hexachlorocyclohexanes (HCH)

HCH Tcos of 7.3 d/kg for egg and 5.1 d/kg for chicken meat were calculated from contaminated feed data provided by Kan (1978) and Szokolay et al. (1977). The beta-isomer tended to have roughly 10-fold greater bioaccumulation in poultry egg and muscle than the other major isomers (i.e., alpha and gamma isomers), but is generally found to a lesser extent in the environment. Hence, the Tcos represent a mean of the three major HCH isomers. MacLachlan (2008) developed a model that adequately reproduced the pattern of lindane (gamma-HCH) residue levels in fat and eggs of hens consuming contaminated feed. Utilizing the authors' data, the egg and muscle Tcos at steady-state were estimated to be 1.3 and 1.5 d/kg, respectively. These lindane Tcos were similar to those calculated from data by Kan (1978) and Szokolay et al. (1977) for eggs, 1.7 and 4.2 d/kg, respectively, and in muscle, 1.8 and 1.2 d/kg, respectively.

As in eggs and meat, the major isomers of HCH (alpha-, beta-, and gamma-HCH) had different patterns of accumulation in cow's milk. The beta isomer has the largest transfer factor, 0.025 d/kg, but generally is in the smallest proportion relative to the other 2 major isomers found in the environment (van den Hoek et al., 1975; Vreman et al., 1976; Vreman et al., 1980). Average Tco values for the alpha- and gamma- (Lindane) isomers were 0.0054 and 0.0014 d/kg, respectively (Williams and Mills, 1964; van den Hoek et al., 1975; Vreman et al., 1980; Surendra Nath et al., 2000). An average Tco for these three HCH isomers is 0.011 d/kg. Surendra Nath et al. (2000) provided data for the industrial grade HCH isomer mixture resulting in a Tco of 0.003 d/kg. The HCH mixture contained 21% gamma-HCH, but further speciation data were not included.

Vreman et al. (1980) fed dairy cows diets containing alpha- and beta-HCH for up to eight months. The calculated muscle Tcos were 0.045 and 0.19 d/kg for alpha- and beta-HCH, respectively. For lindane (gamma-HCH), a Tco of 0.027 d/kg was calculated from a different study following 12-week exposure in non-lactating dairy cattle (Claborn et al., 1960).

We applied a scaling factor by MacLachlan (2009) to estimate the transfer of HCHs from lactating cattle to beef cattle. Using data supplied by Vreman *et al.* (1980) that showed a cow's milk elimination half-life of 9-19 days for alpha- and beta-HCH, and the data by van den Hoek et al. (1975) that showed similar levels of HCH isomers in milk fat and body fat, the PBPK-generated ratio of simulated HCH levels in body fat of steers to body fat of lactating dairy cows is approximately 2. We multiplied the alpha- and beta-

HCH Tcos of 0.045 and 0.19 d/kg, respectively, which were determined in dairy cattle by the scaling factor of 2. The gamma-HCH Tco remained unchanged since non-lactating cows and steers have similar steady state HCH levels in body fat. The average Tco for these three isomers is 0.17 d/kg and is the recommended Tco for beef cattle.

No data for HCH accumulation in pig muscle tissue could be found, so we used a scaling factor by MacLachlan (2009) to estimate the transfer of HCHs from lactating cattle to pigs. Based on the HCH half-lives and milk fat to body fat ratios in dairy cattle discussed above, the PBPK-generated ratio of simulated HCH levels in body fat of pigs to body fat of lactating dairy cows is very close, or slightly greater, than 1. Thus, Tcos of the three isomers in lactating and non-lactating dairy cows were averaged by us and used as the default for pig meat (0.045 + 0.19 + 0.027 d/kg / 3 = 0.087 d/kg).

K.2.1.4 Polycyclic Aromatic Hydrocarbons (PAH)

Although there are a considerable number of studies investigating PAH exposure in the environment, there are surprisingly few studies that provide reliable data for estimating Tcos in food-producing animals. Exposure of fish, poultry and dairy cattle to a mixture of PAHs results in the presence of mainly low molecular weight PAHs (i.e., three or four cyclic rings) in the fat of meat and milk (Meador et al., 1995; Grova et al., 2000; Grova et al., 2002; Schaum et al., 2003; Lutz et al., 2006). Many of the high molecular weight PAHs with five or more cyclic rings, such as benzo[a]pyrene (BaP), are known carcinogens or possible carcinogens. Bioaccumulation of PAHs declines with increasing number of aromatic rings and the associated increase in K_{ow}, likely due to both lower gut assimilation efficiency and increased metabolism rate. Another factor appears to be that lower levels of the larger carcinogenic PAHs contaminate pastures and feed compared to the smaller PAHs, often resulting in animal milk and tissue concentrations below the detection limits of analysis equipment (EC, 2002). For example, Muhlemann et al. (2006) found that the larger carcinogenic PAHs in contaminated feed comprised only 8.3% of total PAHs, while the smaller PAHs of four rings or less contributed most of the remaining fraction.

Broiler chickens fed a diet containing low levels of PAHs found in de-inking paper sludge did not exhibit increased PAH levels in abdominal fat for nearly all carcinogenic PAHs examined (Beauchamp et al., 2002). However, the low molecular weight PAHs fluoranthene and pyrene showed increasing levels in abdominal fat with increasing levels of PAHs from paper sludge in the diet of broilers. The carcinogenic potential of these PAHs are undetermined, due to inadequate evidence of carcinogenicity in animals. The calculated broiler muscle Tco for total PAHs was 0.003 d/kg (due mainly to accumulation of pyrene and fluoranthene), and the individual PAH Tcos for pyrene and fluoranthene were 0.1 and 0.04 d/kg, respectively. The total PAH Tco of 0.003 d/kg was chosen as a poultry muscle default value for PAHs, as Tcos for the larger carcinogenic PAHs would likely not surpass this value. No data could be found for PAH accumulation in eggs. Thus, the poultry muscle Tco was also applied to the egg Tco.

The presence of PAHs in milk and milk products suggests that these foods can represent a significant part of human intake of PAHs (Schaum et al., 2003). Among PAHs, the lightest and least lipophilic ones, such as naphthalene, phenanthrene, fluoranthene and pyrene, are detected in the greatest amounts in milk from farms exposed to airborne PAHs (Grova et al., 2000; Grova et al., 2002; Cavret et al., 2005; Lutz et al., 2006). Higher molecular weight PAHs with more than four rings, including possible carcinogens or known carcinogens such as BaP, chrysene and benz[a]anthracene, have been largely undetectable in cow's milk. Of the larger carcinogenic and possibly carcinogenic PAHs, only benz[a]anthracene was detected in tank milk (pooled milk from many cows) sampled near several potential contamination sources (Grova et al., 2002). Levels of this PAH in milk fat ranged from 1.9-2.2 ng/g in milk fat (approximately 0.08-0.09 ng/g in whole milk).

Based on the pasture grass concentrations and corresponding cow's milk concentrations of the three most abundant PAHs (phenanthrene, anthracene, and pyrene) from 10 rural and urban farms investigated by Grova et al. (2000), the range of PAH Tco values in milk were 0.02 to 0.002 d/kg. However, some assumptions were made to arrive at this estimate, including pasture grass as the only source of ingested PAHs, and intake of pasture grass ranged between 10 to 100% of the cow's diet.

A cow's milk Tco range of 0.002 to 2 x 10^{-5} d/kg for total PAHs was calculated by OEHHA from the risk assessment by Muhlemann et al. (2006), based on measurement of total PAHs (roughly 19 PAHs measured) in contaminated feed. Although BaP consisted of only 1.5% of total PAHs, the calculated Tco was within an expected range of 0.013-0.00013 d/kg for BaP. We chose a cow's milk Tco of 0.01 d/kg for total PAHs based primarily on the high-end accumulation of BaP in cow's milk from Muhlemann et al. The recommended Tco is also within the range of 0.02 to 0.002 d/kg estimated for PAHs from data published by Grova et al. (2000).

No data could be found regarding residue levels of PAHs in cattle muscle. The ratio of simulated PAH residues in body fat of steers to body fat of lactating dairy cows for extensively metabolized lipophilic compounds is about 1.4, based on PBPK modeling (MacLachlan, 2009). Assuming equal PAH concentrations in milk fat and body fat of dairy cattle, and application of a scaling factor of 1.4 for dairy cattle to steers, we calculated a default beef Tco for PAHs of 0.067 d/kg (0.01 d/kg x 0.19/0.04 x 1.4).

Accumulation data are also lacking for PAHs in pigs. Using the assumptions from MacLachlan (2009) for transfer of extensively metabolized lipophilic compounds to body fat in livestock, the ratio of PAHs in body fat of pigs to dairy cattle is close to 1. Based on a milk Tco of 0.01 d/kg, adjusting for fat content in pig meat and a scaling factor of 1, we calculate a default pig meat Tco of 0.058 d/kg (0.01 d/kg x 0.23/0.04 x 1).

K.2.1.5 Polychlorinated Biphenyls (PCB)

Specific congener Tcos are recommended due to variation in absorption and metabolism of PCBs in dairy cattle, and also due to the degree of chlorination and the position of the chlorine atoms. Some PCBs are transferred effectively unchanged from grass to milk and dairy products (e.g. PCBs 118, 138, 153, 180), with the cow acting as an efficient conduit to humans, while others (e.g. PCBs 52, 101, 149) are largely removed from the environment and the human food chain if ingested by the dairy cow because they are readily metabolized by the cow (Thomas et al., 1999b). Tcos for individual PCB congeners were estimated from published data and are presented in Table K-1 (Slob et al., 1995; Thomas et al., 1998; Thomas et al., 1999a; Kerst et al., 2004; Huwe and Smith, 2005). Kerst et al. (2004) provided TEQ-adjusted data from which a Tco (WHO-TEQ) of 0.014 d/kg was estimated for unspeciated PCBs.

In dairy cattle, Willett et al. (1990) reviewed early studies that examined the transfer of Aroclor 1254 applied to feed to cow's milk. Tcos of 0.008 to 0.009 d/kg were obtained with doses ranging from 3.5-200 mg/d and exposures ranging from 60-107 days. A cow's milk Tco of 0.01 d/kg for unspeciated PCBs from data by Thomas et al. (1999a) was calculated for the sum of 28 PCB congeners found both in feed and the milk.

Only one study could be found that allowed development of poultry meat Tcos for a limited number of individual PCB congeners. Pirard and De Pauw (2005) determined bioconcentration factors for coplanar-PCBs (PCBs 77, 81, 126, 169) in chicken breast muscle. Traag et al. (2006) provided bioconcentration data in abdominal chicken fat for all PCBs but exposure lasted only seven days. Because steady-state was not attained, Tcos could not be reliably determined. However, the data do indicate that based on the number of chlorines, the coplanar-PCBs are similarly, or more, bioaccumulative in fat compared to the other PCB congeners with the same number of chlorines. Thus, Tcos for the non-coplanar PCB congeners in Table K-1 were based on the co-planar PCBs with the same number of chlorines.

No reliable data could be found for developing individual congener Tcos for chicken eggs. Thus, the muscle Tcos for individual PCB congeners were also used for eggs, following adjustment for the higher fat content of eggs (11%) compared to muscle (7%).

A general PCB egg Tco of 6.7 d/kg was calculated from a laboratory study in which seven reference congeners (only one of which (#118) is listed in Table K-1) were spiked in the diet of hens (De Vos et al., 2005). Because none of the more bioaccumulative co-planar PCBs were investigated in this study, the co-planar PCB Tco of 10 d/kg was used for unspeciated PCBs. Numerous unspeciated PCB feed-to-muscle tissue studies have been published in chickens, resulting in a range of Tco values of 2.5 to 7.7 d/kg (Hansen et al., 1983; De Vos et al., 2003; Maervoet et al., 2004; De Vos et al., 2005; Pirard and De Pauw, 2005). A Tco of 7 d/kg for unspeciated PCBs was selected as the default value to reflect the median Tco of the individual congeners listed in Table K-1, and because this value is within the range of Tcos for unspeciated PCBs.

No reliable data could be found that estimated transfer of PCBs consumed in food to body fat of beef cattle. In dairy cattle, Willett et al. (1990) reviewed early experiments that examined the transfer of Aroclor 1254 from feed to adipose tissue. Fresh weight dairy beef Tcos of 0.013 to 0.027 d/kg were obtained for doses ranging from 10-200 mg/d with 60 day exposures. In another study, a beef Tco of 0.024 d/kg was calculated for dairy cattle following 14-week consumption of PCBs that naturally contaminated pastures (Thomas et al., 1999a).

On a fat weight basis, Thomas et al. (1999b) observed that not only are the PCB concentrations in body fat and milk fat similar, but that the congener patterns were similar as well. Thus, even though comprehensive congener-specific data are lacking for PCBs in muscle, congener-specific beef Tcos can be estimated from the cow's milk Tco data by adjusting for the greater fat content in muscle tissue (19%) compared to the milk fat content (4%).

We applied a PBPK-generated scaling factor developed by MacLachlan (2009) to estimate the transfer of PCBs from body fat of lactating cattle to body fat of beef cattle. Using data by Huwe and Smith (2005) that found a cow's milk half-life of 39-196 days for some co-planar PCBs, and the data by Thomas et al. (1999b) that showed similar levels of PCBs in milk fat and body fat, the ratio of simulated co-planar PCB levels in body fat of steers to body fat of lactating dairy cows is approximately 10. We multiplied the scaling factor of 10 by the PCB milk Tcos in Table K-1 following adjustment for differences in fat content between milk and beef to generate Tcos for beef.

In swine, Arochlor 1254 was added to feed for 6 months resulting in an unspeciated PCB Tco of 0.52 d/kg (Hansen et al., 1983). Speciated Tcos for 16 PCBs could be determined from the data, although only one PCB (#118) is currently listed in Table K-1. Thus, Tcos for individual PCBs in Table K-1 were based on the highest calculated PCB Tco with the same number of chlorines from the Hansen et al. study.

K.2.1.6 Polychlorinated Dibenzo-p-Dioxins and Furans (PCDD/F)

Numerous studies have investigated the feed-to-cow's milk transfer of PCDD/Fs. Several of these studies were conducted in the field near municipal solid waste incinerators, or estimated the mass balance of PCDD/F intake resulting from exposure to background or elevated levels of PCDD/Fs in pasture and soil (McLachlan et al., 1990; Slob et al., 1995; Schuler et al., 1997b; McLachlan and Richter, 1998; Lorber et al., 2000). These types of studies likely represent the best data for developing individual congener and overall unspeciated transfer factors of PCDD/Fs from "Hot Spots" facilities. Averaged congener Tco values were estimated from these data and are presented in Table K-1.

The milk Tco decreases by an order of magnitude or more for some of the higher chlorinated PCDD/Fs. This trend agrees with models showing that the percent transfer of chemical from feed to milk decreases for compounds with log Kow larger than about 6.5 (McLachlan, 1996). This reduced absorption is attributed to the presence of an aqueous resistance that limits diffusion of very hydrophobic compounds through the

intestinal wall. Thus, a Tco for total PCDD/Fs (unspeciated PCDD/Fs) has not been pursued by researchers in their exposure studies. Nevertheless, a Tco for unspeciated dioxin-like PCDD/Fs of 0.001 d/kg can be calculated from the data by McLachlan et al. (1990).

Several studies provided data from which Tcos could be estimated for individual PCDD/F congeners found in eggs and chicken meat. For eggs, transfer factor data were derived from three studies in which feed was mixed with soil environmentally contaminated with PCDD/Fs (Petreas et al., 1991; Stephens et al., 1995; Schuler et al., 1997a), and one study of feed contaminated with fly ash (Pirard and De Pauw, 2006). Individual congener Tcos among the studies were similar, often within a factor of five between values. An average Tco was calculated for each congener from the four studies and is shown in Table K-1.

Many of the same studies in chickens also estimated accumulation values for the sum of all PCDD/F congeners, or unspeciated PCDD/Fs, in eggs and meat. In egg, four studies in free-range and laboratory chickens exposed to contaminated soil provided an average Tco of 5.5 d/kg (range: 1.9 to 13.1 d/kg) for unspeciated PCDD/Fs (Petreas et al., 1991; Stephens et al., 1995; Malisch et al., 1996; Schuler et al., 1997a). In chicken muscle, three contaminated feed or soil studies provided accumulation data from which an average Tco of 4.6 d/kg (range: 1.0 to 7.6 d/kg) was calculated (Stephens et al., 1995; Iben et al., 2003; Pirard and De Pauw, 2005).

For the controlled laboratory feed-to-egg studies in which PCDD/Fs in fly ash or oil were added to feed (i.e., no contaminated soil was added to the diet), egg Tcos ranged from 8.5 to 17 d/kg with a mean of 12 d/kg (Pirard and De Pauw, 2005; 2006; Van Eijkeren et al., 2006).

For field studies, calculated egg Tcos of free-foraging chickens in various regions with PCDD/F-contaminated soil showed greater variation and was higher (Schuler et al., 1997a; Harnly et al., 2000; Hoogenboom et al., 2006). The Tcos ranged from 12 to 37 d/kg with an average of 23 d/kg. An assumption was made that the PDCC/F source for the free-foraging hens was contaminated soil, and that the soil ingestion rate was 10 g soil/day. There is general support among researchers for this soil ingestion rate by free-foraging chickens (De Vries et al., 2006). The larger egg Tco in field studies compared to controlled laboratory studies may be a result of free-foraging chickens consuming soil organisms and herbs and grass which may also be contaminated. However, greater bioavailability of soil PCDD/Fs in the field, or a higher soil ingestion rate than predicted may also play a role in a larger egg Tco under field conditions.

Overall, the range of mean values for these three types of studies is not large (within a factor of 10), considering the different sources of PCDD/Fs that the poultry were exposed to. A grand mean from the three types of exposure studies (contaminated soil field study, controlled contaminated soil study and contaminated feed study) is 13 d/kg (3.6 + 23 + 12 d/kg / 3), which we recommend as the default egg Tco for PCDD/Fs.

For edible muscle tissue (usually thigh or breast tissue), TEQ-adjusted Tcos could be calculated from several studies that investigated PCDD/F concentrations in chickens given contaminated feed. In a controlled laboratory study in which 10% of the diet was PCDD/F-contaminated soil, a Tco of 7.4 d/kg was calculated (Stephens et al., 1995). In three contaminated feed studies where PCDD/Fs in oil or fly ash were added to diet, similar Tcos of 8.6, 9.0 and 4.1 d/kg were calculated (Iben et al., 2003; Pirard and De Pauw, 2005; 2006).

Congener-specific data for development of beef Tcos were not as comprehensive as that for development of cow's milk Tcos. Two long-term pentachlorophenol (PCP) feeding studies in dairy cattle determined body fat concentrations for several PCDD/F congeners (1, 2, 3, 6, 7, 8- and 1, 2, 3, 7, 8, 9-HxCDD, 1, 2, 3, 4, 6, 7, 8-HpCDD, OCDD, 1, 2, 3, 4, 6, 7, 8-HpCDF, and OCDF) that were contaminants in the PCP formulation (Firestone et al., 1979; Parker et al., 1980). Beef Tcos based on dairy cattle for the other congeners and unspeciated PCDD/Fs were estimated with the assumption that the fat concentration is similar in milk and beef, and were adjusted upward to account for the greater fat content in muscle tissue (19%) compared to the fat content in milk (4%). As noted above, the concentration of PCBs in milk fat and body fat have been shown to be similar in exposure studies (Thomas et al., 1999b). We then applied scaling factors by MacLachlan (2009) to estimate the transfer of PCDD/Fs from body fat of lactating cattle to body fat of beef cattle. Data by Huwe and Smith (2005) found that half-lives were mostly 30-50 days for the PCDD/Fs; the major exceptions were OCDF ($t_{1/2}$ = 14 days) and OCDD ($t_{1/2}$ = 72.6 days). A ratio of 7 is estimated for the simulated PCDD/F levels in body fat of steers to body fat of lactating dairy cows for most PCDD/Fs. A ratio of 4 was estimated for OCDF and a ratio of 10 was estimated for OCDD.

Pig Tcos for individual and unspeciated PCDD/Fs in Table K-1 were estimated from a comprehensive study in which PCDD/Fs were added to the diet in feed of pigs during the 12-week fattening period (Spitaler et al., 2005). This exposure period represents the last 12-weeks prior to slaughter in the typical 6-month life of a pig. Notably, the researchers did not observe a reduction of residues due to roasting of the meat.

K.2.2 Tcos for Inorganic Metals and Chemicals

The studies used to derive inorganic metal Tcos listed in Table K-2 usually presented data as fresh weight concentrations in muscle, milk and eggs. Occasionally, dry weight concentrations were reported. Unless the study noted the water content of the food source, default factors of 0.87 for cow's milk, 0.35 for chicken egg, 0.25 for chicken meat, and 0.30 for beef and pork were used for adjusting to fresh weight concentration (USDA, 1975).

Biotransfer studies for pig muscle could not be found for most of the metals. As noted in the beginning of this appendix, biotransfer data in cattle were more abundant. Where specific metal biotransfer data were missing in pigs but present in cattle, the pig meat Tco was estimated using a simple metabolic weight adjustment from cattle to pig as shown in Eq. K-1.

In general, low concentrations of inorganic metals are transferred from contaminated feed to muscle tissue, cow's milk and eggs and are not as great a concern relative to other potential sources of heavy metals in multipathway exposures. However, many of the inorganic metals such as cadmium, lead and mercury tend to accumulate over time in organs, particularly kidney and liver. Thus, frequent consumption of organs from exposed food animals may present a much greater toxic hazard to humans than consumption of the meat. Cadmium is of particular concern due to its relatively high toxicity and high potential for accumulation in the kidney and liver. Kidney and liver-specific Tcos for cadmium and a few other metals are presented in the text below for some of these food-producing animals only for comparison purposes. Tcos for accumulation in bone for some of the metals (i.e., lead) are also noted or calculated for some of the food products.

Another toxicological concern is that chickens can convert some of the ingested inorganic mercury in controlled feeding studies to methyl mercury, which is then found primarily in the poultry meat and egg white (Kiwimae et al., 1969). The inorganic mercury Tcos for poultry meat and eggs in Table K-2 represents total mercury, although some will be present as organic methyl mercury. Because methyl mercury is not emitted from facilities (i.e., only inorganic or elemental mercury is emitted), it is not accounted for in health risk assessments. However, Tcos for methyl mercury were calculated by OEHHA and presented in Section K.2.2.7 only for comparison to the inorganic mercury Tcos.

K.2.2.1 Arsenic

Only one study could be located that recorded a measurable increase of arsenic in cow's milk following dairy cattle consumption of contaminated feed. We calculated a Tco of 5×10^{-5} d/kg from data in dairy cattle exposed to As(III) as arsenic trioxide for 15-28 months (Vreman et al., 1986).

In poultry, organic arsenic compounds are an approved dietary supplement that can result in increased levels of total arsenic in meat and eggs (Lasky et al., 2004). Both organic and inorganic forms of arsenic are found in poultry, with inorganic forms more toxic than organic forms. Analysis of poultry and meat samples indicates that about 65% of total arsenic is in the inorganic form.

We calculated a Tco of 0.07 d/kg for total arsenic in eggs from hens fed a diet containing arsenic trioxide (Holcman and Stibilj, 1997). In muscle, total arsenic Tcos of 0.06 and 0.02 d/kg were determined in chickens from two studies following addition of arsenic trioxide to feed (Overby and Frost, 1962; Vadnjal et al., 1997). The proportion of arsenic in the inorganic form was not determined. In drinking water, soluble As(V) was added to the water resulting in a total arsenic Tco of 0.2 d/kg in muscle of broiler chickens (Pizarro et al., 2004). However, only 10% of arsenic in muscle was in the inorganic form. Over 50% was present as dimethylarsinic acid, which is considered a methylation detoxification pathway for arsenic. Thus, the inorganic arsenic Tco was 0.02 d/kg. We calculated an average muscle Tco of 0.03 d/kg from the three studies for transfer of arsenic from diet to chicken meat.

In beef cattle, Vreman et al. (1988) administered arsenic trioxide in the feed for 143 days to 16 bulls at about 12.5 mg/d resulting in a muscle Tco of 2.4×10^{-3} d/kg. The same Tco was calculated from data by Ham et al. (1949) that dosed adult steers daily with 270 mg arsenic trioxide for 201 days. In another study in steers, Bruce et al. (2003) estimated the daily intake of arsenic from grazing pasture grass, ingesting dust adhering to pasture, and direct ingestion of soil in an area contaminated with arsenic-laced mine tailings. Based on the daily intake and muscle concentration of arsenic at sacrifice after 237 days of exposure, a Tco of 2.8×10^{-4} d/kg was derived. We calculated an average muscle Tco of 1.7×10^{-3} d/kg from these three studies, which we recommend as the default value for beef cattle. Long-term arsenic feeding studies have also been conducted in lactating dairy cows. A slightly lower muscle Tco of 7.1×10^{-4} d/kg was calculated from these studies (Peoples, 1964; Vreman et al., 1986).

Arsenic exposure in beef and dairy cattle has not shown tissue-specific sequestering in liver or kidney, unlike some of the inorganic metals (e.g., cadmium, lead, and mercury). Similar Tcos were estimated for muscle, liver and kidney (Ham et al., 1949; Peoples, 1964; Vreman et al., 1988).

K.2.2.2 Beryllium

No inorganic beryllium accumulation studies could be found in the literature for poultry. Thus, we calculated poultry egg and meat Tcos for beryllium based on the average Tco value of the other “Hot Spots” divalent, cationic metals in Table K-2 (i.e., cadmium, lead, inorganic mercury, and nickel) providing beryllium Tcos for egg and muscle of 0.09 and 0.2 d/kg, respectively.

No multiple day inorganic beryllium exposure studies have been conducted in cattle or swine. In a single bolus study, Ng (1982) estimated a cow’s milk Tco of 9.1×10^{-7} d/kg based on recovery of radiolabeled beryllium chloride given to dairy cattle. For beef, we determined a beryllium Tco of 3×10^{-4} d/kg based on the average Tco value of the divalent, cationic metals cadmium, lead, and inorganic mercury. Beef Tcos for these three metals were determined directly from published studies. A default pork Tco was determined by us by the same method as that used for beef, resulting in a pig meat Tco of 1×10^{-3} d/kg.

K.2.2.3 Cadmium

Very low accumulation of cadmium occurs in cow’s milk, and concentrations of cadmium in cow’s milk are often below the detection limit. In his review, Stevens (1991) estimated an average Tco of 1.3×10^{-6} d/kg in cow’s milk from two long-term cadmium exposure studies by Vreman et al. (1986). More recently, we estimated a milk Tco of 1.3×10^{-5} d/kg from exposure data in a single cow exposed to cadmium for 77 days (Mehennaoui et al., 1999). The average Tco from the three exposure studies is 5×10^{-6} d/kg, which we recommend as a default Tco.

Numerous cadmium accumulation studies have been conducted in poultry. Similar to cow’s milk, very low accumulation of cadmium occurred in hen’s eggs with exposure in

feed; the levels of cadmium in eggs are sometimes below the detection limit. We calculated an average egg Tco of 0.01 d/kg from the best available data (Leach et al., 1979; Sharma et al., 1979; Hinesly et al., 1985). In muscle, we determined cadmium Tcos in exposed chickens ranging from 0.2 to 1 d/kg (Leach et al., 1979; Sharma et al., 1979; Hinesly et al., 1985; Pribilincova et al., 1995; Bokori et al., 1996). The average value from these studies was 0.5 d/kg, which we recommend as the Tco.

Similar cadmium Tcos in muscle of dairy and beef cattle have been observed in long-term feeding studies lasting 3.5 to 28 months. We calculated an average Tco of 2.0 x 10^{-4} d/kg with a range of 1.2 – 3.2 x 10^{-4} d/kg (Johnson et al., 1981; Vreman et al., 1986; 1988). A muscle Tco of 6.5 x 10^{-5} d/kg was obtained from a feeding study by Lamphere et al. (1984) describing cadmium body burden in calves exposed for 60 days. However, the short exposure duration only during growth of the animal may result in an underestimation of the Tco compared to exposure to adulthood.

Cadmium accumulates to a much greater extent in some organs compared to muscle tissue. In poultry, exposure studies suggest that cadmium accumulation in the kidney and liver increases with increasing exposure duration and may not attain a steady-state concentration. Eighty-week exposure to cadmium in chickens resulted in a Tco of 800 d/kg in the kidney and 70 d/kg in the liver (Hinesly et al., 1985). In dairy and beef cattle, cadmium Tcos for liver and kidney did not vary greatly even though exposure durations varied. Average calculated Tcos were about 0.03 d/kg (range: 0.01 to 0.048 d/kg) for liver, and 0.1 d/kg (range: 0.09 to 0.19 d/kg) for kidney (Sharma et al., 1979; Sharma et al., 1982; Vreman et al., 1986; 1988).

Only one study could be found that measured cadmium muscle levels in pigs following exposure to cadmium in feed. Cousins et al. (1973) only found measurable cadmium levels in skeletal muscle at the highest of four doses tested (1350 ppm) following a six-week exposure, but this level caused severe toxicity. More accurate estimates of muscle uptake were found in heart tissue, which exhibited increased tissue concentration with increasing dose and may represent the upper end of the cadmium concentration found in skeletal muscle. The average Tco we calculated in heart muscle was 0.0051 d/kg. In the liver and kidneys of pigs, cadmium Tcos as high as 0.48 and 2.53 d/kg, respectively, were calculated from a study by Sharma et al. (1979).

K.2.2.4 Chromium (Hexavalent)

Only a portion of ingested hexavalent chromium (Cr(VI)), perhaps 1-2%, is expected to be systemically absorbed in the hexavalent form due to rapid reduction to the less soluble and less toxic trivalent chromium in the acidic environment of the stomach (Costa, 1997; NTP, 2008). Trivalent chromium (Cr(III)) is an essential micronutrient, but no cancer potency or noncancer reference exposure level is currently available for this form of chromium. Cr(VI) that is absorbed can then be actively transported into all cells and tissues of the body in place of anions, such as phosphates. Once inside the cell, the Cr(VI) is reduced to various unstable reactive intermediates and, finally, stable Cr(III) is ultimately formed inside the cell.

Current analytical procedures cannot differentiate between the oxidation states of chromium in biological tissues (NTP, 2008). However, it has been advocated that any Cr(VI) transported into meat and eggs would be converted to the more stable Cr(III) form and would presumably not pose a risk for human consumption (Chundawat and Sood, 2005). Based on these findings no Cr(VI) Tco is currently recommended by OEHHA for meat and eggs.

However, a similar situation may not be the case for cow's milk. Lameiras et al. (1998) found Cr(VI) in cow's milk, which was 25-50% of total chromium. In whole milk, the average total chromium concentration was 2.70 ug/L (range: 1.42-5.70 ug/L) and the average Cr(VI) concentration was 0.68 ug/L (range: 0.20-1.20 ug/L). No multiple day Cr(VI) exposure studies in dairy cattle could be found in the literature. Following a single oral dose of radiolabeled sodium chromate (Na_2CrO_4), Van Bruwaene et al. (1984) calculated a steady-state cow's milk Tco of 1.0×10^{-5} d/kg for total chromium. Stevens (1991) estimated a similar Tco of 1.4×10^{-5} d/kg from the same data based on a half-life of 26 days for total chromium in cow's milk. These studies did not attempt to estimate the proportion of total chromium that was secreted as Cr(VI) into milk.

Multiplying the Stevens total chromium Tco by the fraction of total chromium that is Cr(VI) in normal milk (1.4×10^{-5} d/kg x 0.68/2.70 ug/L) provided a modified Tco of 3.5×10^{-6} d/kg. Until valence-speciated cow's milk data are available from Cr(VI) exposure studies, we chose a midpoint Tco value between the Stevens Tco and this modified Tco adjusted for Cr(VI) content in normal milk (8.75×10^{-6} d/kg) as a health-protective cow's milk default value for Cr(VI).

K.2.2.5 Fluoride

In a series of long-term exposure studies on fluorides' effect on milk production, the fluoride concentration in the milk of dairy cows given fluoride in feed resulted in an estimated cow's milk Tco of 0.0003 d/kg (Stoddard et al., 1963; Harris et al., 1964).

Fluoride in the diet of hens resulted in very low accumulation of fluoride in muscle, and yolk and albumin of eggs (Hahn and Guenter, 1986). We calculated a Tco in whole eggs of 0.008 d/kg from the exposure data. Considerably greater accumulation occurs in egg shell. Muscle accumulation in the fluoride-exposed hens resulted in a Tco of 0.03 d/kg.

Specific data concerning accumulation of fluoride in the skeletal muscle tissue of exposed cattle could not be found. However, in cases of high fluoride intake, fluoride levels in the soft tissue (i.e., brain, liver, kidney, pancreas, intestines, etc.) are reported to increase only two or three times the normal value in meat producing animals. Fluoride does not accumulate in the edible portions of the animal (Suttie et al., 1958; Shupe et al., 1964). However, considerably greater accumulation of fluoride occurred in bone. In heart tissue, we calculated a fluoride Tco of 8.4×10^{-4} d/kg for Holstein cows fed fluoride-contaminated rations for 5.5 years, which we recommend as the default muscle Tco for range cattle (Suttie et al., 1958). It is assumed that similar

pharmacokinetic properties, and similar Tcos, occur for fluoride in both skeletal and heart muscle tissue.

K.2.2.6 Lead

Only three contaminated feed studies observed measurable levels of lead in milk from both control and exposed dairy cows. Based on data from a 15-28 month lead exposure study of dairy cows kept indoors, a cow's milk Tco of 2.6 x 10^{-5} d/kg was calculated (Vreman et al., 1986). A three-month outdoor lead exposure study by the same researchers produced a Tco of 5.4 x 10^{-5} d/kg. Stating that the half-life of lead in dairy cows is about 45 days, Stevens (1991) adjusted the Tco of the three-month outdoor study to 7.1 x 10^{-5} d/kg. However, Willett et al. (1994) observed that steady-state was attained in cow's milk after only 14 days of a 49-day lead exposure study, generating a Tco of 7.9 x 10^{-5} d/kg. Using the steady-state-corrected Tco by Stevens (1991) for the outdoor Vreman study, we recommend an average Tco of 5.9 x 10^{-5} d/kg from these three studies.

An average Tco of 0.4 d/kg in muscle was calculated by OEHHA for lead in broiler chicks fed contaminated feed for 20 days (Stoddard et al., 1963; Harris et al., 1964; Latta and Donaldson, 1986a; 1986b). For comparison, a roughly 10-fold higher Tco was calculated for lead in kidney. However, lead tends to accumulate most in bone, generating a Tco of 70 d/kg. Lead in bone is not expected to be a problem, unless contaminated bone is ground into bone meal and fed to animals. Accumulation of lead in eggs was very low, generating a Tco of 0.04 d/kg (Meluzzi et al., 1996).

Vreman et al. (1988) administered lead acetate in feed to young bulls for 143 days during the fattening period. The resulting muscle Tco was 2.7 x 10^{-4} d/kg. A slightly lower muscle Tco of 6.7 x 10^{-5} d/kg in lactating dairy cows fed lead mixed with their feed (Vreman et al., 1986).

Roughly 10- to 100-fold greater accumulation of lead occurs in the kidney and liver of cattle compared to their muscle tissue. We calculated Tcos of 4.8 x10^{-3} and 1.4 x 10^{-2} d/kg for liver and kidney, respectively, in the bulls from the Vreman et al. (1988) study. In addition to liver and kidney, lead was also found to accumulate in bone. In a three-month feeding study in dairy cattle, a bone Tco of 0.02 d/kg was calculated from the data by Sharma et al. (1982). In one of the few biotransfer studies conducted in pigs, a liver Tco of 1.4 x 10^{-2} d/kg was recorded in pigs fed diets containing either 5 or 25 ppm lead acetate for 90 days (Sharma and Street, 1980).

K.2.2.7 Inorganic Mercury

Addition of inorganic mercury (Hg(II)) to the feed of hens for 140 days resulted in a muscle tissue Tco of 0.1 d/kg (Kiwimae et al., 1969). However, some Hg(II) was converted to methyl mercury (MeHg) in the chickens, resulting in a muscle Tco of 0.09 d/kg for MeHg. When only MeHg is added to the diet in prolonged feeding studies, an average Tco of 10 d/kg was calculated with virtually all the mercury in the muscle as MeHg (Kiwimae et al., 1969; Soares et al., 1973; Hilmy et al., 1978). Some Hg(II) added

to feed is also endogenously methylated in the hens and transported to the eggs. Addition of Hg(II) to the feed of hens for 140 days resulted in a calculated egg Tco of 0.8 d/kg for total mercury, and 0.5 d/kg for MeHg (Kiwimae et al., 1969). An average egg Tco of 11 d/kg was calculated when only MeHg was added to feed (Scott et al., 1975; Hilmy et al., 1978).

Vreman et al. (1986) observed a small, but statistically insignificant increase in mercury in cow's milk with exposure of dairy cattle to inorganic mercury in feed for 15-28 months. The Tco range was 7 to 40 x 10^{-5} d/kg with an average of 2 x 10^{-4} d/kg. Stevens (1991) calculated Tcos of 9.2 x 10^{-6} and 1.3 x 10^{-5} d/kg from oral single bolus studies of radiolabeled inorganic mercury by Mullen et al. (1975) and Potter et al. (1972). The steady-state Tcos were calculated by use of study-specific half-lives of 1.2 (Potter et al., 1972) or 5.5 days (Mullen et al., 1975) for mercury. We calculated an average Tco of 7 x 10^{-5} d/kg from the three studies, which we recommend for transfer of inorganic mercury to cow's milk.

Similar to cow's milk, only a small, but statistically insignificant increase in inorganic mercury could be measured in muscle tissue following long-term exposure of dairy and beef cattle to soluble mercury (Vreman et al., 1986; 1988). Calculated maximum muscle Tco values from these two studies were 6.7-18 x 10^{-4} d/kg, but we lack confidence in this value due to the detection limit of these studies. To calculate the biotransfer of ingested mercury to muscle, Stevens (1992) relied on three oral bolus dose studies that determined the half-life of inorganic mercury in blood of dairy cattle (Potter et al., 1972; Ansari et al., 1973; Mullen et al., 1975). Operating on a reasonable assumption that muscle is a well-perfused tissue and shares the same kinetic compartment as blood, Stevens calculated an average muscle Tco of 3.5 x 10^{-4} d/kg (range: 1.8-4.4 x 10^{-4} d/kg). This value is comparable with the Tcos estimated from the Vreman studies, which we recommend as the point estimate Tco for inorganic mercury in beef.

Although it is not anticipated that human exposure to methyl mercury via cow's milk and beef would be a significant pathway (e.g., as compared to fish), biotransfer information is included here for completeness. There are few published data that investigated ruminant methylmercury uptake and accumulation. However, background exposure and accumulation of inorganic and methylmercury in meat products are reported to be very low (U.S. EPA, 1997). In their risk assessment guidelines, U.S. EPA (2005) suggests that only 13% of total mercury in ruminants is present as methylmercury, an indication that ruminants have little exposure to methylmercury.

In vitro, cow rumen microflora does not methylate added inorganic mercury (as $HgCl_2$) to methylmercury (Kozak and Forsberg, 1979). On the other hand, rumen microflora was found to demethylate up to 40% of added methylmercury to elemental (Hg^0), or metallic, mercury, which would then be presumably excreted with little or no absorption. This finding suggests that ruminants can detoxify some of the ingested methylmercury.

Stevens (1991) estimated that the Tco for methylmercury in cow's milk is roughly one order of magnitude greater than that for inorganic mercury (i.e., 7 x 10^{-4} d/kg). His

finding was based on a study by Neathery et al. (1974), in which two dairy cows were given a bolus dose of radiolabeled methylmercuric chloride and followed for the appearance of label in milk for 14 days. A milk excretion half-life of 6 days was calculated from the data. It was suspected that the lipophilic nature of methyl mercury resulted in its accumulation in milk fat. Of the labeled methylmercury that was absorbed, 72% of the total body burden was found in muscle tissue 15 days after the single bolus dose. However, there are insufficient data to estimate the biotransfer of ingested methylmercury in cattle and pigs with chronic exposure.

K.2.2.8 Nickel

Only two studies were found in the literature that attempted to estimate the nickel concentration in cow's milk following 1.5 to 2 month exposure of the dairy cattle to inorganic nickel-contaminated feed (Archibald, 1949; O'Dell et al., 1970). Neither study used analysis methods that were sensitive enough to record measurable increases of nickel in the cow's milk. Stevens (1991) used the maximum value approach by dividing the detection limit (0.1 ppm) of the studies by two, arriving at an average cow's milk Tco of 2.7×10^{-5} d/kg. Until more sensitive studies are conducted, we recommend this Tco as the default value for inorganic nickel.

Limited data for nickel indicate low accumulation of this metal occurs in eggs and tissues of chickens (Ling and Leach, 1979; Meluzzi et al., 1996). We calculated Tcos of 0.02 d/kg for both eggs and muscle tissue of hens fed inorganic nickel mixed in their diet. As with other inorganic metals, greatest nickel accumulation occurred in the kidney (Tco = 0.68 d/kg), resulting in a Tco over 30-fold higher than that found in muscle or eggs.

No adequate studies investigating biotransfer of ingested inorganic nickel to beef or pork could be located. As with the approach used for beryllium, we determined a beef Tco based on an average of the three divalent cationic metal Tcos (i.e., cadmium, lead and inorganic mercury) that had sufficient biotransfer data available in the literature. The resulting beef Tco was 3×10^{-4} d/kg. We then developed a pig meat Tco of 0.001 d/kg based on the cow-to-pig metabolic weight ratio adjustment (Eq. K-1). OEHHA recognizes that these Tcos developed for beef and pork are more uncertain than would be desirable. However, the data available in other food-producing animals and similar Tcos developed for other cationic metal contaminants indicates the nickel muscle Tco is likely not underestimated in cattle and pigs.

K.2.2.9 Selenium

The selenium concentration in milk tends to increase as intake of selenium increases from about 2 to 6 mg/day (Fisher et al., 1980; Maus et al., 1980; Beale et al., 1990). Secretion of selenium into milk then appears to reach a temporary limit when selenium intake is about 6 to 12 mg/day. The mammary gland is either limited in the limited amount of selenium it can secrete into milk, or, more likely, the net absorption of selenium from the gut is controlled in the face of increased selenium intake. Only when selenium intake increases above 50-100 mg/day does the ability of the protection

mechanism become exceeded, resulting in selenium toxicity and increased selenium concentration in milk. We calculated a Tco of 0.009 d/kg based on the average value for studies that supplemented feed with 6 mg/d selenium or less.

Optimum levels of selenium in the diet of poultry are about 0.1 to 0.2 ppm (Arnold et al., 1973; Moksnes and Norheim, 1982). Concentrations of selenium above 3 ppm may result in toxicity. At concentrations of 1 to 9 ppm selenite in the feed, we calculated an average egg Tco of 3 d/kg (Arnold et al., 1973; Ort and Latshaw, 1978; Moksnes and Norheim, 1982; Davis and Fear, 1996). In broiler chicks, an average Tco of 0.9 d/kg for muscle was calculated (Moksnes and Norheim, 1982; Echevarria et al., 1988a; 1988b). Laying hens had a lower Tco of 0.4 d/kg for muscle tissue, possibly due to eggs acting as an elimination pathway for selenium (Arnold et al., 1973; Ort and Latshaw, 1978; Moksnes and Norheim, 1982). Thus, the muscle Tco for selenium is based on the findings in meat (broiler) chickens.

In beef cattle, groups of calves were fed sodium selenite in a milk replacer at concentrations of 0.2 to 5 ppm for six weeks (Jenkins and Hidiroglou, 1986). We calculated an average muscle Tco of 6.6×10^{-2} d/kg from the exposure data. In another study, inorganic selenium was intraruminally administered in beef cows through two soluble-glass boluses to slowly release Se over approximately 11 months (Hidiroglou et al., 1987). We calculated a Tco of 7.1×10^{-3} d/kg in the muscle tissue. The average muscle Tco from the two studies is 0.037 d/kg, which we recommend as the default selenium transfer factor. Jenkins and Hidiroglou (1986) also observed greater accumulation of selenium in the liver and kidney cattle compared to muscle, resulting in calculated Tcos of 2.7 and 0.25 d/kg, respectively.

In pigs, selenium muscle concentrations have been measured following unsupplemented intake or supplementation of selenium in diets. No studies could be located that estimated tissue levels of selenium following prolonged intake of toxic or near-toxic levels of selenium. Using a study by Ku et al. (1972), we calculated an average muscle Tco of 0.61 d/kg in groups of adult pigs that had been fed diets containing selenium at levels ranging from 0.027 to 0.493 ppm. A positive correlation between selenium level in the diet and muscle concentration was observed. Using another study, which exposed pigs to diets containing 0.78-0.88 ppm selenium during the growth phase, we calculated a muscle Tco of 0.35 d/kg in pigs at market weight (Jenkins and Winter, 1973).

Similar to the phenomena observed in dairy cattle, supplementation of pig diets with selenium (0.1 to 1.0 ppm) did not always result in an increase in tissue selenium levels. Tcos based on these studies are as much as 10-fold lower compared to Tcos calculated from baseline levels of selenium found in feed (Groce et al., 1971). However, it is not known if this protective mechanism also operates at higher selenium levels in feed that may produce toxic effects in pigs. Thus, we recommend a default pig Tco based on the average Tco (0.48 d/kg) determined using Ku et al. (1972) and Jenkins and Winter (1973), which covered a range of baseline selenium intakes in feed from 0.027 to 0.88 ppm.

Appendix L Activity Data Analysis Report

L.1 Introduction

The Office of Environmental Health Hazard Assessment (OEHHA) and the Air Resources Board (ARB) staff have updated the exposure assessment methodologies and the data used for conducting Health Risk Assessments (HRA) as prescribed under the Air Toxics “Hot Spots” Information and Assessment Act (Assembly Bill 2588; Health and Safety Code Section 44300 et seq.). The mandates of the Air Toxics "Hot Spots" Act are to collect emission data, to identify facilities having localized impacts, to ascertain health risks, to notify nearby residents of significant risks, and to reduce those significant risks to acceptable levels. This report focuses on two of the exposure variables (i.e. exposure duration and exposure frequency) used in estimating a person’s lifetime average daily dose by considering the time a person lives in his or her primary residence and the time a person spends daily at home.

Staff looked into various data sources to determine the residency duration at the household level and the daily activity pattern at the individual level. The data sources the staff examined include the National Human Activity Pattern Survey (NHAPS), the National Household Travel Surveys (NHTS), the National Longitudinal Surveys, the American Time Use Survey Data Extract Builder, the Integrated Public Use Microdata Series (IPUMS-USA) census data, the Southern California Association of Governments (SCAG) 2000 regional travel survey data, and the California Department of Transportation (Caltrans) 2000-2001 California Statewide Household Travel Survey (CHTS) data. The staff determined that IPUMS-USA, SCAG 2000 regional travel survey, and Caltrans 2000-2001 CHTS represent the most current and California-specific residence and activity data and therefore were used as the basis for the conclusions stated in this report.

Results show that, from 2006 to 2009, over 91% of California householders had lived at their current home address for less than 30 years, and over 63% of householders had lived at their current residence for 9 years or less. No data were available for householders who lived in their homes over a 70 year period.

The 2000-2001 CHTS data show that, on average, Californians spend approximately 73% of their time at home per day. When looking at the data by age group, the time increases to 85% for children under 2 years old. Individuals that are 2 years or older, but less than 16 years old, spend 72% of their time at home whereas Californians that are 16 years or older spend 73% of their time at home.

L.2 Data Sources Analyzed

L.2.1 IPUMS-USA data

IPUMS-USA consists of more than fifty samples of the American population drawn from fifteen federal censuses and from the American Community Surveys (ACS). ACS is a nationwide survey that collects and produces population and housing information every year from about three million selected housing unit addresses across every county in the nation (ACS). IPUMS-USA samples, which draw on every surviving census from 1850-2000 and the 2000-2009 ACS samples, collectively constitute the quantitative information on long-term changes in the American population. These records for the period since 1940 only identify geographic areas with equal or larger than 100,000 residents (250,000 in 1960 and 1970) (IPUMS-USA).

IPUMS-USA census data contain residency duration, travel to work data, residence and work location, age, household and personal income, and ethnicity data.

L.2.2 SCAG Year 2000 Post-Census Regional Household Travel Survey Data

The second set of data the staff evaluated was the Post-Census Regional Household Travel Survey sponsored by the Southern California Association of Governments (SCAG). SCAG is the federally designated metropolitan planning organization (MPO) for the Los Angeles region of California. The survey targeted households in the six counties of the SCAG region: Imperial, Los Angeles, Orange, San Bernardino, Riverside, and Ventura (SCAG, 2003).

SCAG survey has data of time spent at home, trip data, geo code for locations, home address, age, income, ethnicity, and limited residency duration (months lived at home location).

L.2.3 Caltrans 2000-2001 California Statewide Household Travel Survey Data

Caltrans maintains statewide household travel data to estimate, model, and forecast travel throughout the State. The information is used to help in transportation planning, project development, air quality analysis, and other programs. The CHTS obtained sample household socioeconomic and travel data at the regional and statewide levels.

In the raw survey database obtained from Caltrans, there are data about trip duration, activity duration, location type, geo code for destination, address, age, income, and ethnicity. There are no data about residency duration.

Caltrans is currently developing a new 2011-2012 CHTS, which is a joint effort among Caltrans, SCAG and other MPOs. ARB is part of the Steering Committee.

L.2.4 Data Sources Summary

Table L.1 summarizes the activity data sources the staff analyzed, which include IPUMS census data, SCAG 2000 regional travel survey data, and Caltrans 2000-2001 CHTS data. It shows the data availability based on the HRA related categories.

Table L.1 Activity Data Sources

Sources			
HRA related Categories	**IPUMS-USA Census Data 2000-2009**	**SCAG 2000 Travel Survey**	**Caltrans 2000-2001 CHTS**
Residency duration	Year moved in	Months lived at home location	N/A*
Time at home per day	N/A	At home activity duration	At home activity duration
Time away from home	Hours worked, Travel time to work	Trip duration, activity duration	Trip duration, activity duration
Trip distance	N/A	Geo code for origin and destination	Geo code for destination
Residence location	City. No zip code	Address	Address
Age	Yes	Yes	Yes
Income level	Income Variables	Household income	Household income
Seasonal trend	N/A	N/A	N/A
Ethnicity	Yes	Yes	Yes
Data Set	Federal censuses (1850-2000), American Community Surveys (2000-2009)	2000-2002 Six-county Los Angeles region of CA	2000-2001 CA Statewide weekday travel survey

* N/A: Data are not available.

L.3 Methodologies and Findings:

In this section, we outline the methodologies we used in each of the data sources to estimate a person's time period lived in his or her residence and the time spent in different activities each day. We also examined how different environmental factors such as socioeconomic status, age, and ethnicity affect residency duration and daily activity patterns. We conclude with a discussion of the findings of each of the data sources.

L.3.1 IPUMS-USA data

L.3.1.1 Methodology

The staff used IPUMS online analysis tool (IPUMS Tool) to analyze the residency duration data based on ACS 2006-2009 data. The results are compiled and discussed below.

There are IPMUS_USA ACS data from 2000 to 2005 as well. However, the IPMUS_USA ACS data from 2006 to 2009 are more recent and have the same sample size percentage (i.e. 1%) for each year. In addition, these data include persons in group quarters and the smallest identifiable geographic unit is the Public Use Microdata Area (PUMA) containing at least 100,000 persons (IPUMS Samples). Group quarters consist of both institutions and units housing either a primary family or a primary individual plus a given number of persons unrelated to the head (IPUMA GQ).

L.3.1.2 Findings and Discussions

L.3.1.2.1 California Statewide Residency Duration Distributions

Table L.2 presents California statewide time moved into residence distributions compiled from the analysis results of ACS 2006, 2007, 2008, 2009 single year samples and ACS 2006-2008 3-year sample using IPUMS-USA online data analyzing tool. The time moved into residence variable has 7 values in ACS data as listed in "Time Moved into Residence" column in Table L.2, including "5 to 9 years ago" and "30 years ago". The statistical data provided have the samples' household weight applied. Household weight indicates how many households in the U.S. population are represented by a given household in an IPUMS sample (IPUMS Weights). Each cell besides the row and column headers in Table L.2 contains a household percent and the number of householders presented by that percent.

In summary, IPUMS-USA ACS 2006 to 2009 data show that the percentage of the California householders with a residency period of 30 years or greater is less than 9%. In other words, over 91% of California householders had lived in their current residence location for less than 30 years. These data also show that over 63% California householders had lived at their current residence for 9 years or less.

Table L.2* California Statewide Time Moved into Residence Distribution by Year

(Weighted Household Percent and Number)

Time Moved into Residence	2006	2007	2008	2006-2008 3-year Sample	2009
12 months or less	**17.2** 2,084,533.0	**15.9** 1,939,774.0	**15.4** 1,871,049.0	**16.2** 1,968,717.0	**15.7** 1923501

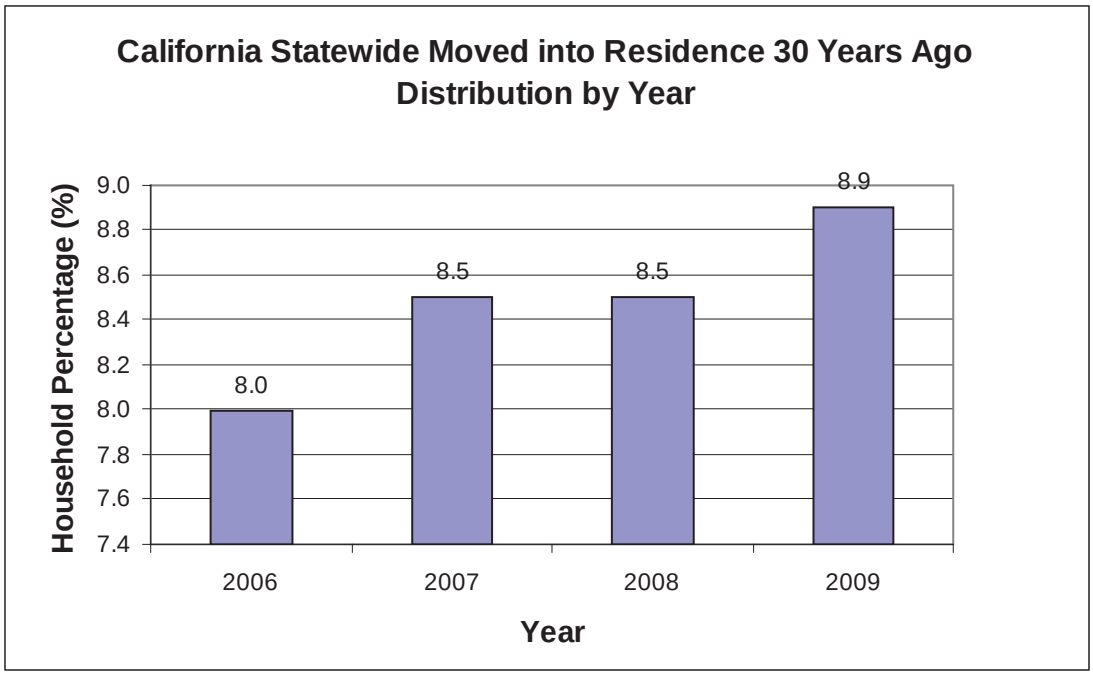
* IPUMS-USA ACS 2006 to 2009 data with household weight applied. As of March 2011, there is no IPUMS-USA multi-year sample with ACS 2009 sample included yet.

Figure L.1 graphically depicts the 2006 to 2009 statewide householder percentages of Californians that moved into their current home location 30 years ago. From 2006 to 2009, this figure shows an increase in the percentage of statewide householders that moved into residence 30 years ago.

Figure L.1*

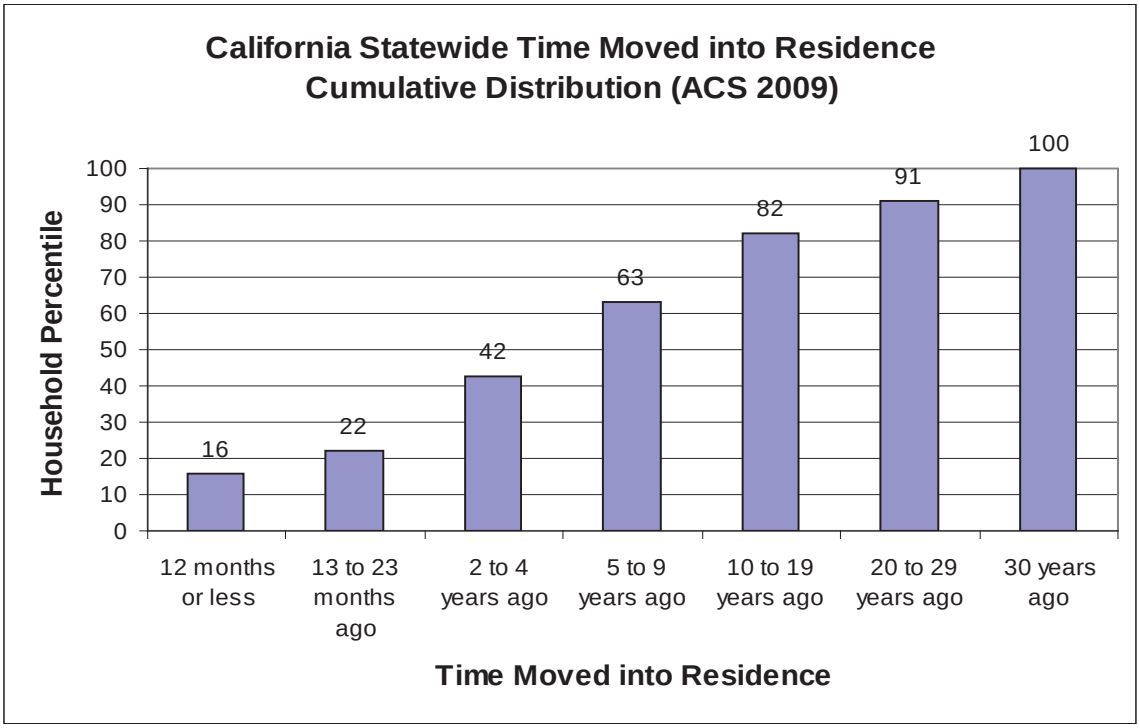


* IPUMS-USA ACS 2006, 2007, 2008, and 2009 single year samples with household weight applied.

Figure L.2 and Figure L.3, respectively, show the California statewide time moved into residence cumulative distributions using IPUMS-USA ACS 2009 sample and 2006-2008 3-year sample with household weight applied. Both of these figures show that over 90 percent of California householders had lived at their current home address for less than 30 years, and approximately 63 to 66 percent of the householders had lived at their current residency location for 9 years or less.

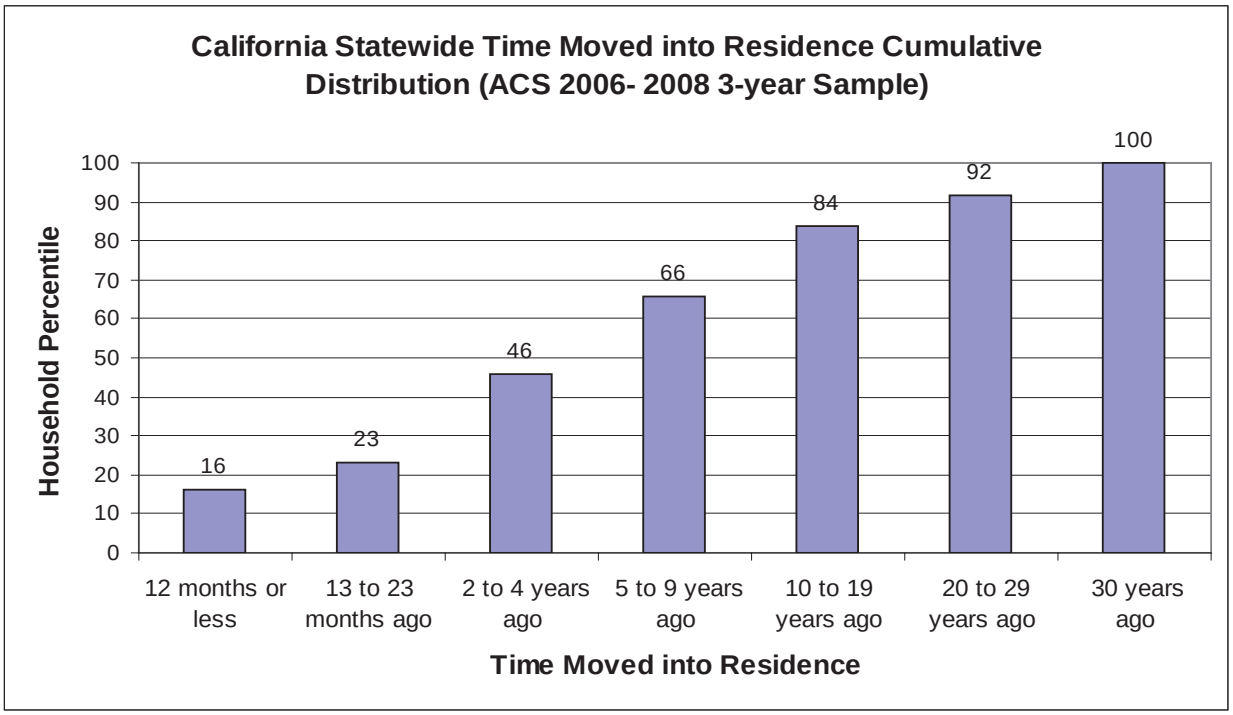
See Supplemental Information section (page 29) for additional information on time moved into residence distributions by California householder's ethnicity, age, and household income from IPUMS-USA ACS 2009 data.

Figure L.2*



* IPUMS-USA ACS 2009 data with household weight applied.

Figure L.3*



* IPUMS-USA ACS 2006-2008 3-year sample with household weight applied. As of March 2011, there is no IPUMS-USA multi-year sample with ACS 2009 sample included available yet.

L.3.1.2.2 Evaluation of Populations and Residency Duration Distributions for California Cities

Table L.3 and Figure L.4 display the populations and population changes for 8 selected California cities from IPUMS-USA ACS 2006 and ACS 2009 data with person weight applied. Person weight indicates how many persons in the U.S. population are represented by a given person in an IPUMS sample (IPUMS Weights). These 8 cities have populations over 100,000 from IPUMS-USA ACS 2006 and 2009 data, and were selected to represent the regions of California and to include an Environmental Justice community (Fresno, CA). If an area consisted of less than 100,000 persons then it was combined with another area so that the total population would be greater than 100,000 persons. The exhaustive distribution data from IPUMS-USA ACS 2006 and 2009 samples contain 41 identifiable California cities.

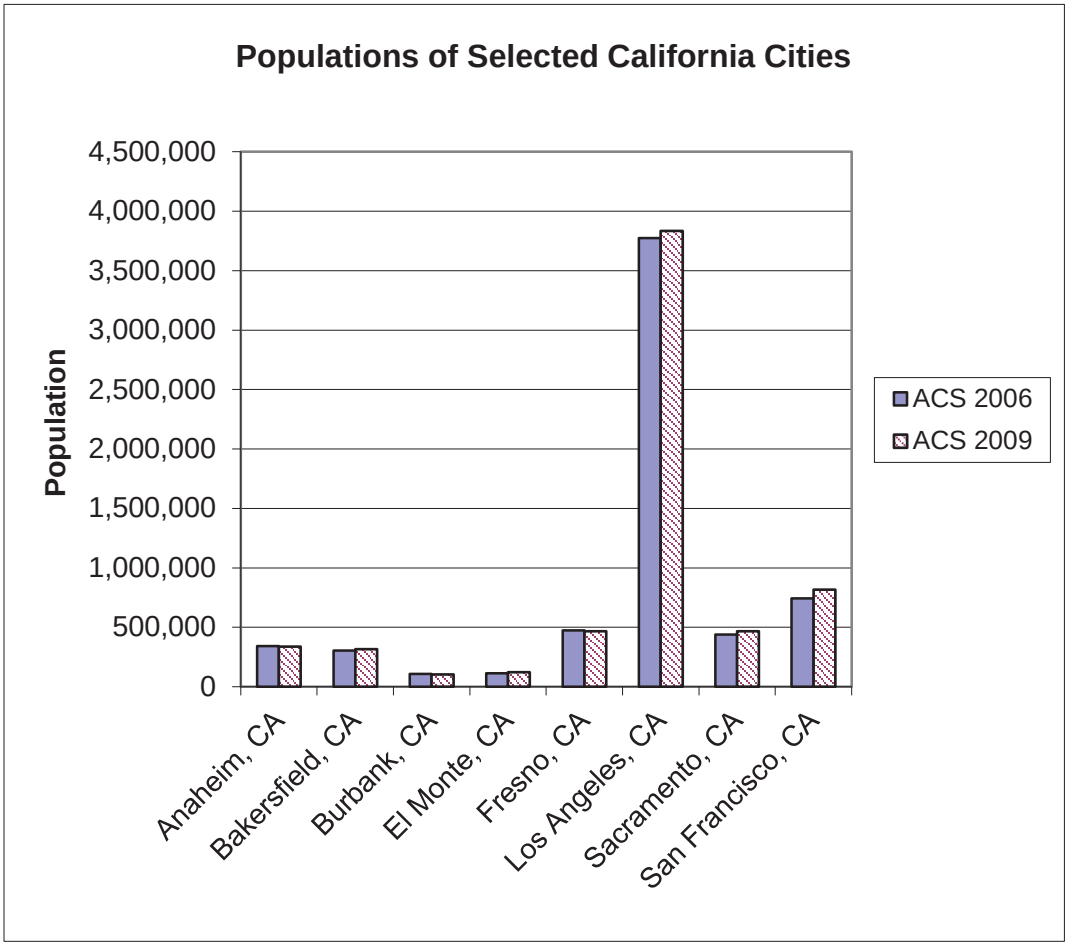
Table L.3* Comparison of Populations of Selected California Cities

(IPUMS-USA ACS 2006 and 2009)

California City	Anaheim	Bakersfield	Burbank	El Monte	Fresno	Los Angeles	Sacramento	San Francisco
2006	343,120	304,813	107,540	113,644	474,466	3,775,106	438,385	744,389
2009	337,966	316,313	103,096	121,183	466,466	3,832,554	466,492	815,575
Population Change Percent	-1.5	3.8	-4.1	6.6	-1.7	1.5	6.4	9.6

* IPUMS-USA ACS 2006 and 2009 data with person weight applied.

Figure L.4*



* IPUMS-USA ACS 2006 and 2009 data with person weight applied.

Table L.4 and L.5 display the time moved into residence distributions for the 8 selected California cities from IPUMS-USA ACS 2006 and 2009 data, respectively, with household weight applied. Both tables show that 89% to 96% of householders had moved out of their residence within 30 years. In other words, about 4% to 11% householders had lived at their current residence for 30 years or longer. The residency duration data from IPUMS-USA ACS also indicate that, for all the 41 identifiable California cities, about 1% to 15% of householders had lived at their current residence for 30 years or longer in 2006, whereas 2% to 15% of householders had lived at their current residence for 30 years or longer in 2009.

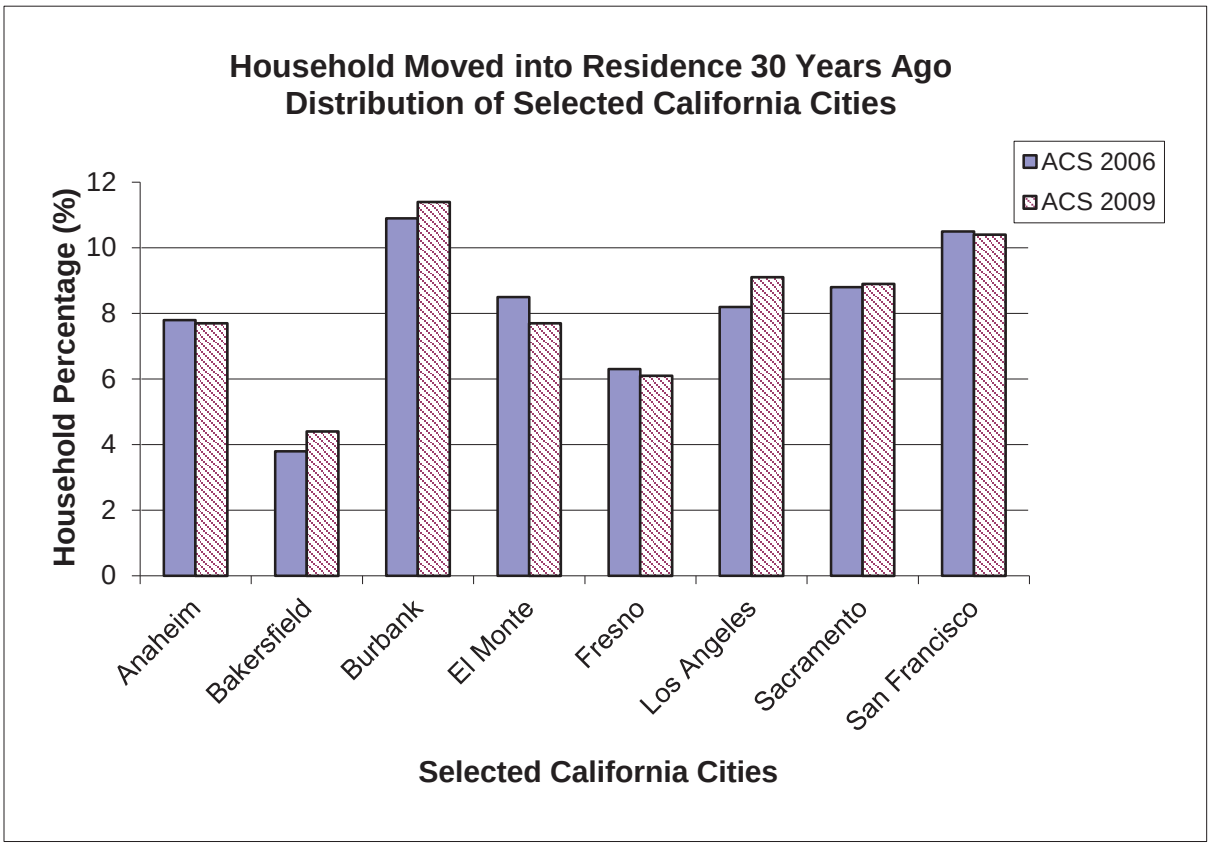
* IPUMS-USA ACS 2009 data with household weight applied.

Figure L.5 shows the distribution of householders with residency periods of 30 years or greater for the 8 selected California cities from IPUMS-USA ACS 2006 and ACS 2009 data with household weight applied.

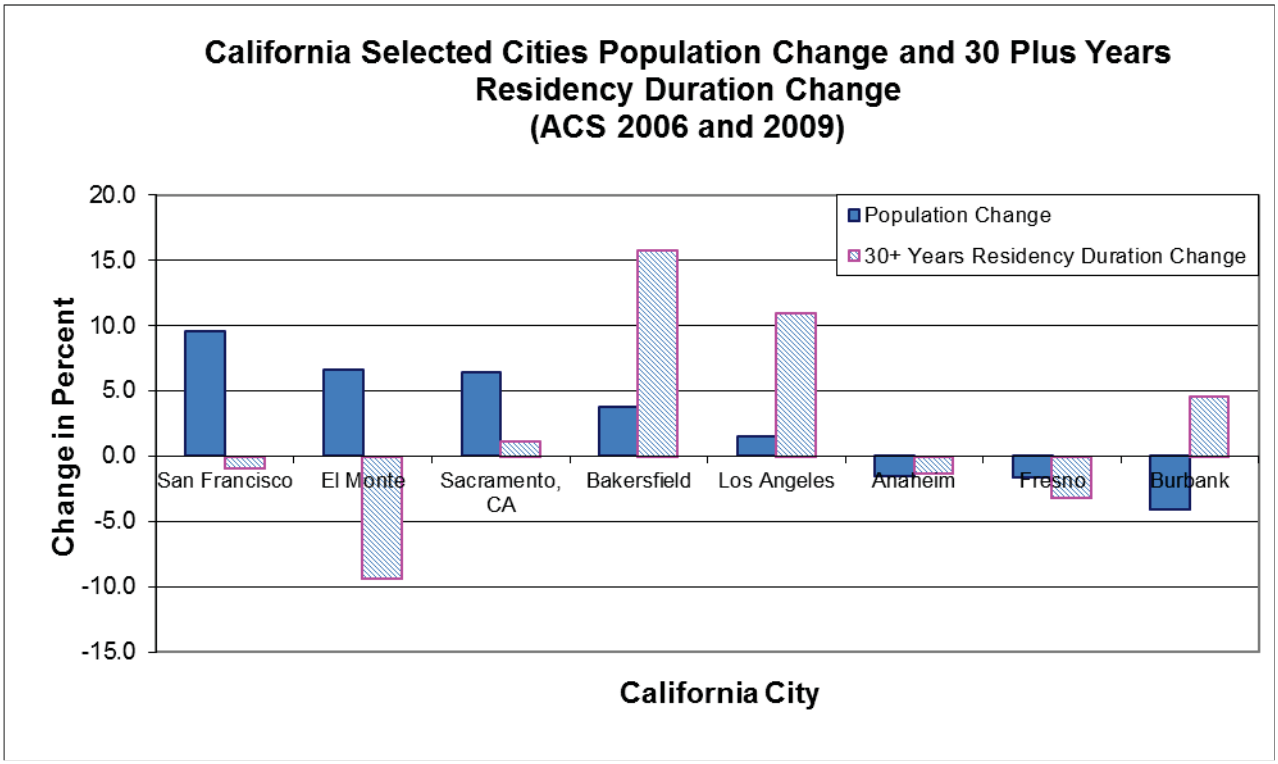
Figure L.5*



* IPUMS-USA ACS 2006 and 2009 data with household weight applied.

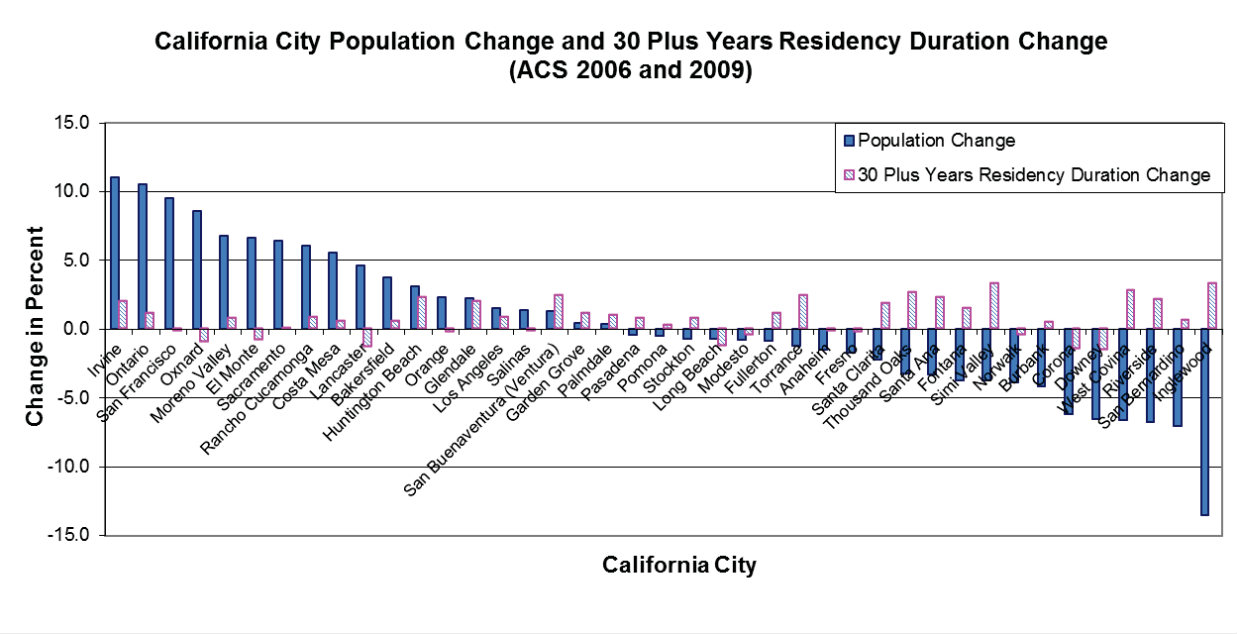
Staff also analyzed the population changes and the 30 years or greater residency duration changes for both the 8 selected cities and the 41 identifiable California cities using IPUMS-USA ACS 2006 to ACS 2009 data. The purpose of this analysis is to see if a rapidly growing city has a different pattern of residency durations. The results are illustrated in Figure L.6 and Figure L.7 respectively. There is no obvious correlation found between the population changes and the 30 years or greater residency duration changes. Figure L.7 shows that, when the population increased from 2006 and 2009, 13 cities showed an increase in 30 years or greater residency duration while 6 cities showed a decrease in 30 years or greater residency duration. And when the population decreased from 2006 to 2009, 15 cities showed an increase in 30 years or greater residency duration while 7 cities showed a decrease in 30 years or greater residency duration.

Figure L.6*



* IPUMS-USA ACS 2006 and 2009 data with household weight applied to the residency duration data, and person weight applied to population data.

Figure L.7*



* IPUMS-USA ACS 2006 and 2009 data with household weight applied to the residency duration data, and person weight applied to population data.

L.3.1.3 Limitations of the IPUMS-USA data for Our Purposes

The ideal data for our purposes would be longitudinal data on the duration of residence of individuals. The IPUMS collects information on how long the person has been in the current residence, but not previous residences. People may continue at the current residence for an indefinite period of time. Likewise people who report living in the current residence for a short period of time may have lived in the previous residence for an extended period time. This could be the case with older people who have recently moved to assisted living. Second, data on the amount of time that a person might have lived beyond thirty years were not collected. There is therefore no way of knowing the number of people who may have lived in the same residence for 40 or 50 years. Third, geographic areas with fewer than 100,000 inhabitants are not identifiable so the impact of living in a smaller community on residency time in California could not be determined. The data are binned into intervals that are as much as 9 years at the longer residency times. These data are the only California specific data that we could locate however, and are generally supportive of the nationwide data.

L.3.2 SCAG Year 2000 Post-Census Regional Household Travel Survey Data

L.3.2.1 Methodology

The survey collected demographic information about persons and households. It also captured activity and travel information for household members during a 24-hour or 48-hour timeframe. The survey coincides with 2000-2001 CHTS. According to the 2000 Census, this region had 5,386,491 households. The total number of households that participated the survey and met the criteria for a completed record was 16,939 (SCAG, 2003). In the survey report, there are some trip time and age information.

Using the SCAG survey database, a statistical analysis for the regional average time spent at home per day was performed.

L.3.2.2 Findings and Discussions

The average time at home per person per day was determined to be 17.6 hours, which is about 73% of a day. This result is based on 44,344 person day records without any weight factor applied.

The residency duration data (months lived at home location) in the database are labeled as 1 to 12, 98-unknown, and 99-refused. Label 1 to 11 represents 1 to 11 months lived at home location, whereas label 12 represents 12 plus months lived at home location. No additional data were collected on residency duration. Therefore, the residency duration data from SCAG survey are limited for long-term health risk assessment evaluations.

L.3.2.3 Limitations on the Use of SCAG Household Travel Survey Data

The limitations of SCAG travel survey data include that the time spent at home analysis does not have weight factors applied due to insufficient user information on weights for personal level analysis (SCAG Manual) and the residency duration is not further categorized for a period that is 12 months or longer, which limits the data usage for long-term health risk assessment.

L.3.3 Caltrans 2000-2001 California Statewide Household Travel Survey Data

L.3.3.1 Methodology

The Survey was “activity” based and included in-home activities and any travel to activity locations. The Survey was conducted among households in each of the 58 counties throughout the State and grouped by region to provide a snapshot of both regional and interregional travel patterns. The participating households were asked to record travel information in their diaries for a specified 24-hour or 48-hour period. The Survey produced a sample size of 17,040 randomly selected households with an overall standard error of 0.8% at the 95% confidence level with respect to household level attributes at the statewide level of analysis (CHTS, 2003).

There are statistical survey reports about income, region, trip purpose, and trip time (home-work travel time percent by five minutes intervals by region). However, no report is based on travel distance, activity duration, season, or weekend.

A statistical analysis was performed by the staff using the CHTS database for the statewide average time spent at home per person per day. The result is based on 40,696 person day respondents’ records without any population weight factor applied.

Further statistical analysis gave us the statewide time at home average by age group, income level, and ethnicity. Time at home by age group and ethnicity results are based on 40,653 person day records. Time at home by income level result is based on 40,696 person day records. These results don’t have any weight factors applied. And five percent of the person day records are weekend records.

L.3.3.2 Findings and Discussions

L.3.3.2.1 California Statewide Average Time Spent at Home and Distributions by Age, Income, and Ethnicity

The statewide average time spent at home per person per day was determined to be 17.5 hours (including weekend samples), which is 73% of a day. This statewide average time at home percentage is about the same as the SCAG's regional average time at home percentage based on its 2000 regional travel survey data.

Table L.6 and Figure L.8 demonstrate California statewide time spent at home distribution by age group. The results show that children less than 2 years old spend 85% of their time at home, which is 12% more than the statewide average of 73%. Children in the age group 2 to <16 spend 72% of their time at home, which is a little less than the statewide average time at home.

Age groups listed in Table L.6 match those used for the application of Age Specific Sensitivity Factors that are listed in OEHHA's *Technical Support Document for Cancer Potency Factors: Methodologies for derivation, listing of available values, and adjustments to allow for early life stage exposures* (May 2009).

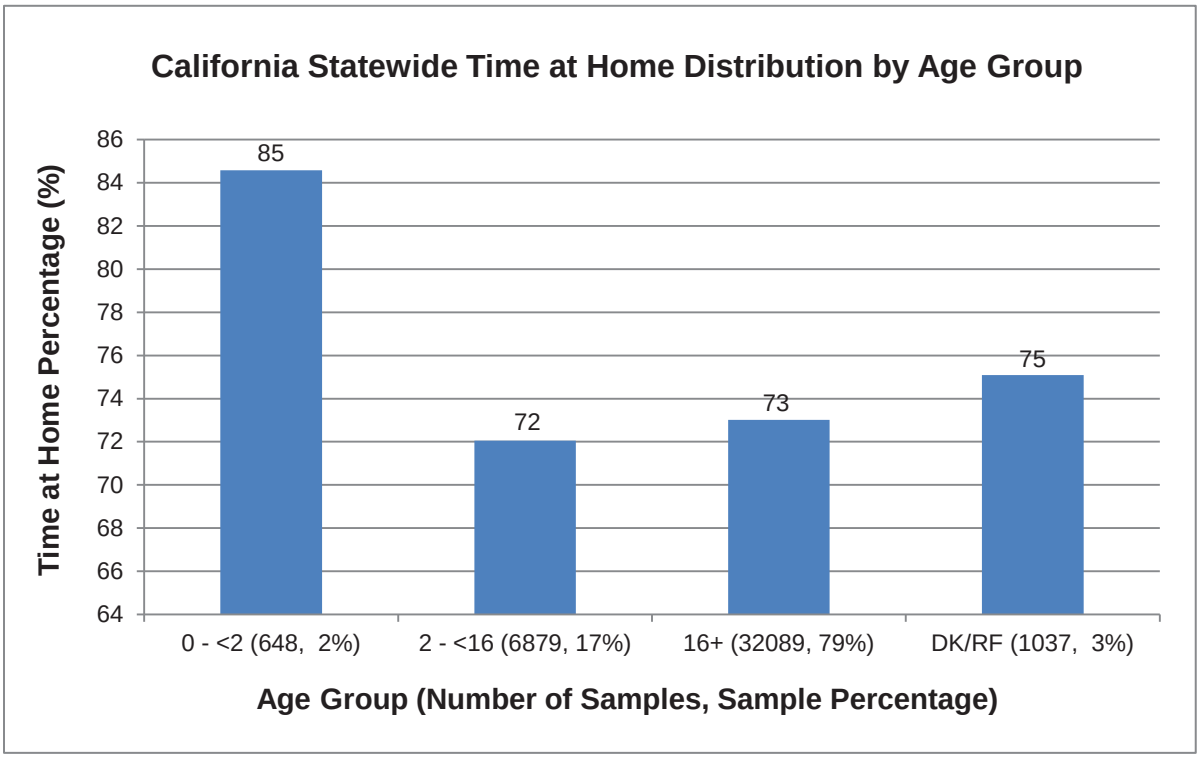
Table L.6 California Statewide Time at Home Distribution by Age Group

Age Group	Time at Home in Minute	Time at Home in Hour	Time at Home Percentage	Number of Samples	Sample Percentage
0 - <2	1218	20.3	85	648	2%
2 - <16	1037	17.3	72	6879	17%
16+	1051	17.5	73	32089	79%
DK/RF	1081	18.0	75	1037	3%
State Avg.	1052	17.5	73	40653	100%

Notes:

1. Caltrans 2000-2001 CHTS Data.
2. DK/RF means Don't Know/Refused.
3. Results don't have any weight factors applied.

Figure L.8



Notes:

1. Caltrans 2000-2001 CHTS Data.
2. DK/RF means Don't Know/Refused.
3. California statewide time at home average is 73%.
4. Total number of samples: 40,653.
5. Results don't have any weight factors applied.

Table L.7 and Figure L.9 demonstrate California statewide time spent at home distribution by household income level. They show a trend: the higher the household income is, the less time people spend at their home. The households with income level less than $10k spend most of their time at home as 81% (19.5 hr.) whereas the households with income level more than $100k but less than $150k spend the least time at home as 68% (16.2hr). The households with income level more than $35k but less than $50k spend the state average time 73% (17.5 hr) at home.

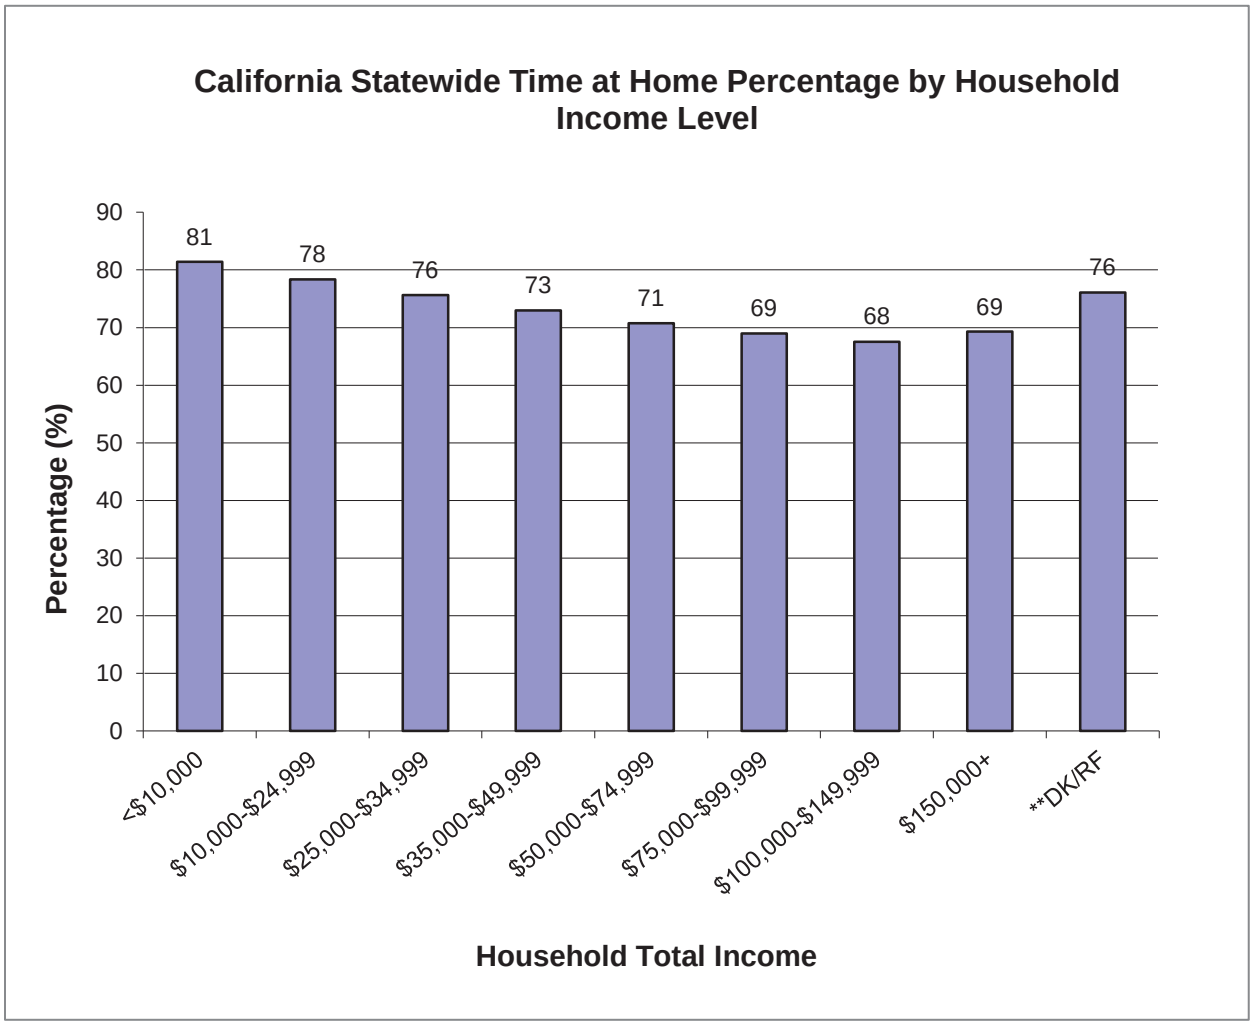
Table L.7 California Statewide Time at Home Distribution by Household Income Level

Household Total Income	Time at Home In Minute	Time at Home In Hour	Time at Home Percentage	Number of Samples	Sample Percentage
<$10,000	1172	19.5	81	1312	3%
$10,000-$24,999	1128	18.8	78	5189	13%
$25,000-$34,999	1089	18.2	76	5265	13%
$35,000-$49,999	1051	17.5	73	5568	14%
$50,000-$74,999	1019	17.0	71	8677	21%
$75,000-$99,999	994	16.6	69	5077	12%
$100,000-$149,999	973	16.2	68	3332	8%
$150,000+	998	16.6	69	1525	4%
DK/RF	1095	18.3	76	4751	12%
Total				**40696**	**100%**

Notes:

1. Caltrans 2000-2001 CHTS Data.
2. California statewide time at home average is 73%.
3. DK/RF means Don't Know/Refused.
4. Results don't have any weight factors applied.

Figure L.9



Notes:

1. Caltrans 2000-2001 CHTS Data.
2. California statewide time at home average is 73%.
3. DK/RF means Don't Know/Refused.
4. Total number of samples: 40,696.
5. Results don't have any weight factors applied.

Table L.8 and Figure L.10 show California statewide time spent at home distribution by ethnicity. They depict that all the ethnic groups spend 71% to 74% time at home per day. The N/A in the ethnicity group in Table L.8 means the description of the ethnicity code 6 in the database is not available. The Caltrans survey data contact person believes that the code 6 should not have existed. This was a mistake in survey reporting. The 532 person day records (1% of the total person day records) with ethnicity code 6 may exist in error.

Table L.8 California Statewide Time at Home Average by Ethnicity

Ethnicity	Ethnicity Code	Time at Home In Minute	Time at Home In Hour	Time at Home Percentage	Number of Samples	Sample Percentage
White/Not Hispanic	1	1051	17.5	73%	29255	72%
Hispanic	2	1059	17.6	74%	6098	15%
African American	3	1067	17.8	74%	941	2%
Asian/Pacific Islander	4	1022	17.0	71%	1054	3%
Native American	5	1024	17.1	71%	319	1%
N/A	6	1077	17.9	75%	532	1%
Other, specify	7	1068	17.8	74%	732	2%
Mixed	8	1031	17.2	72%	581	1%
DK/RF	9	1061	17.7	74%	1141	3%
Total					**40653**	**100%**

5. Results don't have any weight factors applied.

L.3.3.2.2 Comparison of Time at Home Results from CHTS Data with Time inside Home Results from ARB Activity Pattern Studies

Staff compared the time at home by age group statistical results from Caltrans 2000-2001 CHTS data and the time inside home results from 1987-1990 ARB activity pattern studies (ARB, 2005). Table L.9 and Figure L.11 show that, compared to the time spent inside home in 1987-1990, children under age of 12 spent similar amount of time at home in 2000-2001. However, teens (age 12 to17) spent 6% more time at home in 2000-2001, and adults spent 11% more time at home in 2000-2001.

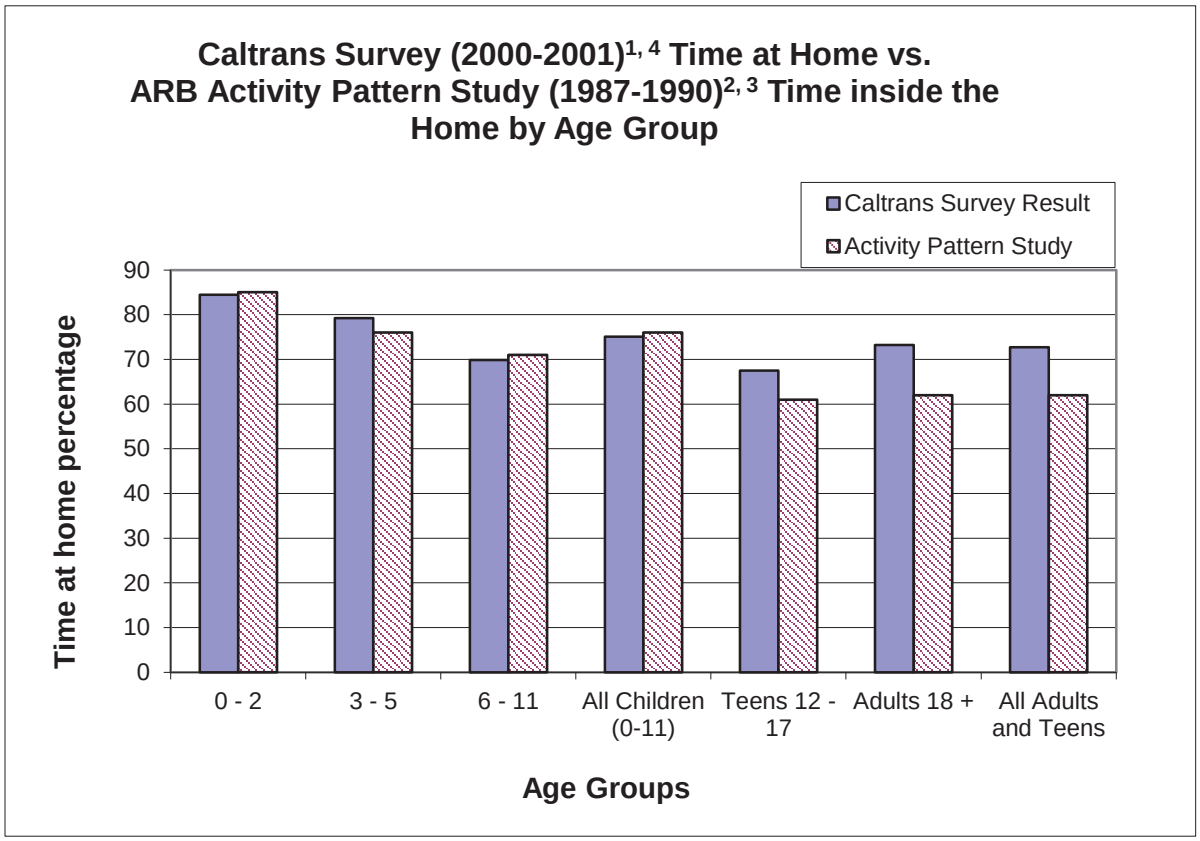
Table L.9 Caltrans Survey (2000-2001) Time at Home vs. ARB Activity Pattern Study (1987-1990) Time inside the Home by Age Group

Age Group	Caltrans[1, 4]			ARB[2, 3]	
	Number of Samples	Time at Home In Hour	Time at Home (%)	Number of Samples	Time Inside Home (%)
0 - 2	1086	20.3	84	313	85
3 - 5	1328	19.0	79	302	76
6 - 11	2985	16.8	70	585	71
All Children (0-11)	5399	18.0	75	1200	76
Teens 12 - 17	3180	16.2	67	183	61
Adults 18 +	31937	17.6	73	1579	62
All Adults and Teens	34217	17.4	73	1762	62

Notes:

1. The 2000 - 2001 California Statewide Household Travel Survey was conducted among households in each of the 58 counties throughout the State and grouped by region. Total person day records are 40,653.
2. The 1989 -1990 Children's Activity Pattern Study's samples are selected from households among three major areas: Southern Coast, S.F. Bay Area, and the rest of state. Total samples are 1,200 (ARB, 1991).
3. The 1987 – 1988 California Residents Activity Pattern Study's samples are selected from the same three major areas as for Children's Activity Pattern Study, with 1579 adult samples and 183 youth samples (ARB, 1992).
4. Results from Caltrans survey data don't have any weight factors applied, whereas the results from the activity pattern studies have the weight factors applied.

Figure L.11



Notes:

1. The 2000 - 2001 California Statewide Household Travel Survey was conducted among households in each of the 58 counties throughout the State and grouped by region. Total person day records are 40,653.
2. The 1989 -1990 Children's Activity Pattern Study's samples are selected from households among three major areas: Southern Coast, S.F. Bay Area, and the rest of state. Total samples are 1,200 (ARB, 1991).
3. The 1987 – 1988 California Residents Activity Pattern Study's samples are selected from the same three major areas as for Children's Activity Pattern Study, with 1579 adult samples and 183 youth samples (ARB, 1992).
4. Results from Caltrans survey data don't have any weight factors applied, whereas the results from the activity pattern studies have the weight factors applied.

L.3.3.3 Limitations on the Use of 2000-2001 CHTS data

The limitations of the use of the 2000-2001 CHTS data are that the analysis results do not have weight factors applied due to in-sufficient user information on weights for personal level analysis (CHTS Guide). And 2000-2001 CHTS does not have residence duration data.

L.4 Other Data Sources Not Used in This Report

L.4.1 The 2009 National Household Travel Survey

The 2009 NHTS updates information gathered in the 2001 NHTS and in prior Nationwide Personal Transportation Surveys. The data are collected on daily trips taken in a 24-hour period (NHTS, 2009). Although we may be able to analyze the 2009 NHTS data to get the time at home statistical results for Californians, the staff didn't use the data because the user manual was not ready at the time the staff was preparing this report.

L.4.2 National Human Activity Pattern Survey

NHAPS was sponsored by the U.S. Environmental Protection Agency. It was conducted between late September 1992 and September 1994, collected 24-hour activity diaries and answers of personal and exposure questions. The survey interviewed 9386 participants across the 48 contiguous states (Klepeis et al., 1995).

NHAPS has time in a residence data from California respondents. However, the staff didn't further analyze these data because the 2000-2001 CHTS provides much larger sample size and more recent California-specific data.

L.5 Conclusion

The staff has evaluated several data sources to identify the California statewide exposure duration and exposure frequency characteristics. Estimates on residence duration and time spent at home have been determined from available data on the California population. The data on residency time are similar to the available national data as discussed in Chapter 11. There is some variability in the residence duration and time spent at home by ethnicity, age, and income.

The IPUMS-USA census data show that, from 2006 to 2009, over 90% of California householders had lived at their current home address for less than 30 years, and over 63% householders had lived at their current residence for 9 years or less.

The 2000-2001 CHTS data show that, on average, Californians spend approximately 73% of their time at home per day. When looking at the data by age group, the time increases to 85% for children under 2 years old. Children that are 2 years or older but less than 16 years old spend 72% of their time at home; whereas Californians that are16 years or older spend 73% of their time at home. In addition, all ethnicity groups spend 71%-74% of their time at home. The data also demonstrate a trend where the higher the total household income is, the less time the residents spend at their home.

These data are the best available on the California population for helping to establish default recommendations for the Hot Spots program.

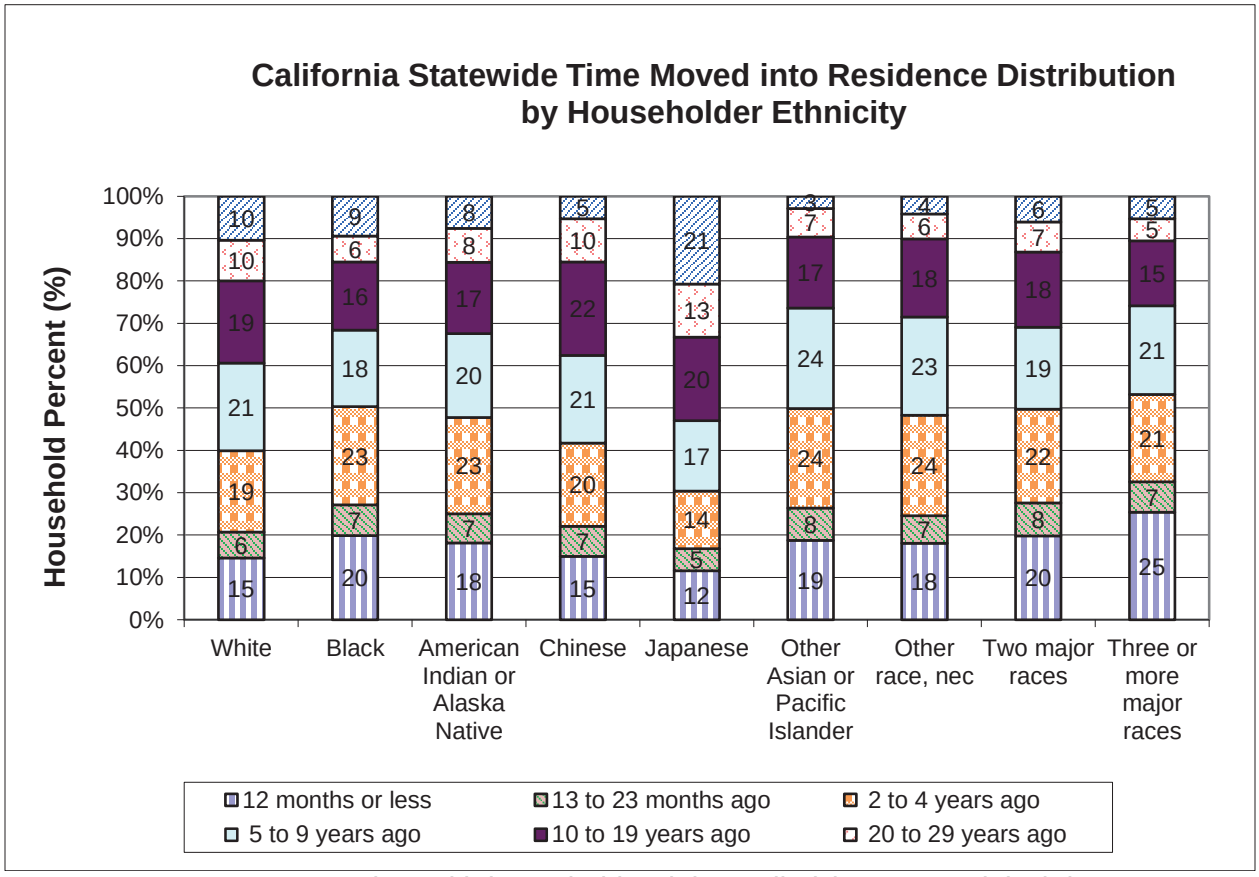
A. Supplemental Information

The following figures graphically present the analysis results of California statewide time moved into residence distribution by householders' ethnicity, age, and household income respectively from IPUMS-USA ACS 2009 data (IPUMS-USA). The data are obtained by using IPUMS online analysis tool (IPUMS Tool). These data may be useful to the risk manager in considering population risk in different communities.

Figure A.1 shows California statewide time moved into residence distribution by householders' ethnicity. In general, the percentages of householders that moved into their residence 12 months or less ago, 2 to 4 years ago, 5 to 9 years ago, and 10 to 19 years ago are larger than the percentages of 13 to 23 months ago, 20 to 29 years ago, and 30 years ago.

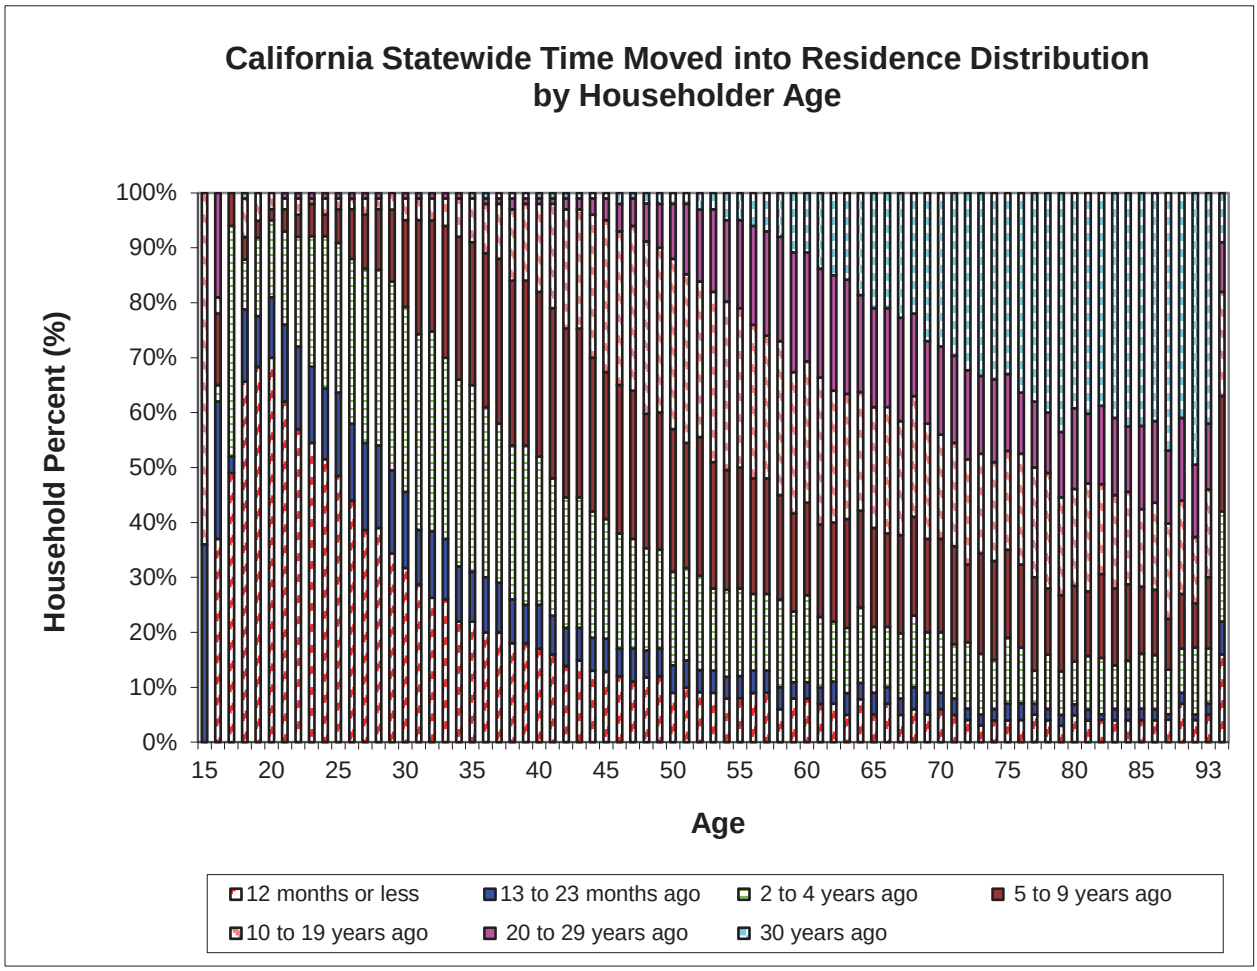
Figure A.1*



* IPUMS-USA ACS 2009 data with household weight applied (IPUMS Weights) (IPUMS Ethnicity).

Figure A.2 presents California statewide time moved into residence distribution by householders' age. It shows a general trend that the younger the householders are, the more householders moved into their residence within the last 12 months. And the older the householders are, the more householders moved into their residence 30 years ago. There are some exceptions at the both ends of the age range.

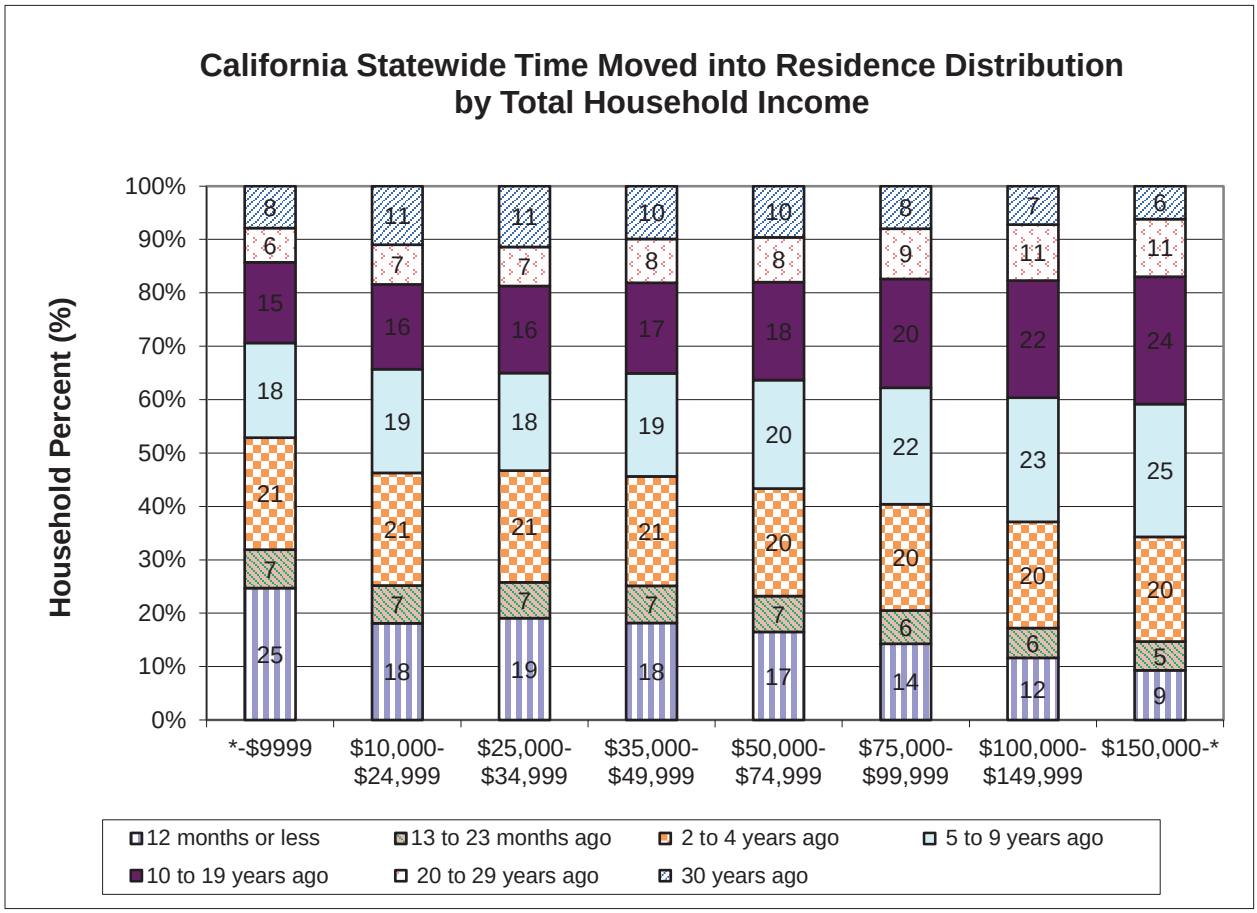
Figure A.2*



* IPUMS-USA ACS 2009 data with household weight applied (IPUMS Weights). The age categories are 15-89 and 93.

Figure A.3 shows California statewide time moved into residence distribution by total household income. It reveals a general trend that the higher the household income is, the smaller percentage of the householders moved into their residence within last the 12 months. And the households with household income of $150,000 or above not only have the smallest percentage of householders moved into their residence within the last 12 months, but also have the smallest percentage of householders moved into their residence 30 years ago.

Figure A.3*



* IPUMS-USA ACS 2009 data with household weight applied (IPUMS Weights).

Appendix M

How to Post-Process Offsite Worker Concentrations using the Hourly Raw Results from AERMOD

This appendix describes how to calculate refined offsite worker concentrations using the hourly raw results from the AERMOD air dispersion model. In some cases, a better representation of what the offsite worker breathes during their work shift is needed for the health risk analysis. To obtain a better representation, the hourly raw results contain enough information to allow the risk assessor to evaluate the concentrations that occurs during the offsite worker's shift. However, since the hourly raw results include all the concentrations for every hour of meteorological data at each receptor for each source in the air dispersion analysis, the results must be filtered and processed to obtain the refined offsite worker concentrations. The basic steps include: 1) determining the averaging periods needed for the offsite worker analysis; 2) outputting the hourly raw results from the AERMOD air dispersion model; 3) extracting the hourly concentrations based on when the receptor is present; and 4) identifying or calculating the required concentration. The calculation methods described in this appendix can be used for assessing acute, 8-hour non-cancer chronic, and inhalation cancer health impacts.

M.1 Determine the Averaging Periods Required for the Offsite Worker Health Risk Analysis

Before any refined offsite worker concentrations can be calculated, the first step is to determine which type of refined concentrations or averaging periods are needed for the health risk analysis. The refined averaging periods needed for the analysis are based on the pollutant-specific health values emitted by the source or sources. Specifically, refined offsite worker concentrations can only be used for pollutants that have inhalation cancer potency factors, 8-hour RELs, and/or acute RELs. This section describes the refined averaging periods required for assessing acute RELs, 8-hour RELs, and inhalation cancer potency factors.

M.1.1 Averaging Period Required for Acute RELs

The maximum 1-hour concentration is typically required for the acute health hazard index calculation. AERMOD can determine and output the maximum 1-hour concentration at each receptor location for each source in the air dispersion analysis. However, if more refined concentrations for the offsite worker are needed, the maximum1-hour concentration that occurs during the offsite worker's shift may be used.

This type of refinement can be processed using the hourly raw results from the air dispersion analysis.

If there are multiple sources in the analysis, an additional refinement step is to examine the coincident acute health impacts at each receptor from all sources at each hour during the offsite worker's shift and identify the total maximum acute health impacts from all sources. For example, if there are two sources that emit a single pollutant for ten hours per day and the offsite worker's shift is from hour three to hour seven, the risk assessor may evaluate the total acute risk from all sources during the offsite worker's shift. Assuming the acute REL is 50 $\mu g/m^3$, the highest acute health impact occurs at hour three with a Health Hazard Index of 0.3 (see Table M.1). This approach is also known as a refined acute analysis.

Table M.1. Example of a Refined Acute Calculation

Hour	***1***	***2***	***3***	***4***	***5***	***6***	***7***	***8***	***9***	***10***
Source 1 Concentration ($\mu g/m^3$)	5	7	8	0	9	11	5	1	12	3
Source 2 Concentration($\mu g/m^3$)	4	6	7	0	2	1	3	4	5	2
Total Acute Health Hazard Index from All Sources	0.18	0.26	**0.3**	0	0.22	0.24	0.16	0.1	0.34	0.1

M.1.2 Averaging Period Required for Inhalation Cancer Potency Values

The period average is typically required for cancer risk assessments. AERMOD calculates this average by summing all the hourly concentrations and dividing it by the number of processed hours over the entire time period of the air dispersion analysis. However, the period averages calculated from AERMOD typically represent exposures for receptors (i.e., residential receptors) that are present 24 hours a day and seven days per week. For the offsite worker, the period average should represent what the worker breathes during their work shift when assessing the cancer inhalation pathway.

To estimate the offsite worker's concentration, there are two approaches. The simple approach is to obtain the period average concentration as calculated by AERMOD and approximate the worker's inhalation exposure using an adjustment factor (See Chapter 2.8.1.1. for more information). For a more representative concentration, the second approach is to calculate a refined period average using the hourly raw results from the air dispersion analysis. This refined period average should reflect only the concentrations that occur during the offsite worker's shift. It is calculated by summing all of the hourly concentrations that occurs during the offsite worker's shift and dividing it by the number of hours that occurs during the offsite worker's shift. The equation for calculating the refined offsite worker concentration is shown in Section 4.3.

M.1.3 Averaging Period Required for 8-Hour RELs

For 8-hour noncancer health impacts, we evaluate if the worker is exposed to a daily (e.g., 8-hour) average concentration that exceeds the 8-hour REL. The daily average concentration is intended to represent the long term average concentration the worker is breathing during their work shift. The long-term 8-hour daily average concentration is required for 8-hour health hazard index calculations. Specifically, this concentration represents the long-term average of repeated 8-hour daily averages that occur when the source's emission schedule and offsite worker's schedule overlap. For example, the 8-hour averages are first calculated for each day in the air dispersion analysis. The 8-hour averages should represent the eight hour sequential concentration for when the source's emission schedule and offsite worker's schedule overlap. All the 8-hour averages are then averaged over the entire time period of the air dispersion analysis.

There are two approaches for calculating the average 8-hour daily concentration. The simple approach is to obtain the long-term concentration (i.e., period average) as calculated by AERMOD and approximate the average 8-hour daily concentration using an adjustment factor (See Chapter 2.8.1.2 for more information). For a more representative concentration, the second approach is to calculate the offsite worker concentration using the hourly raw results from the air dispersion analysis.

Please note that although the duration of work shifts or period of overlap with the source's emission schedule can vary from eight hours, the calculated long-term daily average concentrations can still be applied to the 8-hour RELs. However, the risk assessor may wish to calculate the 8-hour hazard index using the adjustment factor approach as a screening assessment before proceeding with the post-processing approach. Based on the results of the screening assessment, the risk assessor can contact OEHHA for assistance in determining whether further evaluation may be necessary.

M.2 Output the Hourly Raw Results from AERMOD

The hourly raw results from the air dispersion analysis are needed to calculate the refined offsite worker concentrations as described above. AERMOD can output the hourly raw results to a file for post-processing. In order to output a file suitable for post-processing, the AERMOD input file must be modified. The AERMOD input file contains the modeling options, source location and parameter data, receptor locations, meteorological data file specifications, and output options. It is organized into five main sections that include the Control (CO), Source (SO), Receptor (RE), Meteorology (ME), and Output (OU) pathways (U.S. EPA, 2004). This section describes how to modify the pathways in the AERMOD input file to allow the hourly raw results to be saved to a file.

M.2.1 Modify the Control (CO) Pathway to Identify Calm and Missing Hours

By default, AERMOD disregards calm and missing hours when calculating the long-term and short-term averages. When calculating the refined offsite worker concentrations, the calm and missing hours must also be disregarded. However, the hourly raw results from AERMOD do not identify which hours are calm or missing. Since this is the case, an additional file from AERMOD must also be saved in order to post-process the hourly raw results correctly. The AERMOD Detailed Error Listing File will report all calm and missing hours from the air dispersion analysis. The syntax for creating a Detailed Error Listing File in the CO pathway is shown below. This modification in the CO pathway will create a file which will be used to assist with calculating the refined offsite worker concentrations. This process is described in the subsequent sections of this appendix.

Syntax for Creating the Detailed Error Listing File

CO ERRORFIL [Filename]

M.2.2 Modify the Source (SO) Pathway if Unit Emission Rates are used

In an air dispersion analysis, it is typical to use non-substance specific unit emission rates (e.g., 1 g/s) for evaluating multiple pollutants. This precludes modelers from having to run the air dispersion model for each individual pollutant that is emitted from a source. Unit emission rates allow the air dispersion modeling results to be expressed as dilution factors in $(\mu g/m^3)/(g/s)$. When these dilution factors are combined with the pollutant specific emission rate (g/s), it will yield the ground level concentrations ($\mu g/m^3$) for each pollutant in the analysis. When there are multiple sources in the air dispersion analysis and unit emission rates are used, the individual source contributions must be provided in the modeling results so the ground level concentrations can be correctly scaled for each pollutant. To do this, the air dispersion input file must be modified to create individual source groups for each source. The example below shows how individual source groups for two sources (S001 and S002) are specified in the SO pathway of an AERMOD input file. This modification in the SO pathway will allow the individual source contributions to be saved in the hourly raw results.

```
SO STARTING

**S001 and S002 location and source parameters are not shown.**

SRCGROUP SRCGP1 S001

SRCGROUP SRCGP2 S002

SO FINSHED
```

This parameter identifies the sources tied to the source group. Use only one source ID per source group.

This section specifies the name of your source group. The source group name is what is specified when you output the required concentrations files.

Please note that a separate input file is needed for evaluating acute health impacts when unit emission rates are used and the source has a variable emission schedule (e.g., emissions vary by hour-of-day and day-of-week). Acute health impacts are based on maximum hourly emissions whereas cancer and chronic health impacts are based on average hourly emissions. To correctly simulate unit emissions for the acute impacts, a duplicate source with a variable emission rate of "on" (1) or "off" (0) should be used so the maximum hourly inventory is correctly calculated separately from the emission factors placed in the annual file. The example below shows how the variable emission rates should be modified. Alternatively, a source can be duplicated in the same input file instead of rerunning the source using a separate input file.

First Run with Unmodified Emission Rate Factors for Long-Term

```
EMISFACT S002  HROFDY   0.000   0.000   0.000   0.000   0.000
         S002  HROFDY   0.000   2.667   2.667   2.667   2.667
         S002  HROFDY   2.667   2.667   1.333   1.333   1.333
         S002  HROFDY   1.333   1.333   1.333   0.000   0.000
         S002  HROFDY   0.000   0.000   0.000   0.000
```

Second Run with Modified Emission Rates Factors for Acute

```
EMISFACT S002  HROFDY   0.000   0.000   0.000   0.000   0.000
         S002  HROFDY   0.000   1.000   1.000   1.000   1.000
         S002  HROFDY   1.000   1.000   1.000   1.000   1.000
         S002  HROFDY   1.000   1.000   1.000   0.000   0.000
         S002  HROFDY   0.000   0.000   0.000   0.000
```

M.2.3 Modify the Receptor (RE) Pathway to Reduce the Processing Time

AERMOD is capable of outputting the hourly raw results from the air dispersion analysis. However, without taking appropriate precautions, outputting the hourly raw results can produce extremely large file sizes especially when evaluating multiple years of meteorological data, a large number of receptors, and short-term averaging periods (e.g., 1-hour). To minimize the amount of processing time and hard disk space, it is recommended to use only a single discrete receptor representing the off-site worker location. The proper syntax for specifying a discrete receptor is shown below.

Sample Syntax for Creating a Single Discrete Receptor

```
RE DISCCART XcoordYcoord (ZelevZhill) (Zflag)
```

M.2.4 Modify the Output (OU) Pathway to Output the Hourly Raw Results

To create a file containing the hourly raw results, modify the OU pathway to include the POSTFILE keyword and parameters. The sample below shows the syntax for outputting the hourly raw results for a single source. The POSTFILE will list in order the concentration for each receptor and for each hour of meteorological data regardless of the source's emission schedule. Use Table M.2 to help construct the proper syntax for the POSTFILE option. This step must be repeated for each source in the analysis which will result in additional files.

Please note that if the data are outputted as binary file (UNFORM), a separate computer program will be needed to read and parse the data.

Sample Syntax for Outputting the Hourly Concentrations for a Single Source

```
OU POSTFILE 1 SRCGP1PLOT PSTS001.TXT
```

Table M.2. Descriptions of the POSTFILE Parameters

Keyword	Parameters	
POSTFILE	AveperGrpid Format Filnam (Funit)	
where:	Aveper	Specifies averaging period to be output to file. Set this value to 1 to output 1-hour raw results.
	Grpid	Specifies source group to be output to file. If there are multiple sources, you will need to repeat the POSTFILE option for each source. You can combine the different outputs to a single file using the Funit parameter.
	Format	Specifies format of file, either UNFORM for binary files or PLOT for formatted files. Unformatted files offer a smaller file size; however, this file requires programming expertise in order to view and parse the data. Selecting the PLOT option will allow you to view the file in any text editor.
	Filnam	Specifies filename for output file
	Funit (optional)	The file unit is an optional parameter. If the filename and the file unit number are the same, the results for different source groups can be combined into a single file.

M.3 Extract the Hourly Concentrations when the Offsite Worker is Present

To calculate the refined offsite worker concentrations, it is necessary to extract the hourly concentrations based on the offsite worker's schedule. This section provides information on how to extract the hourly concentrations for the offsite worker including the calm and missing hours that may occur during the offsite worker's shift.

At this point, it is recommended the hourly raw results be imported into a spreadsheet or database to assist with the extraction process. Spreadsheets and database contain preprogrammed functions to assist with deciphering data. **Use the information in Section M.3.1 as a guide to help import the hourly raw results into a database or spreadsheet.**

M.3.1 Description of the POSTFILE File Format

AERMOD was created using FORTRAN, a type of programming language. When the AERMOD output files are created, it is based on a specified FORTRAN format. The variables provided on each data record in the POSTFILE include the X and Y coordinates of the receptor location, the concentration value for that location, receptor terrain elevation, hill height scale, flagpole receptor height, the averaging period, the source group ID, and the date for the end of the averaging period (in the form of YYMMDDHH) (U.S. EPA, 2004). Table M.3 shows the equivalent data types based on the POSTFILE format. The POSTFILE will list in order the concentration for each receptor and for each hour of meteorological data regardless of the source's emission schedule (see Figure M.3.1). Use the information in this section as a guide to help import the hourly raw results into a database or spreadsheet.

Table M.3. POSTFILE Variables and Equivalent Data Types

Column Name	Fortran Format	Equivalent Data Type
X	F13.5	Number/Double Precision
Y	F13.5	Number/Double Precision
AVERAGE_CONC	F13.5	Number/Double Precision
ZELEV	F8.2	Number/Double Precision
ZHILL	F8.2	Number/Double Precision
ZFLAG	F8.2	Number/Double Precision
AVE	A6	6-Character String/Text
GRP	A8	8-Character String/Text
NUM_HRS OR DATE	I8.8	8-Character String/Text
NET_ID	A8	8-Character String/Text

Figure M.3.1. Sample of an AERMOD POSTFILE

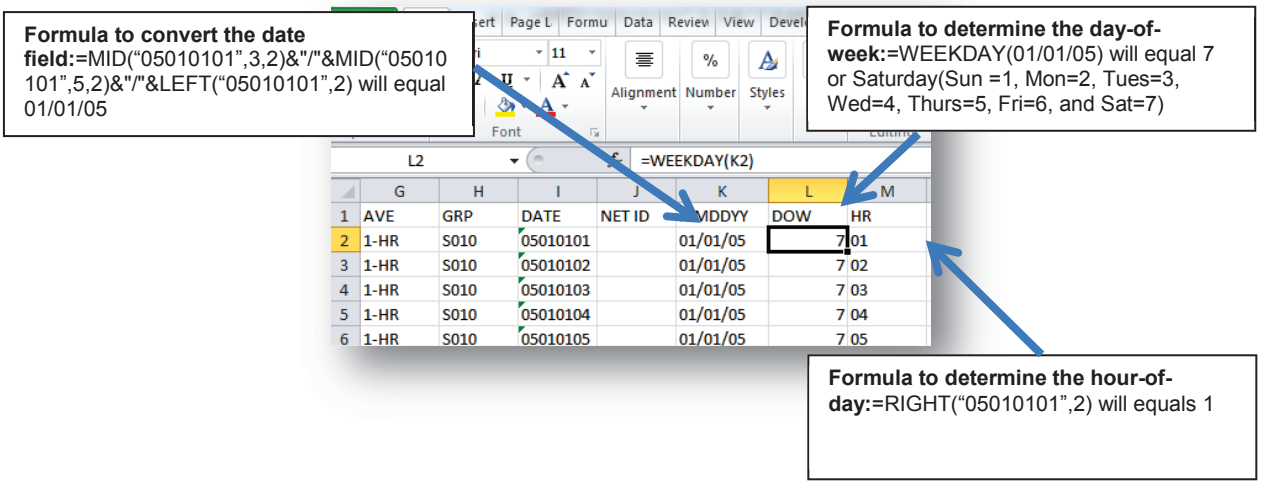
M.3.2 Determine the Day-of-Week and Hour-of-Day

In order to extract only the hourly concentrations that occur when an offsite worker is present, the risk assessor must first determine the day-of-week and hour-of-day for each hourly record using the date field. Since the date outputted by AERMOD cannot be directly interpreted by the day-of-week function in a database or spreadsheet, the date must be first converted. For example, the date field can be first converted using the LEFT and MID functions in Microsoft Excel (See Column K in Figure M.3.2). After which, the WEEKDAY function in Microsoft Excel can be used to determine the day-of-week (See Column L in Figure M.3.2). The hour-of-day can be extracted using the RIGHT function (See Column M in Figure M.3.2).

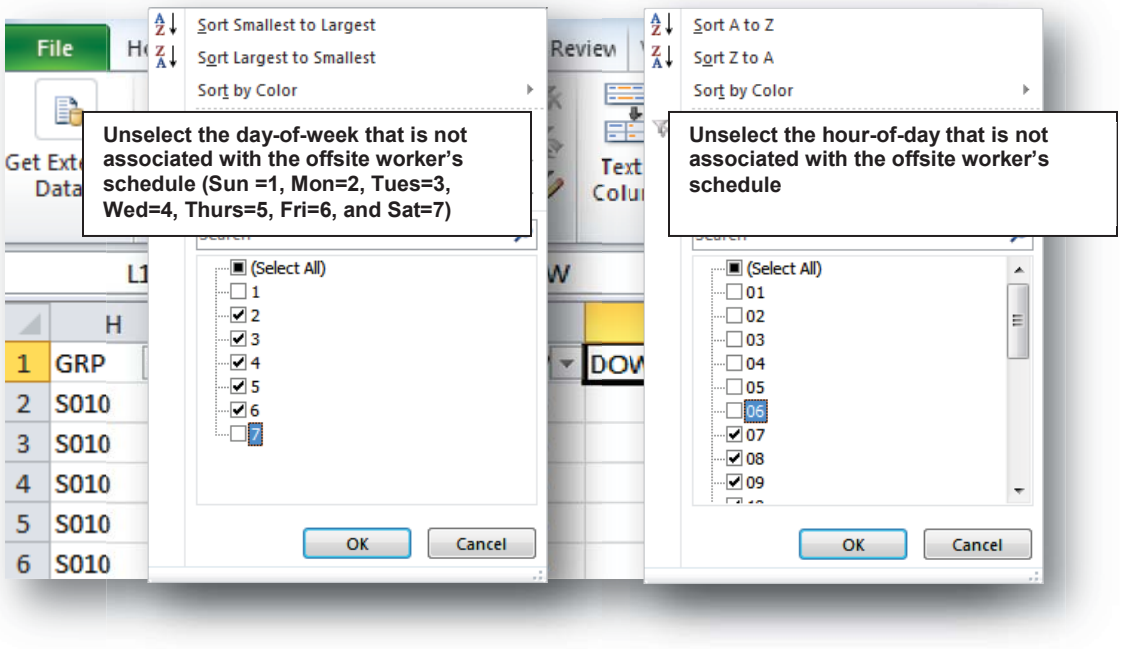
Figure M.3.2. How to Determine the Day-of-Week and Hour-of-Day in Microsoft Excel



M.3.3 Extract the Hourly Concentrations Based on the Offsite Worker's Schedule

After the day-of-week and hour-of-day have been determined, the concentrations can now be extracted or filtered. Based on the offsite worker's schedule, filter or query the hourly concentrations using a spreadsheet or database. For example, in Microsoft Excel, you can filter the data by selecting the data filter option (see Figure M.3.3). Then unselect the records that are not associated with the offsite worker's schedule using the day-of-week and hour-of-day fields that were created in previous section. If the data contains information for multiple receptors, filter the X and Y coordinates to get the concentrations that are specific to each receptor. The results from the filter will now only show hourly concentrations for times when the offsite worker is present.

Figure M.3.3. How to Filter the Data in Microsoft Excel



M.3.4 Count the Number of Calm and Missing Hours that Occur During the Offsite Worker's Schedule

If calm hour processing was used in the air dispersion analysis, then calm and missing hours must also be considered when post-processing the long-term and short-term averages for the offsite worker. To assist in this calculation, the Detailed Error Listing File that was created from the air dispersion analysis (Section 2.1) can be used to count the number of calm and missing hours that occurred during the worker's shift.

To identify the calm and missing hours, it is recommended to import the Detailed Error Listing File into a spreadsheet or database. Then follow the instructions from Sections 3.2 and 3.3 to determine the number of calm and missing hours that occur during the offsite worker's schedule. This information is needed to calculate the averaging periods for the offsite worker.

M.4 How to Identify or Calculate the Refined Concentrations for the Offsite Worker Analysis

Depending on which averaging periods are needed (as determined by Section 1.0), use Sections 4.1 through 4.3 below to identify or calculate refined concentrations for estimating the acute, 8-hour, and cancer health impacts. The equations are based on how the long-term and short-term averages are calculated in AERMOD. These equations also account for how calm and missing hours are handled by AERMOD (U.S. EPA, 2005). After calculating the appropriate averaging periods, the refined concentrations can be used to assess the health impacts for the offsite worker's inhalation pathway.

Please note that if unit emission rates were used in the air dispersion analysis, each averaging period calculated using the methods below must be combined with the pollutant specific emission rate (g/s) to yield the actual ground level concentrations (µg/m^3) for each pollutant in the analysis before the health impacts can be assessed.

M.4.1 How to Determine the Maximum 1-Hour Average for a Simple Acute Assessment

The maximum 1-hour average concentration represents the highest concentration that occurs during the offsite worker's schedule. To determine the maximum 1-hour average, sort the extracted hourly concentrations in descending order using a spreadsheet or a database. The maximum hourly concentration will be at the top of the list (Figure M.4.1). This process must be repeated at each receptor for all sources of interest.

Figure M.4.1. Identifying the Maximum 1-Hour Concentration

A	B	C	D	E	F	G	H	I	J	K	L
X	Y	AVERAGE CONC	ZELEV	ZHILL	ZFLAG	AVE	GRP	DATE	NET ID	MMDD	DOW

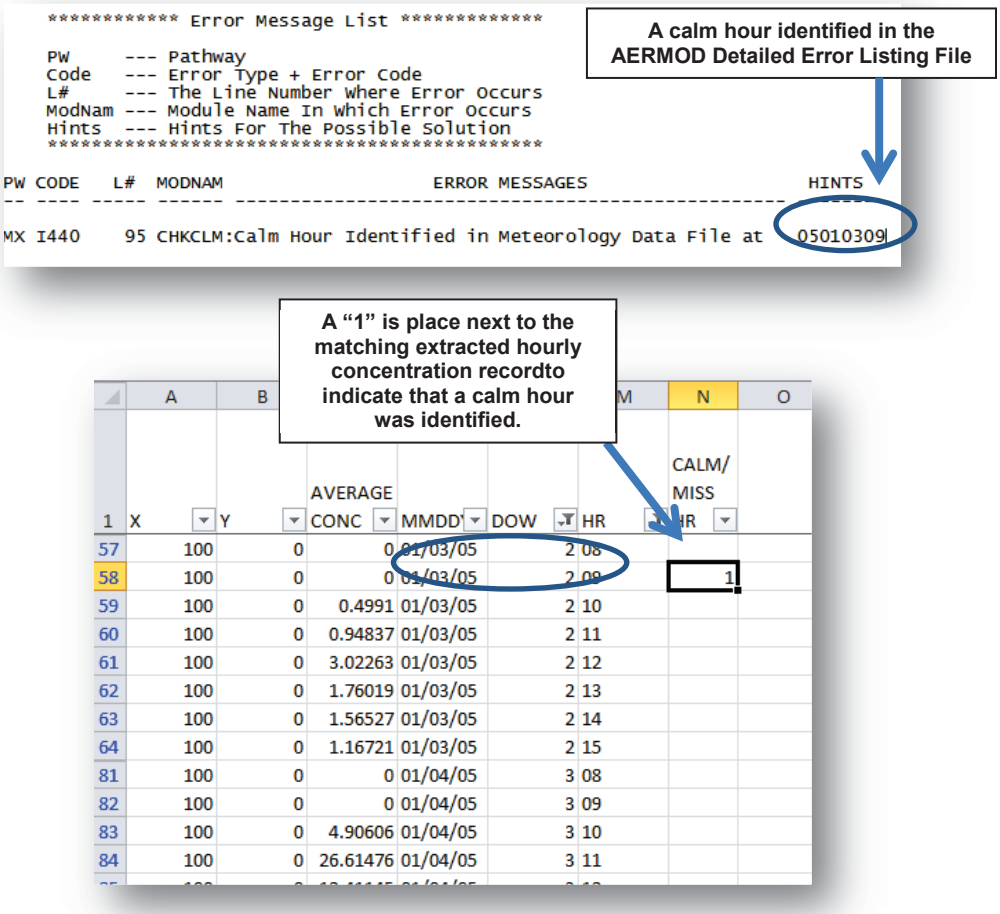
M.4.2 How to Determine the Long-Term Average of 8-Hour Daily Concentrations for an 8-Hour Assessment

To calculate the long-term 8-hour daily average concentration, the 8-hour averages are first calculated for each day in the air dispersion analysis. All the 8-hour averages are then averaged over the entire time period of the air dispersion analysis. However, since the 8-hour daily average is considered a short-term average, the total number of valid hours (i.e., not calm or not missing) must be considered. The total number of valid hours should be 75% of the 8-hour average. If the total number of valid hours in an 8-hour average is less than six (6), the 8-hour total concentration should be divided by six (6) (U.S. EPA, 2005). The following steps below are an example that shows how the average of 8-hour daily concentration is calculated.

- Using the extracted hourly concentrations based on the steps from Section 3.0, identify any calm and missing hours with a “1”. To do this, use the Detailed Error Listing File that was created from the air dispersion analysis (See Section 2.1 for more information).The Detailed Error Listing File will list the calm and missing hours by date. Place a “1” where the dates match up with the extracted hourly concentrations (See Column N in Figure M.4.2.1). Please note that some of the columns are hidden in Figure M.4.2.1 for presentation purposes.

Figure M.4.2.1. Identify Calm and Missing Hours



- Then calculate the 8-hour average for each day throughout the file. The 8-hour average is the sum of the hourly concentrations in a day divided by eight (see Figure M.4.2.2). However, if there are any calm or missing hours in the time period, the sum of hourly concentrations should be divided by total number of valid hours. The total number of valid hours is eight minus the total number of calm and missing hours. If the total number of valid hours is less than six, then the sum of hourly concentrations should be divided by six.

Figure M.4.2.2. 8-Hour Daily Average Calculation

	A	B	C	K	L	M	N	O
1	X	Y	AVERAGE CONC	MMDD	DOW	HR	CALM/ MISS HR	DAILY 8-HR AVERAGE
57	100	0	0	01/03/05	2	08		1.28
58	100	0	0	01/03/05	2	09	1	
59	100	0	0.4991	01/03/05	2	10		
60	100	0	0.94837	01/03/05	2	11		
61	100	0	3.02263	01/03/05	2	12		
62	100	0	1.76019	01/03/05	2	13		
63	100	0	1.56527	01/03/05	2	14		
64	100	0	1.16721	01/03/05	2	15		
81	100	0	0	01/04/05	3	08		11.79
82	100	0	0	01/04/05	3	09		
83	100	0	4.90606	01/04/05	3	10		
84	100	0	26.61476	01/04/05	3	11		
85	100	0	12.41145	01/04/05	3	12		
86	100	0	40.17394	01/04/05	3	13		
87	100	0	8.2986	01/04/05	3	14		
88	100	0	1.93475	01/04/05	3	15		
105	100	0	0	01/05/05	4	08		6.95
106	100	0	0	01/05/05	4	09		

- Assuming that there were only three days in the entire time period of the air dispersion analysis, the average of 8-hour daily concentrations is (1.28 11.79 + 6.95) /3 = 6.78.

M.4.3 Equation for Calculating the Average Concentration for the Inhalation Cancer Pathway

Below is the equation for calculating the period average for the inhalation cancer pathway. This calculation must be repeated at each receptor for each source of interest.

$$C_{worker\_period\_average} = \frac{\sum C_{hourly}}{N_{total\_hrs} - N_{calm\_hrs} - N_{missing\_hrs}}$$

Where:

C_{hourly} = the concentration that occurs during the worker's shift. To obtain the sum of the hourly concentrations for the offsite worker, sum the extracted worker concentrations from Section 3.0.

N_{total_hrs} = the number of processed hours that occur during worker's shift. To obtain the number of processed hours, use the COUNT function to return the total number of extracted worker concentrations from Section 3.0.

N_{calm_hrs}= the number of calm hours that occur during the worker's shift. To obtain the number of calm and missing hours, use the COUNT function to return the total number of missing and calm hours from Section 3.0. Since the total will include missing hours, it is not necessary to repeat this step for the variable below.

$N_{missing\_hrs}$ = the number of missing hours that occur during worker's shift.

Sensitivity Study of the Worker Adjustment Factor using AERMOD

N.1. Introduction

The offsite worker health risk analysis begins with estimating the pollutant concentration at a receptor location. To estimate this concentration, the typical approach is to use the residential annual concentration that is modeled based on the adjacent facility's emission schedule. However, if the facility emissions are non-continuous, the residential concentration may not represent what the worker breathes during their work shift. In lieu of conducting additional special case modeling which can be time-consuming, the residential annual concentration is adjusted upwards using a worker adjustment factor based on the facility's emission schedule with respect to the worker's schedule. For an 8-hour work shift that coincides with an adjacent facility that emits eight hours per day, a worker adjustment factor of 4.2 (24 hours / 8 hours * 7 days / 5 days) is typically used for cancer risk assessment.

A possible problem with using this approach is that wind direction, wind speed, and atmospheric stability can vary throughout the day and night and straight scaling as above may skew the results. If the diurnal variation is considerable, the 4.2 adjustment could be an under- or overestimate depending on the time of day that the offsite worker shift begins and ends. The goal of this study is to test the validity of the 4.2 adjustment using five meteorological data sets from five different locations in California and with three different size point sources. The modeling is performed with 8-hour emissions coinciding with the offsite workers' schedule. The 8-hour shifts are modeled as starting every hour around the clock.

To perform this study, the AERMOD air dispersion model, meteorological data from five locations (i.e., Kearny Mesa, Palomar, Pomona, Redlands, and San Bernardino), and three different size point sources (small, medium, and large) are used. The AERMOD-ready meteorological datasets are selected to represent a range of meteorological conditions around the state. To mirror the assumptions used in the 4.2 worker adjustment factor, the emission rate of each source is simulated for eight continuous hours with 24 different start times for five days a week (Monday through Friday). This will simulate the conditions that result during an 8-hour work schedule starting any hour of the day. In addition, the emitting source and offsite worker are assumed to have coincident schedules.

Using the AERMOD air dispersion modeling results, the Point of Maximum Impact (PMI) is identified and the hourly raw concentrations are post-processed to calculate the long-term offsite worker concentration for each scenario. To test the validity of the worker adjustment factor, the calculated long-term offsite worker concentration is divided by the long term residential average to obtain a quotient that is unique to each

meteorological data location. The quotient is then compared to the 4.2 worker adjustment factor to see which is higher or more health protective.

Although this study is primarily based on an 8-hour work schedule, the actual duration that an offsite worker is present near the emitting source may vary when considering a lunch break or a longer work shift. Thus, 10-hour scenarios are also evaluated. The worker adjustment factor for ten hours is 3.4 (24 hours / 10 hours * 7 days / 5 days).

N.2. Background on the Worker Adjustment Factor for Inhalation Cancer Assessments

There are basically two approaches that can be used to calculate the offsite worker inhalation exposure for cancer assessments. One approach is to post-process the hourly dispersion modeling results and examine the coincident hours between the source's emission schedule and the worker's schedule. The second, and more commonly used approach, is to apply a worker adjustment factor to the modeled long-term residential concentration. While post-processing the hourly modeling output will offer a more representative worker concentration, it is very time consuming and requires the management of large amounts of data. Thus, the simplistic approach of applying a worker adjustment factor to estimate the worker inhalation exposure is typically used.

The worker adjustment factor is used together with the long-term residential concentration to estimate the offsite worker's inhalation exposure. This calculation is summarized below.

a. Obtain the long-term concentrations from air dispersion modeling as is typical for residential receptors (all hours of a year or multi-year analysis are used).

b. Determine the coincident hours per day and days per week between the source's emission schedule and the offsite worker's schedule.

c. Calculate the worker adjustment factor using Equation N.1. When assessing inhalation cancer health impacts, a discount factor (*DF*) may also be applied if the offsite worker's schedule partially overlaps with the source's emission schedule. The discount factor is based on the number of coincident hours per day and days per week between the source's emission schedule and the offsite worker's schedule (see Equation N.2).

Please note that worker adjustment factor does not apply if the source's emission schedule and the offsite worker's schedule do not overlap. Since the worker is not around during the time that the source is emitting, the worker is not exposed to the source's emission (i.e., the DF in Equation N.2 becomes 0).

$$WAF = \frac{H_{residential}}{H_{source}} \times \frac{D_{residential}}{D_{source}} \times DF \qquad \textbf{Eq. N.1}$$

Where:

WAF = the worker adjustment factor

$H_{residential}$ = the number of hours per day the long-term residential concentration is based on (24)

H_{source} = the number of hours the source operates per day

$D_{residential}$ = the number of days per week the long-term residential concentration is based on (7).

D_{source} = the number of days the source operates per week.

DF = a discount factor for when the offsite worker's schedule partially overlaps the source's emission schedule. Use 1 if the offsite worker's schedule occurs within the source's emission schedule. If the offsite worker's schedule partially overlaps with the source's emission schedule, then calculate the discount factor using Equation N.2 below.

$$DF = \frac{H_{coincident}}{H_{worker}} \times \frac{D_{coincident}}{D_{worker}} \qquad \textbf{Eq. N.2}$$

Where:

DF = *the discount factor for assessing cancer impacts*

$H_{coincident}$ = *the number of hours per day the offsite worker's schedule and the source's emission schedule overlap*

$D_{coincident}$ = *the number of days per week the offsite worker's schedule and the source's emission schedule overlap.*

H_{worker} = *the number of hours the offsite worker works per day*

D_{worker} = *the number of days the offsite worker works per week.*

d. The final step is to estimate the offsite worker inhalation exposure by multiplying the worker adjustment factor with the long-term residential concentration.

N.3. Method and Modeling Parameters

For this study, all scenarios are simulated using the AERMOD (Version 09292) air dispersion model. The modeling parameters input to AERMOD and methods used to process the model outputs are discussed below.

N.3.1. Point Source Release Parameters

This study uses three different size point sources representing small, medium, and large. The point source release parameters are shown in Table N.1.

Table N.1. Point Source Modeling Parameters

Source Size	Emission Rate (g/s)	Release Ht (m)	Diameter (m)	Exit Temp (K)	Exit Vel (m/s)	Building Dimensions L (m) x W (m) x H (m)	XBADJ YBADJ [1]
Large	1	30	3	400	10	15 x 15 x 6	7.5
Medium	1	10	1	400	10	12 x 12 x 6	6
Small	1	2.15	0.1	400	10	6 x 6 x 2	3

1 – The XBADJ and YBADJ are keywords defining the along-flow and across-flow distances from the stack to the center of the upwind face of the projected building, respectively (U.S. EPA, 2004).

N.3.2. Temporal Emission Rate

Each point source (i.e., small, medium, and large) is simulated with continuous emissions for eight hours a day from Monday through Friday. In addition, all starting hour combinations (24 scenarios) are evaluated by duplicating each source 24 times with unique start times. Table N.2 shows the 8-hour operating schedule for each scenario. All emissions for Saturday and Sunday are set at zero. This process will also be repeated for the 10-hour evaluation. Table N.3 shows the 10-hour operating schedule for each scenario.

N.3.3. Receptor Grid Parameters

A 1000 meter by 1000 meter receptor grid is centered over each source. The receptors are spaced in 50 meter increments resulting in 441 receptor points. All receptor flagpole heights are set at 1.2 meters above ground.

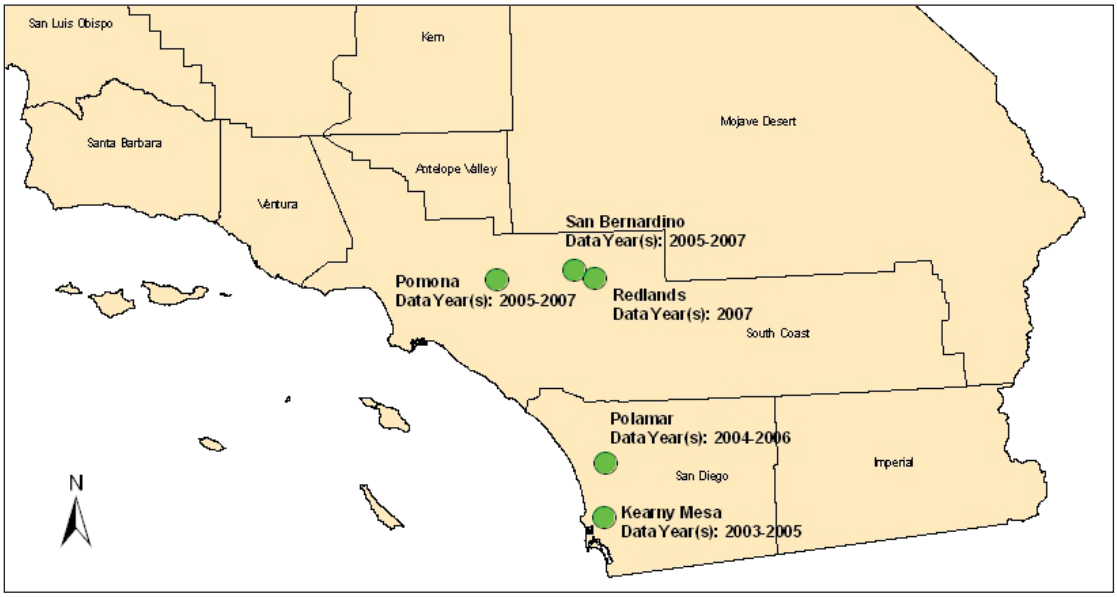
N.3.4. Meteorological Data

The meteorological data input to AERMOD were requested from two local air districts in California (ARB 2009a and ARB 2009b). The meteorological data that were provided by the Districts are, based on the Districts' observations and expertise, datasets that were likely to result in higher than average long-term impacts. The data includes four multi-year files and one single year file. Table N.4 shows the meteorological datasets used in this study. Figure N.1 shows the location of the meteorological station. The AERMOD profile base is defaulted to 10 meters above mean sea level for each meteorological file.

Table N.4. Meteorological Datasets

Data Provider	Area	Data Year(s)	Total Hours	Percent of Calm and Missing Hours	Avg. Wind Speed (m/s)
San Diego Air Pollution Control District	Kearny Mesa	2003-2005	26304	6.9	1.36
	Palomar	2004-2006	26304	8.7	1.36
South Coast Air Quality Management District	Pomona	2005-2007	26280	1.6	1.18
	Redlands	2007	8760	5.5	0.94
	San Bernardino	2005-2007	26280	4.9	1.44

Figure N.1. Meteorological Data Set Locations



N.3.5. Post-Processing the Period Average Concentrations for the Offsite Worker

The period average concentration represents the average concentration of all hours processed within the meteorological set. Equation N.3 shows how the period average is calculated in AERMOD including how calm and missing hours are processed (U.S. EPA, 2005).

$$C_{period\_average} = \frac{\sum C_{hourly}}{N_{total\_hrs} - N_{calm\_hrs} - N_{missing\_hrs}} \qquad \textbf{Eq. N.3}$$

Where:

C_{hourly} = the concentration that occurs at a given hour

N_{total_hrs} = the number of processed hours reported by AERMOD (e.g., 1 yr = 8760 hours)

N_{calm_hrs} = the number of calm hours reported by AERMOD

$N_{missing\_hrs}$ = the number of missing hours reported by AERMOD

Normally to post-process hourly data, the off-site worker hours are extracted from the hourly model output files and then averaged. However, this sensitivity study assumes the hourly emissions are coincident with the off-site worker schedule. Since this is the case, the 8-hour period average for the offsite worker can simply be scaled from the period average reported by AERMOD (see Equation N.4). To make sure this calculation is accurate, a check was performed by processing the hourly concentrations for one receptor with the Pomona data. If the emission schedule was not 100%

coincident with the offsite worker, then all post-processing would have to be completed on an hourly basis. See Appendix M for more information on how to post-process worker concentrations using hourly raw results.

$$C_{worker\_period\_average} = C_{period\_average} \times \frac{N_{total\_hrs} - N_{calm\_hrs} - N_{missing\_hrs}}{N_{worker\_hrs} - N_{worker\_calm\_hrs} - N_{worker\_missing\_hrs}} \quad \textbf{Eq. N.4}$$

Where:

$C_{period\_average}$ = the period concentration reported by AERMOD

N_{total_hrs} = the total number of processed hours reported by AERMOD

N_{calm_hrs} = the total number of calm hours reported by AERMOD

$N_{missing\_hrs}$ = the total number of missing hours reported by AERMOD

N_{worker_hrs}[a] = the total number of hours that occurred during the worker's shift

$N_{worker\_calm\_\_hrs}$[b] = the number of calm hours that occurs during the worker's shift

$N_{worker\_missing\_hrs}$[b] = the number of missing hours that occurred during the worker's shift

a. The worker hours are determined by multiplying the number of weekdays (Monday through Friday) that occurs in the meteorological data set by the work shift duration (8 hours). For example, a meteorological data set ranging from 1/1/2003 to 12/31/2005 contains 783 weekdays. If you multiply the number weekdays by the work shift duration (8 hour/day), this will equal 6264 worker hours. The number of weekdays varies depending on the day of the week January 1st starts on.

b. Calm and missing hours are reported in the AERMOD Detailed Message Listing File. To determine the number of worker calm and missing hours, the calm and missing hours that occur during the worker shift are isolated and summed.

N.4. Results

To test the validity of the worker adjustment factor, the post-processed period average concentration for the offsite worker was divided by the modeled period residential average to obtain a quotient. This calculation was performed at the PMI of each scenario. If the quotient is smaller or equal to the worker adjustment factor, the worker adjustment factor is considered a suitable health protective approximation. If the quotient is greater, the worker adjustment factor will underestimate the long-term average concentration and would not be the most conservative estimation of what the worker breathes. For these scenarios, the 8-hour and 10-hour worker adjustment factors are 4.2 and 3.4, respectively. The results for this study are summarized in the figures and tables below. To view the details for every scenario, see Appendix N-1.

Figure N.2 shows how the post-processed period averages changes over 8-hour rolling work shifts. The value at each 8-hour work shift represents the quotient average across the five meteorological data sets. Values that fall on or below the thick dashed line (i.e., the 4.2 worker adjustment factor) indicate that the worker adjustment factor would be a health protective value. Based on the five metrological data sets, the worker adjustment factor is health protective for work shifts that start approximately between 8 am and 3 pm (i.e., 8-hour work shifts starting at 8 am and ending by 11 pm).

Figure N.2. Summary of the 8-Hour Scenarios

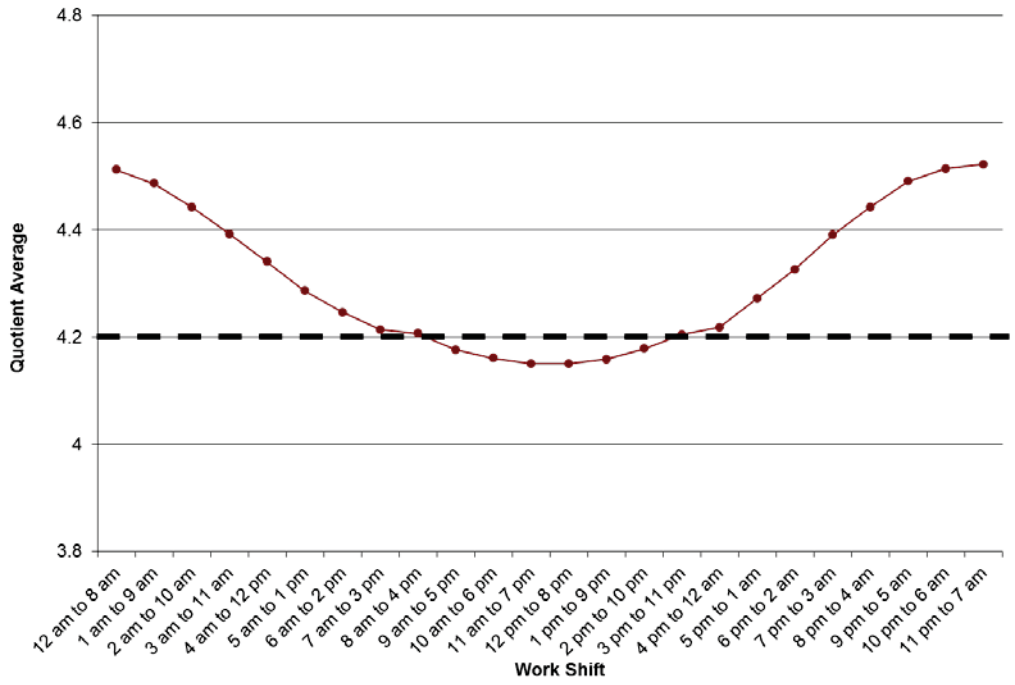


Figure N.3 shows relationship between the worker schedule and the percent of calm and missing hours that occurred during 8-hr work shifts. The figure shows the percent of calm and missing hours are higher during the early morning and evening hour start hours.

Figure N.3. Average Percent of Calm and Missing Hours for 8-Hour Work Shifts

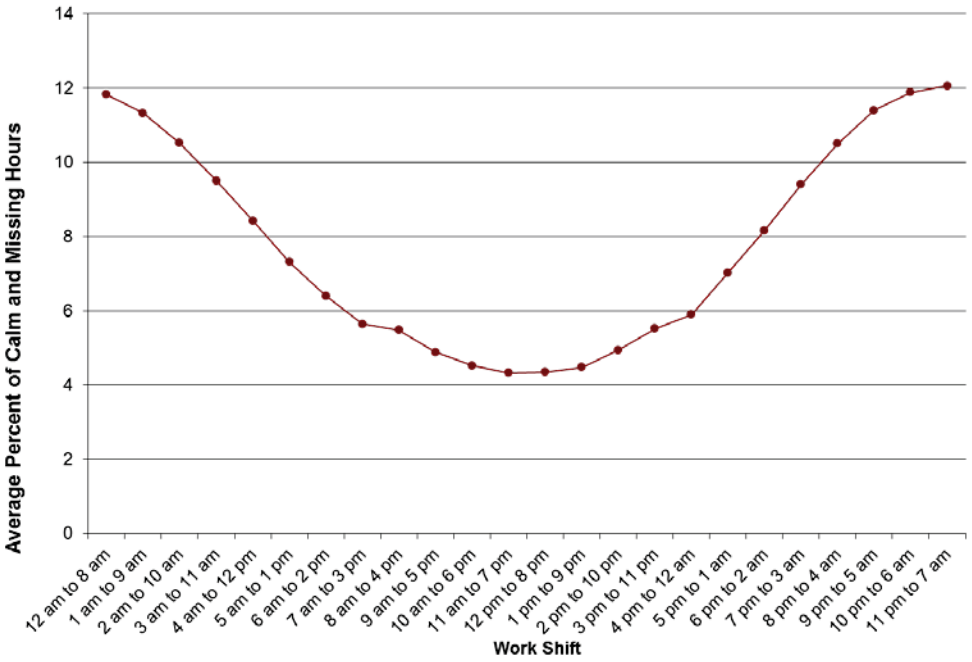

Figure N.4 shows how the post-processed period averages change over 10-hour rolling work shifts. The value at each 10-hour work shift represents the quotient average across the five meteorological data sets. Values that fall on or below the thick dashed line (i.e., the 3.4 worker adjustment factor) indicate that the worker adjustment factor would be a health protective value. Based on the five metrological data sets, the worker adjustment factor is health protective for work shifts that start approximately between 5 am and 4 pm (i.e., 10-hour work shifts starting at 5 am and ending by 2 am).

Figure N.4. Summary of the 10-Hour Scenarios

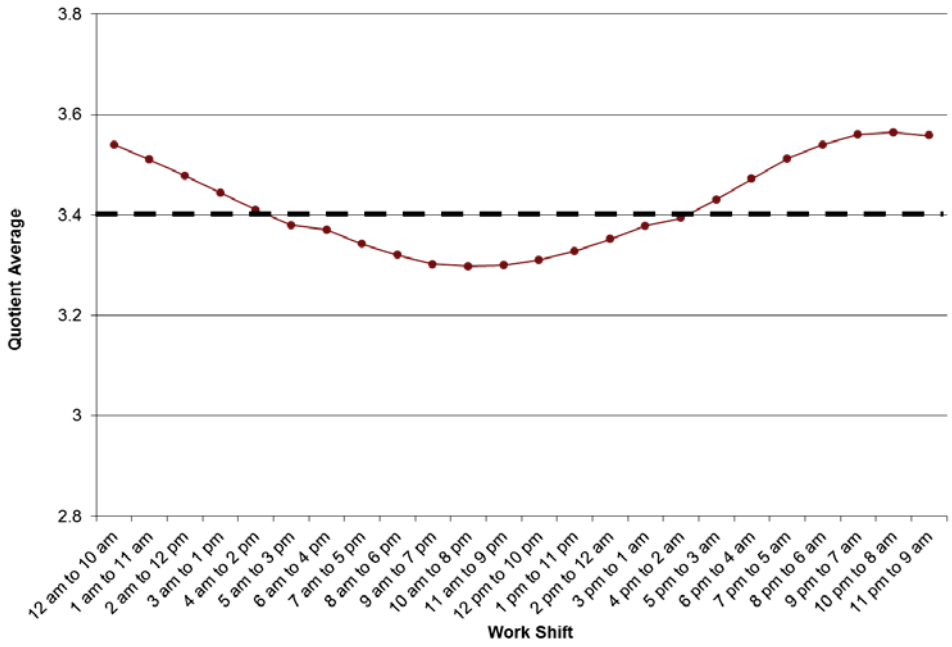

Figure N.5 shows relationship between the worker schedule and the percent of calm and missing hours that occurred during 10-hr work shifts. The figure shows the percent of calm and missing hours are higher during the early morning and evening hour start hours.

Figure N.5. Average Percent of Calm and Missing Hours for 10-Hour Work Shifts

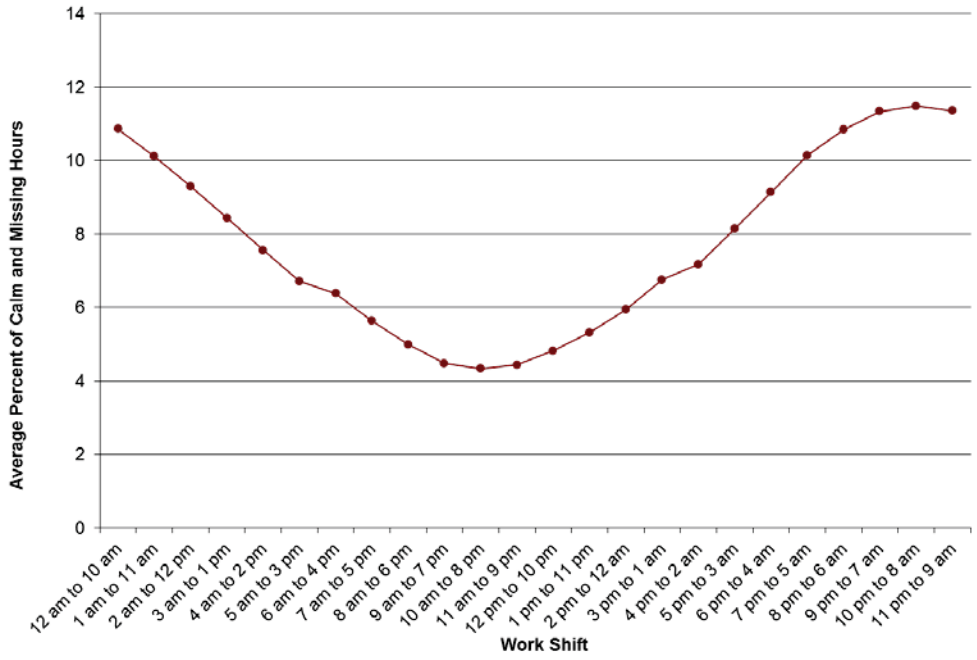

Table N.5 shows the average, minimum, and maximum quotients across all 24 8-hour work shifts for each point source size (i.e., small, medium, and large). The values in the parentheses are the range across the 24 work shifts for each meteorological data set.

Table N.5. Summary of the Average 8-Hour Scenarios by Point Source Size

Meteorological Set	Point Source Size			% Calm/Missing Hours During the Worker's Shift
	Small	Medium	Large	
Kearny Mesa	4.33 (4.19 to 4.43)	4.33 (4.19 to 4.43)	4.33 (4.19 to 4.43)	9.6 (6.8 to 11.8)
Palomar	4.38 (4.18 to 4.65)	4.38 (4.18 to 4.65)	4.38 (4.18 to 4.65)	12.2 (8.2 to 17.5)
Pomona	4.24 (4.23 to 4.25)	4.24 (4.23 to 4.25)	4.24 (4.23 to 4.25)	2.3 (2.1 to 2.5)
Redlands	4.31 (4.00 to 4.75)	4.31 (4.00 to 4.75)	4.31 (4.00 to 4.75)	7.6 (1.0 to 16.5)
San Bernardino	4.31 (4.06 to 4.65)	4.31 (4.06 to 4.65)	4.31 (4.06 to 4.65)	6.9 (1.4 to 14.1)

Table N.6 shows the average, minimum, and maximum quotients across all 24 10-hour work shifts for each point source size (i.e., small, medium, and large). The values in the parentheses are the range across the 24 work shifts for each meteorological data set.

Table N.6. Summary of the Average 10-Hour Scenarios by Point Source Size

Meteorological Set	Point Source Size			% Calm/Missing Hours During the Worker's Shift
	Small	Medium	Large	
Kearny Mesa	3.46 (3.38 to 3.54)	3.46 (3.38 to 3.54)	3.46 (3.38 to 3.54)	9.6 (7.5 to 11.6)
Palomar	3.50 (3.34 to 3.70)	3.50 (3.34 to 3.70)	3.50 (3.34 to 3.70)	12.2 (8.0 to 17.1)
Pomona	3.39 (3.38 to 3.39)	3.39 (3.38 to 3.39)	3.39 (3.38 to 3.39)	2.3 (2.2 to 2.5)
Redlands	3.45 (3.21 to 3.74)	3.45 (3.21 to 3.74)	3.45 (3.21 to 3.74)	7.6 (1.1 to 15.2)
San Bernardino	3.31 (3.12 to 3.54)	3.31 (3.12 to 3.54)	3.31 (3.12 to 3.54)	6.9 (1.5 to 13.1)

N.5. Conclusions

The goal of this study was to determine if the worker adjustment factor of 4.2 (8 hours/day, 5 days/week) or 3.4 (10 hours/day, 5 days/week) would always yield a more conservative or health protective approximation using five meteorological data sets. This study demonstrated that the worker adjustment factor does not always represent the most health protective approximation of long-term hourly model predictions. This is primarily observed during night conditions. Air Districts may wish to evaluate their meteorological data to determine an appropriate worker adjustment factor for their area using the methods described in this appendix.

Although the meteorological data used in this study are site-specific, several general conclusions and recommendations can be made. These conclusions and recommendations are summarized below.

- ***The worker adjustment factor is generally a suitable health protective approximation for daytime work shifts.***

  For the meteorological data used in this study, the results show that the worker adjustment factor is a suitable health protective approximation for work shifts that occur during the daytime hours. When comparing the 8-hour and 10-hour scenarios, the results show that the range of work shifts that were considered a more health protective approximation increased with the longer work shift duration.

- ***The size of the emitting source did not affect the long-term concentration approximated with the worker adjustment factor.***

  The size of the source was inconsequential in determining whether the worker adjustment factor is health protective. This is because the worker adjustment factor is applied to the modeling results after the air dispersion analysis has been completed. However, it should be noted that the size of the source does affect the location of the PMI during a specific time of day. This is shown in the scenario details in Appendix N-1.

- ***The worker adjustment factor may not represent the most conservative estimation of the worker's inhalation exposure for nighttime work shifts.***

  In most cases, the worker adjustment factor will represent a health protective approximation for work shifts that occur during the daytime. However, the worker adjustment factor may not represent the most conservative estimation when the source's emission schedule and offsite worker's schedules are 100% coincident at night. It is recommended that the offsite worker long-term average concentrations be post-processed using the hourly dispersion modeling results when examining work shifts occurring at night. Alternatively, a more conservative worker adjustment factor can be used to account for the calm hours (see the next bullet point below).

- ***Recommended worker adjustment factor for 8 and 10-hour work shifts***

  Based on the five meteorological data sets used in this study, the range of worker adjustment factors (WAF) was between 4.2 and 4.8. We recommend using the 4.2 WAF for most cases. In the event of predominant night time emissions and worker schedule or if only one year of meteorological data are available, then we recommend using 4.8 for the 8-hour WAF.

EXECUTIVE SUMMARY

The Air Toxics "Hot Spots" Information and Assessment Act (AB 2588, Connelly) was enacted in September 1987. Under this Act, stationary sources of air pollution are required to report the types and quantities of certain substances their facilities routinely release into the air. The goals of the Air Toxics "Hot Spots" Act are to collect emission data, identify facilities having localized impacts, ascertain health risks posed by those facilities, notify nearby residents of significant risks and reduce emissions from significant sources.

The Technical Support Document for Cancer Potency Factors (TSD) contains cancer unit risks and potency factors for 107 of the 201 carcinogenic substances or groups of substances for which emissions must be quantified in the Air Toxics Hot Spots program. These unit risks are used in the cancer risk assessment of facility emissions.

The purpose of this revision to the TSD is to provide updated calculation procedures used to derive the estimated unit risk and cancer potency factors, and to describe the procedures used to consider the increased susceptibility of infants and children compared to adults to carcinogens. This updates cancer risk assessment methods originally laid out in the California Department of Health Services' Guidelines for Chemical Carcinogen Risk Assessment (CDHS, 1985), and more recently summarized in the previous Hot Spots technical support document Part II (OEHHA, 2005a). Summaries of cancer potency factors and the underlying data are provided in Appendices A and B, which are subject to ongoing updates but were not changed as part of the revision process which created this TSD.

The procedures used to consider the increased susceptibility to carcinogens of infants and children as compared to adults include the use of age-specific weighting factors in calculating cancer risks from exposures of infants, children and adolescents, to reflect their anticipated special sensitivity to carcinogens

This document is one part of the Air Toxics Hot Spots Program Risk Assessment Guidelines. The other documents originally included in the Guidelines are Part I: Technical Support Document for the Determination of Acute Toxicity Reference Exposure Levels for Airborne Toxicants; Part III: Technical Support Document for Determination of Noncancer Chronic Reference Exposure Levels; Part IV: Technical Support Document for Exposure Assessment and Stochastic Analysis; Part V: Air Toxic Hot Spots Program Risk Assessment Guidelines. As a part of the same revision process which led to production of this revised TSD on cancer potencies, the original TSDs for Acute and Chronic Reference Exposure Levels have been replaced with a new unified TSD for Acute, 8-hour and Chronic Reference Exposure Levels.

The major changes to the TSD include the following:

- Based on the OEHHA analysis of the potency by lifestage at exposure, OEHHA proposes weighting cancer risk by a factor of 10 for exposures that occur from the third trimester of pregnancy to 2 years of age, and by a factor of 3 for exposures that occur from 2 years through 15 years of age. We intend to apply this weighting factor to all carcinogens,

regardless of purported mechanism of action, unless chemical-specific data exist to the contrary. In cases where there are adequate data for a specific carcinogen of potency by age, we would use the data to make any adjustments to risk.

- OEHHA proposes to use the Benchmark Dose method to compute potency factors rather than the more traditional linearized multistage model (LMS), although the LMS will still be used in some instances. The BMDL model essentially uses an empirical fit to the data (usually best with the multistage model), and then extrapolates with a straight line from the 95% lower confidence limit of the BMD (BMDL) to zero. This method is simpler and does not assume any underlying theoretical mechanisms at the low dose range. The BMDL method results in estimates of potency very similar to those obtained using the LMS method.

- OEHHA will use scaling based on body weight to the ¾ power, rather than to the ⅔ power.

- OEHHA's evaluations of the carcinogenicity of chemicals generally follow the guidelines laid out by IARC for identification and classification of potential human carcinogens, which are described in detail in the most recent revision of the *Preamble* to the IARC monographs series (IARC, 2006).

PREFACE

The Air Toxics "Hot Spots" Information and Assessment Act (AB 2588, Connelly) was enacted in September 1987. Under this Act, stationary sources are required to report the types and quantities of certain substances their facilities routinely release into the air. The goals of the Air Toxics "Hot Spots" Act are to collect emission data, identify facilities having localized impacts, ascertain health risks posed by those facilities, notify nearby residents of significant risks and reduce emissions from significant sources.

The Technical Support Document for Cancer Potency Factors (TSD) contains cancer unit risks and potency factors for 107 of the 201 carcinogenic substances or groups of substances for which emissions must be quantified in the Air Toxics Hot Spots program. These unit risks are used in risk assessment of facility emissions. The TSD provides updated calculation procedures used to derive the estimated unit risk and cancer potency factors, and procedures to consider early-life susceptibility to carcinogens. Summaries of cancer potency factors and the underlying data are provided in Appendices A and B.

In this document, OEHHA is responding to the requirements of the 1999 Children's Environmental Health Protection Act (SB25, Escutia) by revising the procedures for derivation and application of cancer potency factors to take account of general or chemical-specific information which suggests that children may be especially susceptible to certain carcinogens (OEHHA, 2001a). The revised cancer potency derivation procedures described will not be used to impose any overall revisions of the existing cancer potencies, although they do reflect updated methods of derivation. However, individual cancer potency values will be reviewed as part of the ongoing re-evaluation of health values mandated by SB 25, and revised values will be listed in updated versions of the appendices to this document as necessary. The revisions also include the use of weighting factors in calculating cancer risks from exposures of infants, children and adolescents, to reflect their anticipated special sensitivity to carcinogens. Similar legal mandates to update risk assessment methodology and cancer potencies apply to the OEHHA program for development of Public Health Goals (PHGs) for chemicals in drinking water, and Proposition 65 No Significant Risk Levels (NSRLs). The NSRLs may also be revised to reflect concerns for children's health. Revising these numbers will require the originating program to reconsider the value in an open public process. For example, OEHHA would need to release any revised potency factors for public comment and review by the Scientific Review Panel on Toxic Air Contaminants (SRP) prior to adoption under the TAC program. The procedures for outside parties to request reevaluation of cancer potency values by the programs which originated those values are listed in Appendix G.

Appendices A and B provide previously adopted Cal/EPA values which were included in the previous version of the TSD for Cancer Potency Factors (OEHHA, 2005a). Cal/EPA values were developed under the Toxic Air Contaminant (TAC) program, the PHG program, the Proposition 65 program, or in some cases specifically for the Air Toxics Hot Spots program. All the Cal/EPA values are submitted for public comments and external peer review prior to adoption by the program of origin. In the future, new values developed by the Toxic Air Contaminants or Hot Spots programs or other suitable sources will be added as these are approved.

Some U.S. EPA IRIS cancer unit risk values were adopted under the previous versions of these guidelines, and these values will continue to be used unless and until revised by Cal/EPA. U.S. EPA has recently revised its cancer risk assessment guidelines (U.S. EPA, 2005a). Some of the recommended changes in methodology could result in slightly different potency values compared to those calculated by the previous methodology, although in practice a number of the recommendations (for example, the use of ¾ power of the body weight ratio rather than ⅔ power for interspecies scaling) have been available in draft versions of the revised policy for some time and appear in many more recent assessments. U.S. EPA has stated that cancer potency values listed in IRIS will not be revisited solely for the purpose of incorporating changes in cancer potency value calculation methods contained in the revised cancer risk assessment guidelines. U.S. EPA has also issued supplementary guidelines on assessing cancer risk from early-life exposure (U.S. EPA, 2005b).

OEHHA uses a toxic equivalency factor procedure for dioxin-like compounds, including polychlorinated dibenzo-*p*-dioxins, dibenzofurans and polychlorinated biphenyls (PCBs). The Toxicity Equivalency Factor scheme (TEF_{WHO-97}) developed by the World Health Organization/European Center for Environmental Health (WHO-ECEH) is used for determining cancer unit risk and potency values for these chemicals where individual congener emissions are available (Appendix C).

This document is one part of the Air Toxics Hot Spots Program Risk Assessment Guidelines. The other documents originally included in the Guidelines are Part I: Technical Support Document for the Determination of Acute Toxicity Reference Exposure Levels for Airborne Toxicants; Part III: Technical Support Document for Determination of Noncancer Chronic Reference Exposure Levels; Part IV: Technical Support Document for Exposure Assessment and Stochastic Analysis; Part V: Air Toxic Hot Spots Program Risk Assessment Guidelines. As a part of the same revision process which led to production of this revised TSD on cancer potencies, the original TSDs for Acute and Chronic Reference Exposure Levels have been replaced with a new unified TSD for Acute, 8-hour and Chronic Reference Exposure Levels.

TABLE OF CONTENTS

APPENDICES

Appendix A. A lookup table containing unit risk and cancer potency values.

Appendix B. Chemical-specific summaries of the information used to derive unit risk and cancer potency values.

Appendix C. A description of the use of toxicity equivalency factors for determining unit risk and cancer potency factors for polychlorinated dibenzo-*p*-dioxins, dibenzofurans and dioxin-like polychlorinated biphenyls.

Appendix D. A listing of Toxic Air Contaminants identified by the California Air Resources Board.

Appendix E. Descriptions of the International Agency for Research on Cancer (IARC) and U.S. Environmental Protection Agency (U.S. EPA) carcinogen classifications.

Appendix F. An asbestos quantity conversion factor for calculating asbestos concentrations expressed as 100 fibers/m^3 from asbestos concentrations expressed as µg/m^3.

Appendix G. Procedures for revisiting or delisting cancer potency factors by the program of origin.

Appendix H. Exposure routes and studies used to derive cancer unit risks and slope factors.

Appendix I. "Assessing susceptibility from early-life exposure to carcinogens": Barton *et al*., 2005 (from *Environmental Health Perspectives)*.

Appendix J. "In Utero and Early Life Susceptibility to Carcinogens: The Derivation of Age-at-Exposure Sensitivity Measures" – conducted by OEHHA's Reproductive and Cancer Hazard Assessment Branch.

INTRODUCTION

The Technical Support Document (TSD) for Describing Available Cancer Potency Factors provides technical information support for the Air Toxics Hot Spots Program Risk Assessment Guidelines. The TSD consists of 12 sections:

1. The TSD introduction.

2. A description of the methodologies used to derive the unit risk and cancer potency values listed in the lookup table.

3. A lookup table containing unit risk and cancer potency values. (Appendix A)

4. Chemical-specific summaries of the information used to derive unit risk and cancer potency values. (Appendix B).

5. A description of the use of toxicity equivalency factors for determining unit risk and cancer potency factors for polychlorinated dibenzo-*p*-dioxins, dibenzofurans and dioxin-like polychlorinated biphenyls (Appendix C).

6. A listing of Toxic Air Contaminants identified by the California Air Resources Board (Appendix D).

7. Descriptions of the International Agency for Research on Cancer (IARC) and U.S. Environmental Protection Agency (U.S. EPA) carcinogen classifications (Appendix E).

8. An asbestos quantity conversion factor for calculating asbestos concentrations expressed as 100 fibers/m^3 from asbestos concentrations expressed as µg/m^3 (Appendix F).

9. Procedures for revisiting or delisting cancer potency factors by the program of origin (Appendix G).

10. Exposure routes and studies used to derive cancer unit risks and slope factors (Appendix H).

11. "Assessing susceptibility from early-life exposure to carcinogens": Barton *et al*., 2005 (from *Environmental Health Perspectives)* (Appendix I).

12. "In Utero and Early Life Susceptibility to Carcinogens: The Derivation of Age-at-Exposure Sensitivity Measures" – conducted by OEHHA's Reproductive and Cancer Hazard Assessment Branch (Appendix J)

SELECTION OF CANCER POTENCY VALUES

The Office of Environmental Health Hazard Assessment (OEHHA) has developed a number of cancer potencies for use in the Toxic Air Contaminants and Air Toxics Hot Spots programs. This document also provides summaries of cancer potency factors which were originally developed for other California Environmental Protection Agency (Cal/EPA) programs, or by the U.S. EPA. These were reviewed for accuracy, reliance on up-to-date data and methodology, and applicability in the context of the Air Toxics Hot Spots program. Values found appropriate were adopted after public and peer review rather than devoting the resources necessary for a full *de novo* assessment. Thus, cancer potency values (CPF) included in the Technical Support Document (TSD) for Cancer Potency Factors were from the following sources:

1. Toxic Air Contaminant documents

2. Standard Proposition 65 documents

3. U.S.EPA Integrated Risk Information Systems (Office of Health and Environmental Assessment, U.S.EPA)

4. Expedited Proposition 65 documents

5. Other OEHHA assessments , for example for the drinking water program.

All the cancer potency value sources used generally follow the recommendations of the National Research Council on cancer risk assessment (NRC, 1983, 1994). All Cal/EPA program documents undergo a process of public comment and scientific peer review prior to adoption, although the procedures used vary according to the program. The publication procedure for Toxic Air Contaminant documents includes a public comment period and review by the Scientific Review Panel on Toxic Air Contaminants (SRP) before identification of a Toxic Air Contaminant by the Air Resources Board of the California Environmental Protection Agency (Cal/EPA). Furthermore, a petition procedure is available to initiate TAC document review and revision if appropriate because of new toxicity data. Documents developed for the Air Toxics Hot Spots program similarly undergo public comment and peer review by the SRP before adoption by the Director of OEHHA. The standard Proposition 65 document adoption procedure includes a public comment and external peer review by the Proposition 65 Carcinogen Identification Committee. The expedited Proposition 65 document adoption procedure included a public comment period. Risk assessments prepared for development of Public Health Goals (PHGs) for chemicals in drinking water are subject to two public comment periods before the final versions and responses to comments are published on the OEHHA Web site. PHG documents may also receive external peer review. Documents from U.S. EPA's Integrated Risk Information System (IRIS) receive external peer review and are posted on the Internet for public viewing during the external peer review period, and any public comments submitted are considered by the originating office. Additionally, public comment may be solicited during the document posting period. Future preference for use of developed cancer potency factors/unit risks will be done on a case by case basis. Preference will be given to those assessments most relevant to inhalation exposures of the California population, to the most recent derivations using the latest data sets and scientific methodology, and to those having undergone the most open and extensive peer review process.

CANCER RISK ASSESSMENT METHODOLOGIES

This section describes in general the methodologies used to derive the cancer unit risk and potency factors listed in this document. As noted in the Preface to this document, no new cancer unit risks or potency factors were developed for this document. All of the values contained here were previously developed in documents by Cal/EPA or U.S. EPA. Following the recommendations of the National Academy of Sciences (NRC, 1983), Cal/EPA and U.S. EPA have both used formalized cancer risk assessment guidelines, the original versions of which (California Department of Health Services, 1985; U.S. EPA, 1986) were published some time ago. Both these guidelines followed similar methodologies.

In the twenty years since these original guidelines were published there have been a number of advances in the methodology of cancer risk assessment. There have additionally been considerable advances in the quantity of data available not only from animal carcinogenesis bioassays and epidemiological studies, but also from mechanistic studies of carcinogenesis and related phenomena. Some of these advances have been incorporated into newer risk assessments by both agencies on a more or less *ad hoc* basis. There has also been an ongoing effort to provide updated risk assessment guidance documents. In 1995, U.S. EPA released for public comment the "Proposed and Interim Guidelines for Carcinogen Risk Assessment", which was the first of several drafts released for public comment. Many risk assessments appearing since then have used elements of the recommendations contained in that document, in spite of its draft status. A final version of the U.S. EPA's revised cancer risk assessment guidelines has now been released (U.S. EPA, 2005a). Although these new guidelines incorporate a number of substantial changes from their predecessors (U.S. EPA, 1986; 1995), U.S. EPA has stated that cancer potency values listed in IRIS will not be revisited solely for the purpose of incorporating changes in cancer potency value calculation methods.

Cal/EPA has not produced a revised cancer risk assessment guideline document to replace the original version (DHS, 1985). Rather, Cal/EPA has relied on incorporating new data and methodologies as these became available, and described the methods used on a case by case basis in the individual risk assessment documents where these went beyond the original guidance. However, this revision of the TSD for cancer potencies provides a convenient opportunity to summarize the current status of the methodology used by OEHHA for the air toxics programs, and also to highlight points of similarity to, and difference from, the recommendations of U.S. EPA (2005a).

In this document, OEHHA intends to follow the recommendations of the NRC (1994) in describing a set of clear and consistent principles for choosing and departing from default cancer risk assessment options. NRC identified a number of objectives that should be taken into account when considering principles for choosing and departing from default options. These include, "protecting the public health, ensuring scientific validity, minimizing serious errors in estimating risks, maximizing incentives for research, creating an orderly and predictable process, and fostering openness and trustworthiness". The OEHHA cancer risk methodologies discussed in this document are intended to generally meet those objectives cited above.

Hazard Identification

This section will describe: 1) how weight of evidence evaluations are used in hazard evaluation; 2) guidelines for inferring causality of effect; 3) the use of human and animal carcinogenicity data, as well as supporting evidence (*e.g.*, genetic toxicity and mechanistic data); 4) examples of carcinogen identification schemes.

Evaluation of Weight of Evidence

In evaluating the range of evidence on the toxicity and carcinogenicity of a compound, mixture or other agent, a "weight-of-evidence" approach is generally used to describe the body of evidence on whether or not exposure to the agent causes a particular effect. Under this approach, the number and quality of toxicological and epidemiological studies, as well as the consistency of study results and other sources of data on biological plausibility, are considered. Diverse and sometimes conflicting data need to be evaluated with respect to possible explanations of differing results. Consideration of methodological issues in the review of the toxicological and epidemiological literature is important in evaluating associations between exposure to an agent and animal or human health effects. This aspect of the evaluation process has received particular emphasis with respect to epidemiological data, where concerns as to the statistical and biological significance and reliability of the data and the impacts of confounding and misclassification are pressing. Such concerns are also relevant to some extent in the interpretation of animal bioassay data and mechanistic studies. Although the test animals, laboratory environment and characterization of the test agent are usually much better controlled than the equivalent parameters in an epidemiological study, the small sample size can be problematic. In addition, there are uncertainties associated with extrapolation of biological responses from test animal species to humans.

Criteria for Causality

There has been extensive discussion over the last two centuries on causal inference. This has particularly related to epidemiological data, but is also relevant to interpretation of animal studies. Most epidemiologists utilize causal inference guidelines based on those proposed by Bradford Hill (1971). OEHHA has relied on these and on recommendations by IARC (2006), the Institute of Medicine (2004), the Surgeon General's Reports on Smoking (U.S. DHHS, 2004) and standard epidemiologic texts (*e.g.*, Lilienfeld and Lilienfeld, 1980; Rothman and Greenland, 1998). The criteria for determination of causality used by OEHHA have been laid out in various risk assessment documents. The summary below is adapted from the Health Effects section of the document prepared to support the identification of environmental tobacco smoke (ETS) as a Toxic Air Contaminant (OEHHA, 2005b).

1. *Strength of Association*. A statistically significant strong association, which is easier to detect if there is a high relative risk, between a factor and a disease is often viewed as an important criterion for inferring causality because, all other things being equal, a strong and statistically significant association makes alternative explanations for the disease less likely. However, as discussed in Rothman and Greenland (1998), the fact that a relative risk is small in magnitude does not exclude a casual association between the risk factor

and the outcome in question. Since it is more difficult to detect (*i.e.*, reach statistical significance) a small magnitude risk, it is just as likely to indicate causality as a larger magnitude risk.

When assessing all evidence, it is important to consider the strength of the study design (particularly controlling for confounding variables, obtaining an unbiased sample, measurement error) and the level of statistical significance (*i.e.*, the ability to exclude a Type I [false positive] error). The power of the study to detect biologically meaningful effects (*i.e.*, the risk of a Type II [false negative] error) is important in considering studies that do not reach traditional (*i.e.*, $P < 0.05$) statistical significance, particularly if the biological endpoint is serious. If the outcome is serious and the study small (*i.e.*, low power), a larger P value (*e.g.*, $P < 0.10$) may be adequate evidence for identifying an effect.

There are a number of examples of statistically significant, small magnitude associations that are widely accepted as causal, such as causal links between air pollution and cardiovascular/pulmonary mortality and between second-hand smoke exposure and various cancers and heart disease. From a public health perspective, even a small magnitude increase in risk for a common disease can mean large numbers of people affected by the health outcome when exposure is frequent and widespread, as measured by the population attributable risk or attributable fraction. Small magnitude of association must not be confused with statistical significance, which is much more important.

2. *Consistency of Association.* If several investigations find an association between a factor and a disease across a range of populations, geographic locations, times, and under different circumstances, then the factor is more likely to be causal. Consistency argues against hypotheses that the association is caused by some other factor(s) that varies across studies. Unmeasured confounding is an unlikely explanation when the effect is observed consistently across a number of studies in different populations.

   Associations that are replicated in several studies of the same design or using different epidemiological approaches or considering different sources of exposure and in a number of geographical regions are more likely to represent a causal relationship than isolated observations from single studies (IARC, 2006). If there are inconsistent results among investigations, possible reasons are sought, such as adequacy of sample size or control group, methods used to assess exposure, or range in levels of exposure. The results of studies judged to be rigorous are emphasized over those of studies judged to be methodologically less rigorous. For example, studies with the best exposure assessment are more informative for assessing the association between ETS and breast cancer than studies with limited exposure assessment, all else being equal.

3. *Temporality.* Temporality means that the factor associated with causing the disease occurs in time prior to development of the disease. The adverse health effect should occur at a time following exposure that is consistent with the nature of the effect. For example, respiratory irritation immediately following exposure to an irritant vapor is temporally consistent, whereas irritation noted only years later may not be. On the other

hand, tumors, noted immediately following exposure, might be temporally inconsistent with a causal relationship, but tumors arising after a latency period of months (in rodents) or years (in rodents or humans) would be temporally consistent.

4. *Coherence and Biological Plausibility.* A causal interpretation cannot conflict with what is known about the biology of the disease. The availability of experimental data or mechanistic theories consistent with epidemiological observations strengthens conclusions of causation. For example, the presence of known carcinogens in tobacco smoke supports the concept that exposure to tobacco smoke could cause increased cancer risk. Similarly, if the mechanism of action for a toxicant is consistent with development of a specific disease, then coherence and biological plausibility can be invoked. It should be noted that our understanding of the biology of disease, and therefore biological plausibility, changes in light of new information which is constantly emerging from molecular biology (including epigenetics), and from new clinical and epidemiological investigations revealing effects influenced by genetic polymorphisms, pre-existing disease, and so forth.

5. *Dose-Response.* A basic tenet of toxicology is that increasing exposure or dose generally increases the response to the toxicant. While dose-response curves vary in shape and are not necessarily always monotonic, an increased gradient of response with increased exposure makes it difficult to argue that the factor is not associated with the disease. To argue otherwise necessitates that an unknown factor varies consistently with the dose of the substance and the response under question. While increased risk with increasing levels of exposure is considered to be a strong indication of causality, absence of a graded response does not exclude a causal relationship (IARC, 2006).

   The dose-response curves for specific toxic effects may be non-monotonic. Under appropriate circumstances, where the dose response shows saturation, the effect of exposures could be nearly maximal, with any additional exposure having little or no effect. In some instances, a response is seen strongly in susceptible subpopulations, and the dose-response is masked by mixing susceptible and non-susceptible individuals in a sample. Further, there are examples of U-shaped or inverted U-shaped dose-response curves, (*e.g.*, for endocrine disrupters) (Almstrup et al., 2002; Lehmann et al., 2004). Finally, timing of exposure during development may mask an overall increase in risk with increasing dose.

6. *Specificity.* Specificity is generally interpreted to mean that a single cause is associated with a single effect. It may be useful for determining which microorganism is responsible for a particular disease, or associating a single carcinogenic chemical with a rare and characteristic tumor (*e.g.*, liver angiosarcoma and vinyl chloride, or mesothelioma and asbestos). However, the concept of specificity is not helpful when studying diseases that are multifactorial, or toxic substances that contain a number of individual constituents, each of which may have several effects and/or target sites.

7. *Experimental evidence.* While experiments are often conducted over a short period of time or under artificial conditions (compared to real-life exposures), experiments offer the opportunity to collect data under highly controlled conditions that allow strong causal

conclusions to be drawn. Experimental data that are consistent with epidemiological results strongly support conclusions of causality. There are also "natural experiments" that can be studied with epidemiological methods, such as when exposure of a human population to a substance declines or ceases; if the effect attributed to that exposure decreases, then there is evidence of causality. One example of this is the drop in heart disease death and lung cancer risk after smoking cessation.

It should be noted that the causal criteria are guidelines for judging whether a causal association exists between a factor and a disease, rather than hard-and-fast rules. Lilienfeld and Lilienfeld (1980) note that "*In medicine and public health, it would appear reasonable to adopt a pragmatic concept of causality. A causal relationship would be recognized to exist whenever evidence indicates that the factors form part of the complex of circumstances that increases the probability of the occurrence of disease and that a diminution of one or more of these factors decreases the frequency of that disease. After all, the reason for determining the etiological factors of a disease is to apply this knowledge to prevent the disease.*" Rothman and Greenland (2005) discuss the complexities of causation and the use of rules and deductive methods in causal inference. They also concur with Bradford Hill and others that a determination of causality is a pragmatic conclusion rather than an absolute verdict, and advocate that these criteria should be seen as "*deductive tests of causal hypotheses".*

Data Sources

Human studies: epidemiology, ecological studies and case reports

The aim of a risk assessment for the California Air Toxics programs is to determine potential impact on human health. Ideally therefore, the hazard identification would rely on studies in humans to demonstrate the nature and extent of the hazard. However, apart from clinical trials of drugs, experimental studies of toxic effects in human subjects are rarely undertaken or justifiable. Pharmacokinetic studies using doses below the threshold for any toxic effect have been undertaken for various environmental and occupational agents, but are not usually regarded as appropriate for suspected carcinogens.

The human data on carcinogens available to the risk assessor therefore mostly consist of epidemiological studies of existing occupational or environmental exposures. It is easier to draw reliable inferences in situations where both the exposures and the population are substantial and well-defined, and accessible to direct measurement rather than recall. Thus, many important findings of carcinogenicity to humans are based on analysis of occupational exposures. Problems in interpretation of occupational epidemiological data include simultaneous exposure to several different known or suspected carcinogens, imprecise quantification of exposures and confounding exposures such as active or passive tobacco smoking. The historical database of occupational data has a bias towards healthy white adult males. Thus, the hazard analysis of these studies may not accurately characterize effects on women, infants, children or the elderly, or on members of minority ethnic groups. Nevertheless, the analysis of occupational epidemiological studies, including meta-analyses, has proved an important source for unequivocal identification of human carcinogens.

Epidemiological evidence may also be obtained where a substantial segment of a general population is exposed to the material of interest in air, drinking water or food sources. Rigorous cohort and case-control studies may sometimes be possible, in which exposed individuals are identified, their exposure and morbidity or mortality evaluated, and compared to less exposed but otherwise similar controls. More often at least the initial investigation is a cross-sectional study, where prevalence of exposures and outcomes is compared in relatively unexposed and exposed populations. Such studies are hypothesis-generating, but are important sources of information nevertheless, and can often also justify more costly and labor-intensive follow-up cohort and/or case-control studies.

The clinical medical literature contains many case reports where a particular health outcome is reported along with unusual exposures that might have contributed to its occurrence. These reports typically describe a single patient or a small group, and have no statistical significance. They are nevertheless useful as indications of possible associations that deserve follow-up using epidemiological methods, and as supporting evidence, addressing the plausibility of associations measured in larger studies.

Animal studies

Although the observation of human disease in an exposed population can provide definitive hazard identification, adequate data of this type are not always available. More often, risk estimates have to be based on studies in experimental animals, and extrapolation of these results to predict human toxicity. The animals used are mostly rodents, typically the common laboratory strains of rat and mouse.

Rats and mice have many similarities to humans. Physiology and biochemistry are similar for all mammals, especially at the fundamental levels of xenobiotic metabolism, DNA replication and DNA repair that are of concern in identifying carcinogens. However, there are also several important differences between rodents and humans. Rodents, with a short life span, have differences in cell growth regulation compared to longer-lived species such as the human. For instance, whereas laboratory investigations have suggested that mutations in two regulatory genes (*e.g.*, H-ras and p-53) are sometimes sufficient to convert a rodent cell to a tumorigenic state, many human cancers observed clinically have seven or eight such mutations. In addition, cultured normal human cells have a very stable karyotype, whereas cultured rodent cells facilely undergo tetraploidization and then aneuploidization in cell culture. Further, cultured human cells senesce and rarely undergo spontaneous immortalization (frequency is 10^{-7} or less), whereas cultured rodent cells facilely undergo immortalization at frequencies on the order of 10^{-3}. The use of genomics to study chemical carcinogenesis is relatively new, but the differences at present appear to be a matter of degree rather than kind.

Differences in regulation of cell division are another likely reason for variation between species in the site of action of a carcinogen, or its potency at a particular site. A finding of carcinogenesis in the mouse liver, for instance, is a reasonably good indicator of potential for carcinogenesis at some site in the human, but not usually in human liver (Huff, 1999). The mouse liver (and to a lesser extent that of the rat) is a common site of spontaneous tumors. It is also relatively sensitive to chemical carcinogenesis. The human liver is apparently more resistant to carcinogenesis; human liver tumors are unusual except when associated with

additional predisposing disease, such as hepatitis B or alcoholic cirrhosis, or exposure to aflatoxin B1, or simultaneous exposure to hepatitis B virus and aflatoxin B1. Conversely, other tumor sites are more sensitive in the human than in experimental animals. Interspecies variation in site and sensitivity to carcinogenesis may also arise from differences in pharmacokinetics and metabolism, especially for carcinogens where metabolic activation or detoxification is important. This variability may cause important differences in sensitivity between individuals in a diverse population such as humans. Variability between individuals in both susceptibility and pharmacokinetics or metabolism is probably less in experimental animal strains that are bred for genetic homogeneity.

Animal carcinogenesis studies are often designed to maximize the chances of detecting a positive effect, and do not necessarily mimic realistic human exposure scenarios. Thus extrapolation from an experimentally accessible route to that of interest for a risk assessment may be necessary. Even for studies by realistic routes such as oral or inhalation, doses may be large compared to those commonly encountered in the environment, in order to counter the limitation in statistical power caused by the relatively small size of an animal experiment. Whereas the exposed population of an epidemiological study might number in the thousands, a typical animal study might have fifty individuals per exposure group. With this group size any phenomenon with an incidence of less than about 5% is likely to be undetectable. Statistically significant results may be obtained even with groups as small as ten animals per dose group, when incidence of a tumor that is rare in the controls approached 100% in a treated group. The consensus experimental design for animal carcinogenesis studies, which has evolved over the last 50 years of investigation, is represented by the protocol used by the U.S. National Toxicology Program (NTP) for studies using oral routes (diet, gavage or drinking water) or inhalation. These carcinogenesis bioassays usually involve both sexes of an experimental species, and most often two species. NTP has standardized the use of the C57BlxC3H F_1 hybrid mouse, and the Fischer 344 rat as the standard test species, although NTP has announced plans to substitute use of the Wistar Han rat for the Fischer 344 rat. There is now an extensive database of background tumor incidences, normal physiology, biochemistry, histology and anatomy for these strains, which aids in the interpretation of pathological changes observed in experiments. Nevertheless, there is enough variation in background rates of common tumors that the use of concurrent controls is essential for hazard identification or dose-response assessment. "Historical control" data are mainly used to reveal anomalous outcomes in the concurrent controls. The fact that a significantly elevated incidence of a tumor relative to the concurrent control group is within the range of historical controls at that site for the test sex and strain is not necessarily grounds for dismissing the biological significance of the finding.

Groups of fifty animals of each sex and species are used, with control groups, and several dose groups, the highest receiving the maximum tolerated dose (MTD). Recent study designs have emphasized the desirability of at least three dose levels covering a decade with "logarithmic" spacing (*i.e.* MTD, 1/2 MTD or 1/3 MTD, and 1/10 MTD). This extended design is aimed at providing better dose-response information, and may contribute important additional information, such as mechanistic insights, for the hazard identification phase.

Supporting evidence: genetic toxicity, mechanistic studies

Investigators have developed additional data sources that can support or modify the conclusions of animal carcinogenesis bioassays, and provide information on mechanisms of action of agents suspected of being carcinogenic based on epidemiological studies or animal bioassays.

Genetic damage in exposed organisms includes both gene mutations (point or frameshift), and larger scale effects such as deletions, gene amplification, sister-chromatid exchanges, translocations and loss or duplication of segments or whole chromosomes. These genetic effects of chemical exposures are deleterious in their own right. In addition, since carcinogenesis results from somatic mutations and similar genetic alterations, agents that cause genetic damage generally have carcinogenic potential. Conversely, many known carcinogens are also known to be genotoxic, although there is also a significant class of carcinogens that are not directly genotoxic according to the usual tests. These latter agents presumably work by some other mechanism, such as methylation of tumor suppressor genes or demethylation of cellular proto-oncogenes, although recent genetic studies have shown that even tumors induced by these agents may show mutations, deletions or amplification of growth regulatory genes.

Experimental procedures to demonstrate and measure genetic toxicity may involve exposure of intact animals, and examination of genetic changes in, for example, bone marrow cells (or cells descended from these, *e.g.*, the micronucleus test, which detects remnants of chromosomal fragments in immature erythrocytes), mutations in flies (*Drosophila)*, or appearance of color spots in the coat of mice. However, many tests have employed single celled organisms or mammalian cells in culture. The best known of these tests is the *Salmonella* reverse mutation assay, popularly known as the Ames test after its inventor. This is representative of a larger class of tests for mutagenic activity in prokaryotic organisms (bacteria), which necessarily only look at gene-level mutations. Similar tests in eukaryotic microorganisms (yeasts, *Aspergillus*) and cultured mammalian cells also detect chromosomal effects. Many tests using microorganisms *in vitro* involve addition of activating enzymes (*e.g.*, liver postmitochondrial supernatant – "S9") to mimic the metabolism of promutagenic chemicals *in vivo*. Another type of test examines the induction in mammalian cells of morphological transformation or anchorage-independent growth. These two chemically induced, *in vitro* changes are considered two of the many changes that fibroblastic cells must undergo on their route to neoplastic transformation (tumorigenicity). These various genetic tests contribute different information, which may be used to amplify and confirm conclusions drawn from human studies or animal bioassays, or to draw conclusions in the absence of epidemiological or bioassay data. In the latter case they have also been used in prioritizing agents for further evaluation by means of bioassays.

Carcinogen Identification Schemes

Some regulatory programs, such as California's Safe Drinking Water and Toxics Enforcement Act ("Proposition 65") and various activities of the U.S. EPA, require that explicit lists of substances having the potential to act as human carcinogens be maintained. Other such lists are developed by non-regulatory research organizations, such as the U.S. National Toxicology Program and the International Agency for Research on Cancer (IARC), an international program of the World Health Organization. The California air toxics programs do not have any statutory requirement to "identify" carcinogens. The requirement instead is to identify hazardous

substances as Toxic Air Contaminants, and to determine whether or not a threshold concentration, below which no adverse effects are expected, is likely to exist:

> ***HEALTH AND SAFETY CODE, Division 26 (Air Resources), § 39660.***
>
> *(2) The evaluation shall also contain an estimate of the levels of exposure that may cause or contribute to adverse health effects. If it can be established that a threshold of adverse health effects exists, the estimate shall include both of the following factors:*
>
> *(A) The exposure level below which no adverse health effects are anticipated.*
>
> *(B) An ample margin of safety that accounts for the variable effects that heterogeneous human populations exposed to the substance under evaluation may experience, the uncertainties associated with the applicability of the data to human beings, and the completeness and quality of the information available on potential human exposure to the substance. In cases in which there is no threshold of significant adverse health effects, the office shall determine the range of risk to humans resulting from current or anticipated exposure to the substance.*

In practice however this requirement amounts to the need to establish whether or not a substance is carcinogenic. Any such effects are clearly harmful. Whereas the great majority of non-cancer health effects of chemicals are regarded as having a threshold, the default assumption for carcinogens is that there is no threshold (as described below). OEHHA follows the guidelines laid out by IARC for identification and classification of potential human carcinogens, which are described in detail in the most recent revision of the *Preamble* to the IARC monographs series (IARC, 2006). The IARC Monograph series provides evaluations of the carcinogenicity of individual substances or commonly occurring mixtures. The evaluation guidelines used are similar to those used by other scientific or regulatory authorities, including U.S.EPA.

The data inputs to hazard identification for carcinogens are human epidemiological studies, animal bioassays, along with supporting evidence such as mechanistic and genotoxicity data and structure-activity comparisons. IARC also assembles data on the structure and identity of the agent. The list of agents considered includes specific chemicals and also complex mixtures, occupational and lifestyle factors, physical and biological agents, and other potentially carcinogenic exposures.

IARC evaluations determine the quality of evidence for both animal and human evidence as falling into one of four categories: sufficient evidence of carcinogenicity, limited evidence of carcinogenicity, inadequate evidence of carcinogenicity and evidence suggesting lack of carcinogenicity. Stringent requirements for data quality are imposed. In view of their crucial importance, these definitions are quoted directly from the *Preamble* (IARC 2006):

> **"(a) Carcinogenicity in humans**
>
> ***Sufficient evidence of carcinogenicity:*** The Working Group considers that a causal relationship has been established between exposure to the agent and human cancer. That is, a positive relationship has been observed between the exposure and cancer in studies in which chance, bias and confounding could be ruled out with reasonable confidence. A statement that there is *sufficient evidence* is followed by a separate sentence that

identifies the target organ(s) or tissue(s) where an increased risk of cancer was observed in humans. Identification of a specific target organ or tissue does not preclude the possibility that the agent may cause cancer at other sites.

***Limited evidence of carcinogenicity*:** A positive association has been observed between exposure to the agent and cancer for which a causal interpretation is considered by the Working Group to be credible, but chance, bias or confounding could not be ruled out with reasonable confidence.

Inadequate evidence of carcinogenicity: The available studies are of insufficient quality, consistency or statistical power to permit a conclusion regarding the presence or absence of a causal association between exposure and cancer, or no data on cancer in humans are available.

Evidence suggesting lack of carcinogenicity: There are several adequate studies covering the full range of levels of exposure that humans are known to encounter, which are mutually consistent in not showing a positive association between exposure to the agent and any studied cancer at any observed level of exposure. The results from these studies alone or combined should have narrow confidence intervals with an upper limit close to the null value (*e.g.*, a relative risk of 1.0). Bias and confounding should be ruled out with reasonable confidence, and the studies should have an adequate length of follow-up. A conclusion of *evidence suggesting lack of carcinogenicity* is inevitably limited to the cancer sites, conditions and levels of exposure, and length of observation covered by the available studies. In addition, the possibility of a very small risk at the levels of exposure studied can never be excluded.

(b) Carcinogenicity in experimental animals

Carcinogenicity in experimental animals can be evaluated using conventional bioassays, bioassays that employ genetically modified animals, and other in-vivo bioassays that focus on one or more of the critical stages of carcinogenesis. In the absence of data from conventional long-term bioassays or from assays with neoplasia as the end-point, consistently positive results in several models that address several stages in the multistage process of carcinogenesis should be considered in evaluating the degree of evidence of carcinogenicity in experimental animals.

The evidence relevant to carcinogenicity in experimental animals is classified into one of the following categories:

***Sufficient evidence of carcinogenicity*:** The Working Group considers that a causal relationship has been established between the agent and an increased incidence of malignant neoplasms or of an appropriate combination of benign and malignant neoplasms in (a) two or more species of animals or (b) two or more independent studies in one species carried out at different times or in different laboratories or under different protocols. An increased incidence of tumours in both sexes of a single species in a well-conducted study, ideally conducted under Good Laboratory Practices, can also provide *sufficient evidence*.

A single study in one species and sex might be considered to provide *sufficient evidence of carcinogenicity* when malignant neoplasms occur to an unusual degree with regard to

incidence, site, type of tumour or age at onset, or when there are strong findings of tumours at multiple sites.

***Limited evidence of carcinogenicity*:** The data suggest a carcinogenic effect but are limited for making a definitive evaluation because, *e.g.*, (a) the evidence of carcinogenicity is restricted to a single experiment; (b) there are unresolved questions regarding the adequacy of the design, conduct or interpretation of the studies; (c) the agent increases the incidence only of benign neoplasms or lesions of uncertain neoplastic potential; or (d) the evidence of carcinogenicity is restricted to studies that demonstrate only promoting activity in a narrow range of tissues or organs.

***Inadequate evidence of carcinogenicity*:** The studies cannot be interpreted as showing either the presence or absence of a carcinogenic effect because of major qualitative or quantitative limitations, or no data on cancer in experimental animals are available.

***Evidence suggesting lack of carcinogenicity*:** Adequate studies involving at least two species are available which show that, within the limits of the tests used, the agent is not carcinogenic. A conclusion of *evidence suggesting lack of carcinogenicity* is inevitably limited to the species, tumour sites, age at exposure, and conditions and levels of exposure studied."

IARC utilizes the evaluations of animal and human data, along with supporting evidence including genotoxicity, structure-activity relationships, and identified mechanisms, to reach an overall evaluation of the potential for carcinogenicity in humans. The revised *Preamble* (IARC, 2006) includes a description of the data evaluation criteria for this supporting evidence, and indications as to the situations where the availability of supporting evidence may be used to modify the overall conclusion from that which would be reached on the basis of bioassay and/or epidemiological evidence alone. The overall evaluation is expressed as a numerical grouping, the categories of which are described below, as before by directly quoting IARC (2006):

"Group 1: The agent is *carcinogenic to humans*.

This category is used when there is *sufficient evidence of carcinogenicity* in humans. Exceptionally, an agent may be placed in this category when evidence of carcinogenicity in humans is less than *sufficient* but there is *sufficient evidence of carcinogenicity* in experimental animals and strong evidence in exposed humans that the agent acts through a relevant mechanism of carcinogenicity.

Group 2.

This category includes agents for which, at one extreme, the degree of evidence of carcinogenicity in humans is almost *sufficient*, as well as those for which, at the other extreme, there are no human data but for which there is evidence of carcinogenicity in experimental animals. Agents are assigned to either Group 2A (*probably carcinogenic to humans*) or Group 2B (*possibly carcinogenic to humans*) on the basis of epidemiological and experimental evidence of carcinogenicity and mechanistic and other relevant data. The terms *probably carcinogenic* and *possibly carcinogenic* have no quantitative significance and are used simply as descriptors of different levels of evidence of human

carcinogenicity, with *probably carcinogenic* signifying a higher level of evidence than *possibly carcinogenic*.

Group 2A: The agent is *probably carcinogenic to humans*.

This category is used when there is *limited evidence of carcinogenicity* in humans and *sufficient evidence of carcinogenicity* in experimental animals. In some cases, an agent may be classified in this category when there is *inadequate evidence of carcinogenicity* in humans and *sufficient evidence of carcinogenicity* in experimental animals and strong evidence that the carcinogenesis is mediated by a mechanism that also operates in humans. Exceptionally, an agent may be classified in this category solely on the basis of *limited evidence of carcinogenicity* in humans. An agent may be assigned to this category if it clearly belongs, based on mechanistic considerations, to a class of agents for which one or more members have been classified in Group 1 or Group 2A.

Group 2B: The agent is *possibly carcinogenic to humans*.

This category is used for agents for which there is *limited evidence of carcinogenicity* in humans and less than *sufficient evidence of carcinogenicity* in experimental animals. It may also be used when there is *inadequate evidence of carcinogenicity* in humans but there is *sufficient evidence of carcinogenicity* in experimental animals. In some instances, an agent for which there is *inadequate evidence of carcinogenicity* in humans and less than *sufficient evidence of carcinogenicity* in experimental animals together with supporting evidence from mechanistic and other relevant data may be placed in this group. An agent may be classified in this category solely on the basis of strong evidence from mechanistic and other relevant data.

Group 3: The agent is *not classifiable as to its carcinogenicity to humans*.

This category is used most commonly for agents for which the evidence of carcinogenicity is *inadequate* in humans and *inadequate* or *limited* in experimental animals.

Exceptionally, agents for which the evidence of carcinogenicity is *inadequate* in humans but *sufficient* in experimental animals may be placed in this category when there is strong evidence that the mechanism of carcinogenicity in experimental animals does not operate in humans.

Agents that do not fall into any other group are also placed in this category.

An evaluation in Group 3 is not a determination of non-carcinogenicity or overall safety. It often means that further research is needed, especially when exposures are widespread or the cancer data are consistent with differing interpretations.

Group 4: The agent is *probably not carcinogenic to humans*.

This category is used for agents for which there is *evidence suggesting lack of carcinogenicity* in humans and in experimental animals. In some instances, agents for

> which there is *inadequate evidence of carcinogenicity* in humans but *evidence suggesting lack of carcinogenicity* in experimental animals, consistently and strongly supported by a broad range of mechanistic and other relevant data, may be classified in this group."

The IARC hazard evaluation system provides a detailed and generally accepted scheme to classify the strength of evidence as to the possible human carcinogenicity of chemicals and other agents. This includes careful consideration of mechanistic data and other supporting evidence, the evaluation of which is also important to inform selection of models or defaults used in dose response assessment, as is described below. The extended consideration of supporting evidence is in fact the primary difference between more recent versions of the guidance from IARC, and also by other organizations including U.S. EPA, and the original versions of that guidance. In fact, the basic criteria for hazard identification based on bioassay and epidemiological data have not changed substantially in other respects from earlier guidance documents, including that originally published by California (DHS, 1985). Although as noted earlier the California Air Toxics programs do not categorize identified carcinogens, it has generally been the practice to regard any agent with an IARC overall classification in Group 1 or Group 2 as a known or potential human carcinogen. This implies the selection of various policy-based default options, including absence of a threshold in the dose-response curve, unless specific data are available to indicate otherwise. The same basic identification criteria are used by OEHHA scientific staff to determine the appropriate treatment of agents not evaluated by IARC, or for which newer data or revised interpretations suggest that an earlier IARC determination is no longer appropriate.

U.S. EPA has also proposed a scheme for carcinogen hazard identification and strength of evidence classification in their recently finalized Guidelines for Carcinogen Risk Assessment (U.S. EPA, 2005). These principally differ from the IARC guidance in recommending a more extensive narrative description rather than simply a numerical identifier for the identified level of evidence, and also to some degree in the weight accorded to various types of supporting evidence. However, for most purposes they may be regarded as broadly equivalent to the scheme used by IARC, and OEHHA has chosen to cite the IARC (2006) *Preamble* as representing the most up-to-date and generally accepted guidance on this issue.

Dose Response Assessment

The dose-response phase of a cancer risk assessment aims to characterize the relationship between an applied dose of a carcinogen and the risk of tumor appearance in a human. This is usually expressed as a cancer slope factor ["potency" – in units of reciprocal dose - usually $(mg/kg\text{-}body\ weight.day)^{-1}$ or "unit risk" – reciprocal air concentration – usually $(\mu g/m^3)^{-1}$] for the lifetime tumor risk associated with lifetime continuous exposure to the carcinogen at low doses. Cancer potency factors may also be referred to as "cancer slope factors". (As will be described later, additional algorithms may need to be applied to determine risk for specific age groups, or at higher doses where toxicokinetic factors have significant effect.) The basic methodologies recommended in this document are similar to those described by U.S. EPA (2005a) in their Carcinogen Risk Assessment Guidelines. This document therefore refers to U.S. EPA (2005a) for explanation of detailed procedures, and will provide only a brief summary except in cases where OEHHA recommendations are different from or more explicit than those of U.S. EPA.

The following descriptions of methods for dose response assessment, and considerations in their application, apply in principle to the analysis of both animal and human (epidemiological) cancer incidence data. Indeed, the original formulation of the multistage model (Armitage and Doll, 1954) described below was developed based on human cancer incidence. Nevertheless, the number and quality of human cancer incidence datasets are limited. The more complex analyses have usually only been possible for animal experimental data, where the interindividual variability and the exposure conditions can be both measured and controlled. Most commonly, epidemiological studies have necessarily used a form of multivariate analysis to separate the effects of several different variables relating to exposure, demographics and behaviors (*e.g.*, smoking). In these analyses it is usually assumed that the effect measure(s) vary linearly with the exposure: any more complex variance assumptions might exceed the power of the data to determine the required model parameters. However, there are exceptions, especially for occupational studies where the critical exposure is measured as a continuous variable (rather than just categorical) and where the effect of this exposure is substantial relative to other confounding factors. For example, OEHHA (1998) used a multistage model dealing with both exposure intensity and duration in the analysis of cancer incidence in railroad workers exposure to diesel exhaust (Garshick et al., 1988)

Interspecies Extrapolation

The procedures used to extrapolate low-dose human cancer risk from epidemiological or animal carcinogenicity data are generally health-protective in that they determine an upper confidence bound on the risk experienced by an exposed population. As statistical estimates they cannot be regarded as definite predictions of the risk faced by any one specific individual, who might for a variety of reasons, including individual exposure and susceptibility, experience a risk different from the estimate. The risk assessment procedures used aim to include the majority of variability in the general human population within the confidence bounds of the estimate, although the possibility that some individuals might experience either lower or even no risk, or a considerably higher risk, cannot be excluded. Additionally, differences may exist between the characteristics of the general public and those of studied populations. For example, healthy workers, the subject of most epidemiological studies, are often found to have lower rates of morbidity and mortality than the general population (Wen et al., 1983; Monson, 1986; Rothman and Greenland, 1998). Most human data are derived from studies of largely male adult workers and risk estimates cannot take into account specific physiological factors of women, children, and older populations that may affect the potency of a carcinogen, including early age-at-exposure.

Dose-response assessment based on environmental epidemiological studies may involve evaluation of health impacts at exposure levels within the range of those measured in the study population. However, more usually the source data are studies of occupationally exposed humans or of animals, in which case the exposures in the study are likely to be much higher than those of concern for risk assessments relating to community or ambient exposures. Further, even when extrapolation from animal species to humans is not required, the general population to which the URF is applied may differ in characteristics relative to the occupational population studied. It is therefore necessary to extrapolate from the available data to the population and exposure range of concern, which is done by using a dose-response model derived from the source data. The models used fall into three main classes: mechanistically based models, empirical models and (where data are lacking to support a true data-based model) default

assumptions. The factors affecting the dose-response relationships for carcinogenesis may also be divided into those relating to absorption, distribution, metabolism and excretion on the one hand (*i.e.* toxicokinetics), and those relating to the underlying dose-response characteristics of carcinogenesis at the tissue or cellular level (*i.e.* toxicodynamics). In this sense the problem of dose response assessment for carcinogens is similar to that for non-cancer toxic effects. The toxicokinetic models used may in fact be similar for both situations, but the toxicodynamic models are generally different.

Intraspecies Extrapolation and Inter-individual Variability

In estimating the impact of a particular level of exposure to a carcinogen on a target human population, it is necessary to consider the range of susceptibility in the target population. In the present case this is typically defined as the general population of the State of California, including of course women (some of whom are pregnant), infants and children, the elderly, the sick, and those with genetic polymorphisms or acquired differences which affect their susceptibility to carcinogens. In general it has been assumed that the upper-bound risk estimates obtained from the standard toxicodynamic models described below are sufficiently health-protective to cover the intrinsic variability of the adult human target population, in spite of the fact that these models do not explicitly address this type of variability, except in the few cases where an estimate is based on epidemiological data from a large and unselected study group (U.S. EPA, 2005a). However, various analyses (Drew et al., 1983; Barton et al., 2005; Appendix J) have suggested that this assumption is inadequate to cover the expected variability within a human population that includes infants and children. Accordingly both U.S. EPA (2005b) and this document now offer guidance on the use of age-specific adjustment factors to allow for the potentially greater sensitivity of infants and children to chemical carcinogenesis.

The ability to accommodate human variability with regard to the toxicokinetic factors affecting susceptibility to carcinogens varies with the level of detail used in the particular assessment. If the generic interspecies extrapolation approach based on body weight is used without any explicit toxicokinetic model, then the assumption is made, as in the case of toxicodynamic variability, that the overall health-protective assumptions made are sufficient to cover the toxicokinetic variability. On the other hand if explicit models such as those referenced in the following paragraph are used, this variability may be more explicitly accommodated by using parameter values which are taken as point estimates from measured distributions of population values, or by using Monte Carlo techniques to include those distributions in the model (Bois et al., 1996; OEHHA, 1992; 2001b).

Toxicokinetic Models

Considerable literature exists showing the importance of understanding the toxicokinetics of carcinogens in understanding their mechanism of action, sites of impact and dose-response relationships. U.S. EPA (2005) in Section 3.1 refers to the importance of identifying an appropriate dose metric for the dose-response analysis. Early cancer risk assessments typically used applied dose as the dose metric, which is adequate in simple cases provided appropriate correction factors are applied for interspecies extrapolation. However, it is often observed that the uptake, metabolism and elimination of the carcinogenic substance (and/or a procarcinogen and metabolites) is non-linear, especially at the higher doses employed in experimental animal

studies (Hoel *et al*., 1983, Gaylor *et al*., 1994). Extrapolation to lower doses where such relationships tend to linearity (Hattis, 1990) is aided by the use of toxicokinetic models. These may be relatively simple compartment models, or sophisticated "physiologically based pharmacokinetic (PBPK) models" which to a greater or lesser degree model the actual biochemical and physiological events of toxicokinetic importance. Applications of both types of model may be found in various risk assessment documents prepared for the Toxic Air Contaminants program (and other OEHHA risk assessments). Since the details vary widely according to the nature of the chemical and the availability of appropriate kinetic data these general guidelines will defer to those examples rather than attempt a fuller exposition here. Further analysis of the use of toxicokinetic modeling in extrapolation from animals to humans, and in accounting for interindividual variability among adult humans, infants and children is presented in the Air Toxics Hot Spots *Technical Support Document for the Derivation of Noncancer Reference Exposure Levels* (OEHHA, 2008). Although this refers to the use of toxicokinetic modeling in non-cancer risk assessment, the primary considerations are similar for cancer risk assessment.

Toxicodynamic Models

An early use of mechanistic analysis to support risk assessment was the development of the Armitage-Doll multistage model of dose-response for carcinogenesis. The multistage model was initially developed on theoretical grounds, and by examination of epidemiological and animal data on time to tumor incidence. Subsequent discovery of the molecular biology of proto-oncogenes has provided a basis for explaining the model in terms of actual biological events and systems (Barrett and Wiseman, 1987). This model was developed by Crump and others into the "linearized multistage model", which has been extensively used for carcinogen risk assessment. It leads to a number of partially verifiable predictions, including linearity of the dose-response relationship at low doses, which is observed for many genotoxic carcinogens. It also predicts the form of the dose-response relationship at higher doses, which generally follow a polynomial form (subject to sampling and background corrections) except where other identifiable factors such as pharmacokinetics intervene.

It has been argued that the simple linearized form of the multistage model has limitations as a description of carcinogenic mechanisms, which detract from its usefulness and generality. Cell proliferation is known to be important in the progression of cancer. It may actually be the primary mechanism of action for a few carcinogens, as opposed to the direct modification of DNA by the carcinogen or a metabolite which is assumed to cause the mutational event at each stage in the original multistage description. A cell proliferation model has been developed (Moolgavkar and Knudson, 1981), which retains the concept of an initiating mutational event (in most cases caused by interaction of the chemical with DNA, although it could also be a spontaneous mutation) as in the original multistage model, but also considers proliferation, death or terminal differentiation of both normal and initiated cells. This model is thought to better describe the biological events in carcinogenesis. However, it has not been used extensively in risk assessment because it requires many parameters that are difficult to define and measure (such as proliferation and death rates for various classes of cell). If these cannot be accurately determined, the model has too many free parameters and is not helpful in defining extrapolated values for risk assessment purposes. This highlights a general problem in using mechanistic models in carcinogen risk assessment, which is that the carcinogenesis data themselves are

generally insufficient to define fully the dose response curve shape at low doses or provide much mechanistic information. The analysis is therefore supplemented with policy-based assumptions (such as the expectation of linearity at low doses) and, wherever possible, additional experimental measurements relating to the mechanism of action, in order to make meaningful prediction of risk from environmental exposures to humans.

Because of the difficulties in validating simplified mechanistic models such as the basic multistage model, and the additional difficulty of parameter estimation with more complex mechanistic models, the new U.S. EPA guidelines (U.S. EPA, 2005a) and some recent California risk assessments have chosen instead to use a less overtly mechanistic approach. This approach combines benchmark dose methodology (described below) with an explicit choice of the method for low-dose extrapolation, either assuming low-dose linearity or, for certain carcinogens where data indicate that this is appropriate, a "margin of exposure" or safety/uncertainty factor based approach. This benchmark method is now normally recommended for carcinogen dose response analysis, and the results generally differ little from those derived by the linearized multistage model. Although the linearized multistage method is no longer recommended as the default approach for cancer potency estimation it remains a plausible alternative in many cases, and still has useful applications, such as for time-to-tumor analyses for which benchmark methods are not yet widely available. Additionally, a considerable number of existing cancer potencies in Appendices A and B, and used in the Air Toxics Hot Spots program were derived by this method. Many of these would not be significantly different if calculated by the benchmark approach, and are unlikely to be replaced soon by newly calculated values. The linearized multistage method will therefore also be briefly described here.

Benchmark Dose Methodologies

The use of benchmark dose methodology has been explored by various investigators [including Gaylor et al. (1998); van Landingham et al. (2001) and Crump (1984, 1995, 2002)] as a tool for dose response extrapolation. This has been recommended in regulatory guidelines for both carcinogenic (U.S. EPA, 2005a) and non-carcinogenic (U.S. EPA, 1995) endpoints. The basic approach is to fit an arbitrary function to the observed incidence data, and to select a "point of departure" (POD) (benchmark dose) *within the range of the observed data.* From this a low dose risk estimate or assumed safe level may be obtained by extrapolation, using an assumed function (usually linear) or by application of uncertainty factors. The critical issue here is that no assumptions are made about the nature of the underlying process in fitting the data. The assumptions about the shape of the dose response curve (linear, threshold, etc.) are explicitly confined to the second step of the estimation process, and are chosen on the basis of policy, mechanistic evidence or other supporting considerations. The benchmark chosen is a point at the low end of the observable dose-response curve. Usually a dose at which the incidence of the tumor is 10% is chosen for animal studies, although lower effect levels may be appropriate for large epidemiological data sets. Because real experimental data include variability in the response of individual subjects, and measurement errors, likelihood methodology is applied in fitting the data. A lower confidence bound (usually 95%) of the effective dose (LED_{10}), rather than its maximum likelihood estimate (MLE), is used as the point of departure. This properly reflects the uncertainty in the estimate, taking a cautious interpretation of highly variable or error-prone data. It also reflects the instability of MLE values from complex curve-fitting routines, which has been recognized as a problem also with the linearized multistage model.

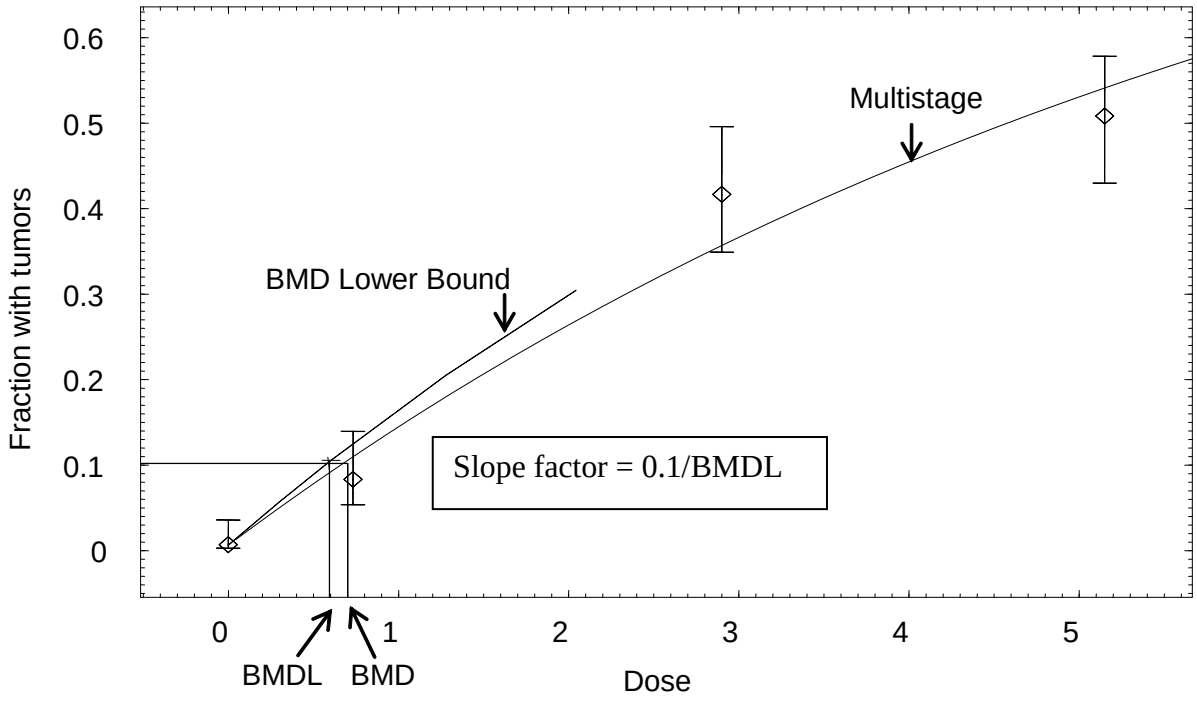
For cancer dose-response estimation using the benchmark dose method, either animal bioassay data or epidemiological data provide a suitable basis. In the absence of a pharmacokinetic model (which could provide tissue-specific dose metrics), the potency would ordinarily be based on the time-weighted average exposure during the exposure or dosing period. The model used to fit the data can be chosen from a range of available alternative quantal models, depending on which provides the best fit to the data in the observable range. In practice, the multistage polynomial fit developed for the linearized multistage model works well for most tumor data sets. Here it is being used merely as a mathematical curve-fitting tool, where the model well fits the data set, without making assumptions about its validity as a biological model of carcinogenesis.

Suitable polynomial fits and estimates of the benchmark may be obtained using U.S. EPA's BMDS software. The benchmark often used is the 95% lower confidence bound on the dose producing 10% tumor incidence. However, if data are available which include a significant dose-response at less than 10% tumor incidence, then that lower benchmark should be used (*e.g.*, LED_{05} or LED_{01}). Other software such as Tox_Risk, which was used for the linearized multistage model, has been used successfully, although the earlier GLOBAL program and its relatives are less suitable as curve-fitting tools for benchmark dose analysis.

Since it is usually assumed in cancer risk estimation that the low-dose response relationship is linear, risk estimates and a potency value (slope factor) may be obtained by linear extrapolation from an appropriate benchmark dose. The potency is the slope of that line ($0.1/LED_{10}$). The low dose linearity assumption is a general default for any carcinogen, and it is unlikely to be altered for genotoxic carcinogens.

A calculation using the benchmark dose approach (using a polynomial model with exponents restricted to zero or positive values), and linear extrapolation from the LED_{10} to obtain a potency estimate is shown in Figure 1 (the figure was generated by the U.S. EPA's BMDS program). This is based on tumor incidence data from an actual experiment with vinyl bromide in rats (Benya *et al*., 1982), with metabolized dose calculated by means of a pharmacokinetic model (Salmon *et al.*, 1992). The value of q_1* obtained by this calculation would then be corrected for the duration of the experiment if it had lasted for less than the standard rat lifetime, and for bodyweight and route-specific pharmacokinetic factors as described below. This is in addition to the correction for exposure duration that would be necessary if the study had not lasted for 105 weeks, and the interspecies correction, both of which are described below.

Figure 1. Benchmark dose calculation for tumor data in rats exposed to vinyl bromide



From Salmon *et al*. (1992), based on data from Benya *et al*. (1982)

Linearized Multistage Model

Quantal Analyses

A "multistage" polynomial (U.S. EPA, 1986, 2005a; Anderson *et al.*, 1983), based on the mechanistic insights of the original Armitage and Doll model of cancer induction and progression, has been used extensively by U.S. EPA, OEHHA and other risk assessors to model the dose response for lifetime risk of cancer. It usually is used for analysis of animal bioassay data, although related approaches have occasionally been used with epidemiological data. In mathematical terms, the probability of dying with a tumor (P) induced by an average daily dose (d) is:

$$P(d) = 1 - \exp[-(q_0 + q_1 d + q_2 d^2 + ... + q_j d^j)]$$

with constraints

$$q_i \geq 0 \text{ for all i.}$$

Equivalently, $A(d) = 1 - \exp [- (q_1 d + q_2 d^2 + \cdots + q_k d^k)]$,

where $A(d) = \dfrac{P(d) - P(0)}{1 - P(0)}$ is the extra risk over background at dose d.

The q_i model parameters are constants that can be estimated by fitting the polynomial to the data from the bioassay, *i.e.* the number of tumor bearing animals (as a fraction of the total at risk) at each dose level, including the controls. The fit is optimized using likelihood methodology, assuming that the deviations from expected values follow a χ^2 distribution, with the number of degrees of freedom (and hence the maximum number of terms allowed in the polynomial) determined by the number of points in the data set. All the coefficients of the terms are constrained to be zero or positive, so the curve is required to be straight or upward curving, with no maxima, minima or other points of inflection. In addition to the maximum likelihood estimates of the parameters, the upper 95% confidence limits on these parameters are calculated.

The parameter q_0 represents the background lifetime incidence of the tumor. The 95% upper confidence limit of the slope factor q_1 (q_1^*), is termed the cancer potency. The maximum likelihood estimate (MLE) of q_1 is not usually regarded as a reliable estimate for several reasons. First, it fails to reflect the uncertainty and variability in the data which affect the value of the estimate. This is an important issue for protection of public health, which is emphasized by current regulatory guidelines. Secondly, due to the variable order of the polynomial and the effect of some terms being zero as opposed to having a small but finite value, the MLE is unstable, and may show large and unpredictable changes in response to very slight changes in the input data. It may also erratically have a zero value, even when the data imply a significant positive dose-response relationship. The MLE is not a measure of central tendency for this estimate distribution (which is always asymmetrical and often multi-peaked). For small doses, the cancer potency is the ratio of excess lifetime cancer risk to the average daily dose received. Details of the estimation procedure are given in Crump (1981) and Crump, Guess, and Deal (1977). Several software programs are available to perform the necessary calculations, including U.S. EPA's BMDS, Tox_Risk and the earlier GLOBAL programs by Crump and colleagues, and Mstage, written by Crouch (1987).

When dose is expressed in units of mg/kg-d, the potency is given in units of $(\text{mg/kg-d})^{-1}$. Likewise, when the model input is in units of concentration ($\mu g/m^3$, ppb), the potency is given in units of $\mu g/m^3)^{-1}$ pr $(\text{ppb})^{-1}$. As in the case of potencies obtained by the benchmark approach, the experiment-based potency value needs to be corrected for less-than lifetime or intermittent exposure, and extrapolated from the test species to humans. Risk calculations using potency value estimated using the linearized multistage model predict the cancer risk at low doses only, with the higher order terms of the fitted polynomial being ignored since their contribution is negligible at low doses.

Selection of Site and Tumor Type

In developing cancer potency estimates from animal data, standard practice has been to use dose-response data for the most sensitive tumor site as the basis of the estimate (CDHS, 1985). Where tumors of more than one histological type (*e.g.*, adenomas and carcinomas) are observed at a single site, the combined incidence, *i.e.* proportion of animals affected with at least one tumor of any of the relevant types, is used for dose-response assessment. The same rules for combining

tumor types are generally applied in determining statistical significance for carcinogen identification (IARC, 2006). Tumor types considered to represent different stages of progression following initiation of a common original normal cell type are combined, whereas tumor types having different cellular origins are generally not combined by this procedure. Other considerations that may influence choice of site for dose response estimation include the quality of the data (especially, the statistical impact of a high or variable rate of a particular tumor type and site in control animals), and biological relevance to humans. However, it is an important principle that, just as for the hazard identification phase, concordance of site or tumor type between animal models and human health effects may occur but is not assumed or required.

Carcinogens Inducing Tumors at Multiple Sites

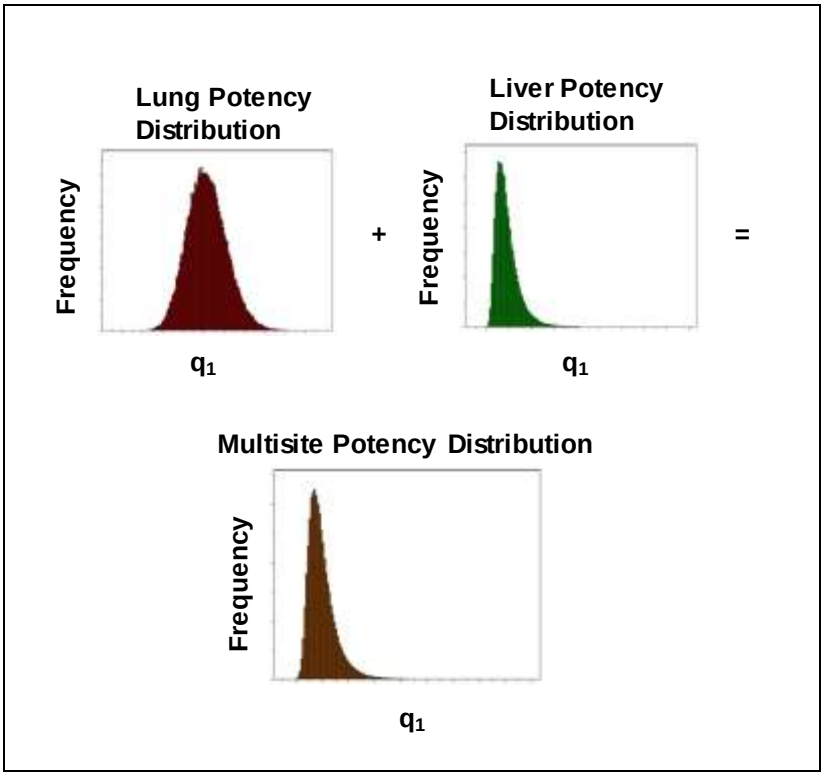
For most carcinogens, the selection of the most sensitive site in the animal studies is recognized as providing a risk estimate which is appropriate to protect human health. However, for chemicals that induce tumors at multiple sites, the single-site approach may underestimate the true carcinogenic potential. For example, the overall assessment of cancer risk from cigarette smoking (U.S. DHHS, 1982) or ionizing radiation (NRC, 1990) is not based on risk at one site, such as lung cancer. Instead, total cancer risk is estimated from all the sites at which agent-induced tumors are observed (lung, bladder, leukemia, etc), combined.

For carcinogens that induce tumors at multiple sites and/or with different cell types in a particular species and sex, OEHHA derives the animal cancer potency by probabilistically summing the potencies from the different sites and/or cell types. Using the combined potency distribution takes into account the multisite tumorigenicity and provides a basis for estimating the cumulative risk of all treatment-related tumors.

The linear term (q_1) of either the multistage model or the multistage-in-dose, Weibull-in-time model is first estimated based on the dose-response data for each of the treatment-related tumor sites. Statistical distributions, rather than point estimates, are generated at each site by tracing the profile likelihood of the linear term (q_1) (Zeise et al., 1991). The distributions of q_1 for each of the treatment-related sites are then statistically summed using a Monte Carlo approach and assuming independence (Figure 2). The sum is created by adding the linear term for each tumor site, according to its distribution, through random sampling. The upper 95 percent confidence limit on the summed distribution is taken as the multisite animal cancer potency estimate (McDonald et al., 2003, McDonald and Komulainen, 2005).

OEHHA has applied this approach in several recent dose-response analyses, including that for naphthalene presented in Appendix B of this document.

Figure 2. Addition of potency distributions for multi-site cancer potency derivations.



Early-Lifestage Cancer Potency Adjustments

In recent years, there have been growing concerns regarding the exposure of children to environmental chemicals, including the possibility that they may be more susceptible than adults to injury caused by those chemicals. The California Legislature passed the Children's Environmental Health Protection Act (Senate Bill 25, Escutia; Chapter 731, Statutes of 1999; "SB 25") to help address these concerns. Under SB25, OEHHA is mandated to consider infants and children specifically, where data permit, in evaluating the health effects of Toxic Air Contaminants (TACs).

The development of cancer is one of the adverse health effects that may occur in children as a result of exposure to environmental chemicals. The document "Prioritization of Toxic Air Contaminants under the Children's Environmental Health Protection Act" (OEHHA, 2001a) noted that risks of cancer from exposures to carcinogens occurring from conception through puberty can be different than those from exposures occurring in adulthood. Exposure to a carcinogen early in life may result in a greater lifetime risk of cancer for several reasons:

1. Cancer is a multistage process and the occurrence of the first stages in childhood increases the chance that the entire process will be completed, and a cancer produced, within an individual's lifetime.
2. Tissues undergoing rapid growth and development may be especially vulnerable to carcinogenic agents. During periods of increased cell proliferation there is rapid turnover of DNA, and more opportunity for misrepair of damage (*e.g.*, DNA breaks, crosslinks, adducts) or alterations to result in permanent changes to the DNA (*e.g.*, mutations, altered DNA methylation) that may ultimately lead to cancer.
3. During early development, a greater proportion of the body's cells are relatively undifferentiated stem cells, and as such represent a large target population of somatic cells capable of passing along permanent changes to the DNA during future cell divisions.
4. There may be greater sensitivity to hormonal carcinogens early in life since the development of many organ systems is under hormonal control (*e.g.*, male and female reproductive systems, thyroid control of CNS development).
5. Other factors that may play a role in increased cancer risk from exposures during critical developmental periods include differences in immunological activity, intestinal absorption, biliary and kidney excretion, blood and fat distribution, and expression of enzyme systems that activate or detoxify carcinogens.

Data in humans and animals for a variety of carcinogens suggest that exposures to such carcinogens early in life may result in a greater lifetime risk of cancer compared to exposures later in life. Examples of this effect in humans are carcinogenicity due to ionizing radiation, diethylstilbestrol (DES), chemotherapeutic agents, and tobacco smoke.

Ionizing radiation exposure carries an increased risk of cancer when exposures occur early in life compared to adult exposures for a number of tumor types. Children exposed to ionizing radiation (diagnostic X-rays) *in utero* demonstrate a larger excess of leukemia cases than

children exposed to ionizing radiation postnatally (NRC, 1990). Exposure to radioisotopes (^{131}I, ^{137}Cs, ^{134}Cs, ^{90}Sr) as a consequence of the 1986 Chernobyl nuclear accident resulted in an elevated thyroid cancer incidence in children but not adults (Moysich, 2002). Treatment of children for Hodgkin's lymphoma with both chemotherapeutic agents and irradiation has been shown to increase the risk of secondary tumors (Swerdlow et al., 2000; Franklin et al., 2006). Age at irradiation in Hodgkin's disease patients treated with radiotherapy strongly influenced the risk of developing breast cancer. The relative risk (RR) of developing breast cancer was 136 for women treated before 15 years of age, 19 for women 15-24 years of age, and 7 for those 24-29 years of age. In women above 30 years of age, the risk was not increased (Hancock *et al*., 1993).

DES was administered to pregnant women in the 1940s-1960s for the purpose of preventing pregnancy loss. In 1970, Herbst and Scully described 7 cases of vaginal adenocarcinoma (6 cases of the clear-cell type) in women aged 15-22 years. This type of cancer is extremely rare in that age range. A follow-up epidemiological study included an additional case, and noted the fact that the mothers of 7 of the 8 patients had been treated with DES during their pregnancy (Herbst *et al*., 1971). Reports by other investigators confirmed the association between maternal use of DES during pregnancy and the development of vaginal adenocarcinoma in their female offspring (Preston-Martin, 1989). It was observed that *in utero* DES exposure resulted in female genital tract morphological changes which correlated with both dose and duration of exposure, and those changes were not related to the maternal conditions which were the reason for the DES administration. Additionally, the risk of occurrence of those morphological changes declined with increasing gestational age at first exposure (O'Brien *et al*., 1979; Preston-Martin, 1989). In contrast, vaginal adenocarcinoma incidence did not increase in the exposed mothers themselves, indicating an increased early-life susceptibility to the carcinogenic effects of DES.

There is evidence in the epidemiological literature indicating that exposure to tobacco smoke during puberty may increase risk of breast cancer later in life, particularly among women who are NAT2 slow deacetylators (Marcus *et al*., 2000; Morabia *et al*., 2000; Lash and Aschengrau, 1999). Wiencke *et al*. (1999) report that early age at initiation of smoking is associated with a higher level of DNA adducts in lung tissue of former-smokers with lung cancer.

It has also been observed by Smith *et al*. (2006) that human *in utero* or early childhood exposure to arsenic in drinking water results in significantly increased lung cancer incidences during adult life.

Data from animal studies provide additional examples of increased sensitivity to early life (typically postnatal and juvenile) exposures. These effects span a range of target tissues, including the liver (vinyl chloride, safrole), brain (methylnitrosourea), reproductive tract (DES, tamoxifen), and lung (urethane) (OEHHA, 2001a).

In the following sections we summarize two efforts to evaluate quantitatively the effect of lifestage at exposure on carcinogenic response in experimental animal studies. The first section provides a description of OEHHA's analysis of data on the effect of age at exposure on carcinogenic potency. (Details of this analysis are in Appendix J.) The second section describes U.S. EPA's work in this area. (We also provide the published paper in Appendix I that presents the U.S. EPA analyses.) Both analyses used extant data available in the published literature. U.S. EPA used their analysis to modify the procedures they have used to estimate cancer risk by

weighting risk by specific factors for childhood exposures. The weighting factors are a policy choice supported by U.S. EPA's data analysis. The results of OEHHA's analysis, summarized below and described in detail in Appendix J, support the decision to modify policy to weight risk when exposure occurs during childhood.

OEHHA Analysis of the Effect of Age at Exposure on Cancer Potency

The analysis of animal cancer studies which include early life exposure by the Reproductive and Cancer Hazard Assessment Branch (RCHAB) of OEHHA also supports the application of lifestage-specific cancer potency factor adjustments. This analysis is provided in detail as Appendix J of this document.

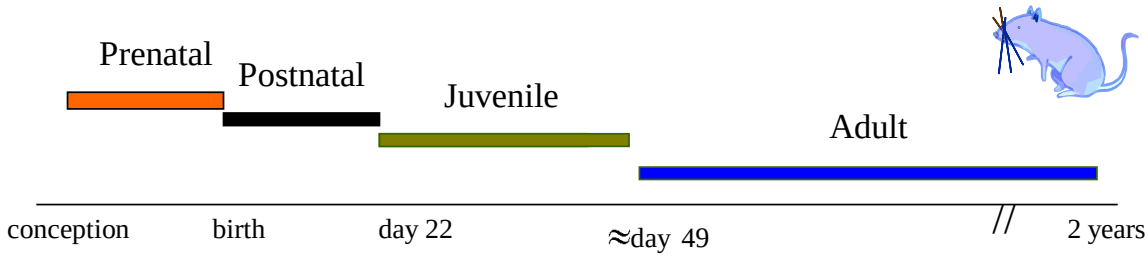
Early-in-life susceptibility to carcinogens has long been recognized by the scientific community and clinicians as a public health concern. Numerous scientific publications and symposia have addressed this issue over the years and the scientific literature contains a number of human clinical findings and epidemiological studies of early life cancer susceptibility. While there are many indications of increased human cancer susceptibility in early life, the magnitude of the impact has been difficult to gauge. Until recently risk assessment procedures have not in general addressed the issue. As described in the next section, in 2005 the U.S. EPA adopted an approach to weight carcinogens by age at exposure if they act via a mutagenic mode of action. The California legislature in 2000 directed OEHHA to assess methodologies used in addressing early-in-life risk, compile animal data to evaluate those methods, and develop methods to adequately address carcinogenic exposures to the fetus, infants, and children (Children's Environmental Health Initiative [AB 2872, Shelly]; California Health and Safety Code [HSC] section 901 [a] through [e]).

OEHHA assessed cancer risk assessment methodologies, and found that the existing risk assessment approaches did not adequately address the possibility that risk from early-in-life and adult exposures may differ. OEHHA further concluded that there was a need to address early-in-life cancer risk, and undertook studies to develop methods for doing so. Age-related cancer susceptibility data were identified from published animal cancer bioassays in which these issues were addressed. Two types of studies with early-in-life exposures were compiled. The first type are "multi-lifestage exposure studies." These studies have at least two groups exposed during different lifestages: One dose group is exposed to a chemical only during one of the following lifestages (Figure 3):

- prenatal (from conception to birth),
- postnatal (from birth to weaning),
- juvenile (from weaning to sexual maturity).

The second dose group is exposed for some period of time at an older age, preferably during the adult lifestage, that is, after sexual maturity. This group served as the reference group. In some cases where there was no adult exposure group, animals exposed as juveniles served as the reference group. Multi-lifestage exposure studies are available for many chemicals, enabling the exploration of patterns in early-life susceptibility across chemicals.

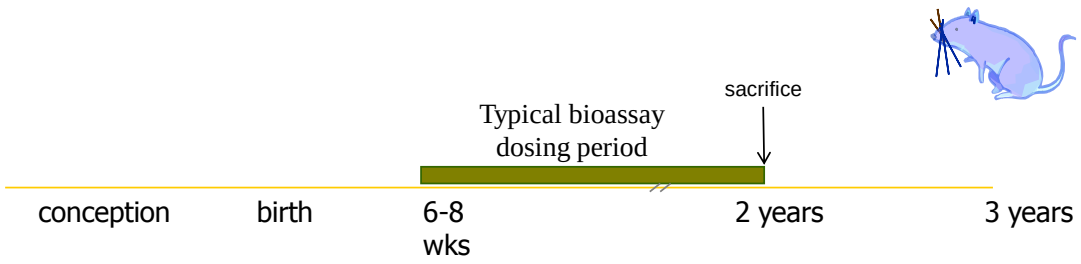
Figure 3. Definition of Rodent Lifestage Adopted in the OEHHA Analyses



OEHHA also conducted "chemical-specific case studies" of early-life sensitivity for two carcinogens, ethyl-N-nitrosoamine (DEN) and N-ethyl-N-nitrosourea (ENU) that combine data from a number of studies. These "chemical-specific case studies" were conducted to explore the feasibility of analyzing chemical-specific data on age susceptibility from single-lifestage exposure experiments. For these chemicals, OEHHA compiled from the literature a second type of study, "single-lifestage exposure experiments." In these experiments dose groups were exposed only during a particular lifestage and, unlike the "multi-lifestage exposure studies," there was no requirement that the same study also include groups exposed during a different lifestage. Thus, single-lifestage exposure experiments were identified as being either prenatal, postnatal, juvenile, or adult exposure studies. For each of the two chemicals, there were many prenatal studies conducted that were compiled, analyzed, and grouped together. Postnatal studies from different publications were similarly compiled, analyzed and grouped together, as were juvenile studies. Adult studies were not available for either DEN or ENU, thus for both chemicals juvenile exposure studies served as the referent for prenatal studies, and for postnatal studies.

Typical cancer bioassays such as those conducted in rats and mice by NTP involve exposing animals starting at six to eight weeks of age, which is the time at which these animals reach sexual maturity (late teenagers relative to humans). The experiments are run for two years, ending when the animal is in late middle age. Thus, early and very late life exposures are not included in the typical rodent bioassay (see Figure 4). If the NTP bioassay is used as a basis for estimating cancer potency, the potency and resulting risk estimates may be too low. Thus OEHHA focused on finding studies that evaluated early in life exposures.

Figure 4. Dosing Period for Typical Rodent Bioassays.



Since bioassays examining the effect of age at exposure on carcinogenesis were conducted by various investigators for different purposes, there is a great deal of variation across studies in terms of dose selection, duration of exposure, number of animals, and length of study duration. To be included in the compilation of studies with early life exposure, a study or an experimental group in a study had to meet minimum requirements.

The criteria for study inclusion are as follows:

- Treated groups were exposed to a single chemical carcinogen or a single carcinogenic chemical mixture.
- Study groups were not compromised by severe treatment-related non-cancer toxicity.
- Overall the duration of exposure period plus observation period exceeded 40 weeks, unless animals died of tumor.
- For included dose groups, the study must report age at dosing, age at sacrifice, and site-specific tumor incidence.
- Each lifestage exposure treatment group has an appropriate concurrent control group, or, for rare tumors only, an appropriate historical control.
- The studies were on mammals.
- Each treatment and control group consists of at least ten animals, unless the conduct and design of the study was well done in all other aspects (*e.g.*, the length of the study was sufficiently long to observe treatment-related tumors) and tumor incidence was high in treated groups and very low in controls.
- Site specific tumor data were reported, not only total number of tumor bearing animals.
- The test compound was administered in the diet, water, via gavage, or by intraperitoneal (i.p.), intravenous (i.v.), or subcutaneous (s.c.) injection. For dermal and subcutaneous injection studies, distal tumor findings are utilized (for dermal, other than skin tumors; for injection, non-injection site tumors).

- While studies designed to histopathologically examine tumors at multiple sites were preferred, studies that examined only a select set of organ/tissue sites were not excluded if the sites examined were known with confidence to be the only target tissues for the chemical and lifestage in question in that particular strain of animal.

Different approaches were taken to identify animal cancer studies that included groups of animals exposed during early life stages. First, MEDLINE and TOXLINE (National Library of Medicine) databases were searched using combinations of various key words for cancer (*e.g.*, tumor(s), neoplasm(s), cancer, neoplasia, cancerous, neoplasms-chemically induced) and for early-life exposure (*e.g.*, age, age-at-exposure, development (al), prenatal, *in utero*, gestation (al), postnatal, neonatal, juvenile, weaning, weanling, adolescent, adolescence, young). Second, the extensive compilation of bioassays in the *Survey of Compounds which have been Tested for Carcinogenic Activity*, was reviewed. This survey, formerly maintained by the National Cancer Institute as Public Health Service Publication Number 149, or PHS 149, is now available from a private source electronically as CancerChem, 2000. Third, from bibliographies from relevant published papers additional studies were identified. Finally the Single Dose Database developed by Calabrese and Blain (1999) was obtained and utilized to identify additional publications that appeared to contain potentially useful data. All of these publications were evaluated to determine if the study dosed separate groups of animals early in life and at or near adulthood. A total of 145 publications, providing data on 84 chemicals, were identified as meeting the criteria for study inclusion. A subset of these met the criteria for inclusion in the multi-lifestage exposure analysis.

Finally, for the OEHHA multi-lifestage analyses, we define "experiment" as a study component consisting of a control group as well as a treated group(s) exposed during the same lifestage (*i.e.*, prenatal, postnatal, juvenile or adult), and using the same experimental protocol (*e.g.*, route of exposure, strain, species, laboratory). Thus, by our definition one publication may report multiple experiments.

In the OEHHA analysis, data from studies on 23 unique carcinogens, 20 of which are considered to act via primarily genotoxic modes of action, were analyzed. Of these 20 carcinogens, 15 are thought to require metabolic activation to the ultimate carcinogenic species (Table 1). Fourteen carcinogens, including one thought to act via primarily nongenotoxic modes of action, were included in the prenatal multi-lifestage exposure studies. Eighteen carcinogens, including two thought to act via primarily nongenotoxic modes of action, were included in the postnatal multi-lifestage exposure studies. Five carcinogens were included in the juvenile multi-lifestage exposure studies. The case study chemicals, DEN and ENU, are both genotoxic. ENU is a direct acting alkylating agent, while DEN requires metabolic activation.

Table 1. Carcinogens for which studies with multi-lifestage exposures in animal studies are available

Genotoxic carcinogens requiring metabolic activation
Benzidine
Benzo[a]pyrene
Dibutylnitrosamine
Diethylnitrosamine (DEN)
7,12-Dimethylbenz[a]anthracene (DMBA)
Dimethylnitrosamine (DMN)
Di-n-propylnitrosamine (DPN)
1 -Ethyl-nitrosobiuret
2-Hydroxypropylnitrosamine
3-Hydroxyxanthine
3-Methylcholanthrene (3-MC)
4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK)
Safrole
Urethane
Vinyl chloride
Genotoxic carcinogens not requiring metabolic activation
Butylnitrosourea
1,2-Dimethylhydrazine
Ethylnitrosourea (ENU)
Methylnitrosourea (MNU)
ß-Propiolactone
Nongenotoxic carcinogens
1,1-Bis(p-chlorophenol)-2,2,2-trichloroethane (DDT)
Diethylstilbestrol (DES)
2,3,7,8-Tetrachlorodibenzodioxin (TCDD)

Cancer Potency Estimation

Statistical methods were developed and used to analyze the data and derive measures of early-life susceptibility. These are described in detail in Appendix J. In brief, a cancer potency (the slope of the dose response curve) was developed for each of the experiments selected using the linearized multistage model. This model was chosen because of widespread use in risk assessment, and its flexibility in being able to fit many different data sets needed to evaluate the effect of lifestage-at-exposure on cancer potency. The dose metric used for the potency analyses is cumulative dose normalized to body weight. The cancer potency is thus expressed as the increase in tumor probability with increasing cumulative dose in units of mg/kg body weight.

To take into account uncertainty in potency estimation, cancer potencies are depicted by a statistical distribution, rather than by a single, fixed value, using methods described in Appendix J. While these methods have typically been used to obtain and report the 95th percentile of the cancer slope parameter for cancer risk assessment purposes, here OEHHA utilized the full distribution of the cancer slope parameter to derive measures of early-life susceptibility to carcinogens. This was done to systematically take into account uncertainty in the analysis.

For experiments where treatment related tumors were observed at multiple sites or at the same site but arising from different cell types, slopes from these sites were statistically combined by summing across the potency distributions (assuming independence across the sites that were observed) to create an overall multisite cancer potency. It is not uncommon that a carcinogen causes more than one type of cancer or causes tumors at different sites depending on lifestage at exposure. For example, in humans tobacco smoke causes cancers of the lung, bladder, and certain other organs. This multi-site carcinogenicity is frequently observed in animal experiments as well. In order to account for this, all treatment-related tumors that were observed in a given lifestage were taken into account in estimating cancer potency from that particular experiment.

Addressing Early-Age Sensitivity in Estimating Cancer Risk: Age Sensitivity Factors

Inherent Sensitivity of Lifestages – Lifestage Potency Ratios

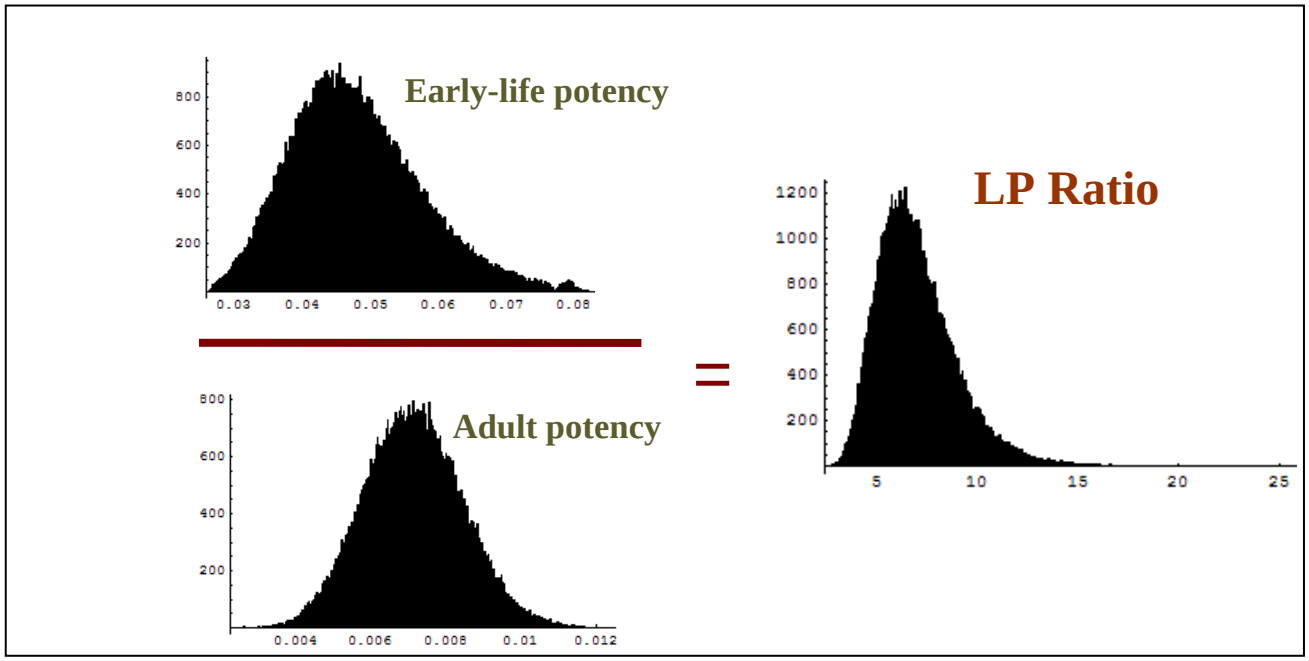
For this analysis, OEHHA calculates the ratio of cancer potency derived from an early lifestage exposure experiment(s) to that derived from an experiment(s) conducted in adult animals. OEHHA used the potency distributions for the individual lifestage exposures, rather than a point estimate, to derive the ratios. The lifestage cancer potency ratio is then described as a distribution and one can select specific percentiles from the distribution to better understand and bound the uncertainty (Figure 5). Of particular importance is the location of the ratio distribution in relation to the reference value of 1.0, which would mean no difference in risk from exposures at early versus adult lifestages. A lifestage cancer potency ratio distribution that primarily lies above the value of 1.0 indicates early life exposures to a carcinogen result in a stronger tumor response relative to adult exposure. Conversely, a lifestage cancer potency ratio distribution that mainly lies below the value of 1.0 indicates early life exposure to a carcinogen results in a weaker tumor response relative to adult exposure.

A lifestage potency (LP) ratio distribution was derived for each multi-lifestage study, resulting in 22 prenatal ratio distributions representing 14 unique carcinogens, 55 postnatal LP ratio distributions representing 18 unique carcinogens, and seven juvenile LP ratio distributions representing five unique carcinogens. The LP ratio distributions for a given early lifestage were combined into a single "LP ratio mixture distribution," in order to show the range of susceptibilities of that lifestage to the carcinogens studied.

LP ratio mixture distributions for a given early lifestage were developed by (1) obtaining a single LP ratio distribution for each chemical (when a chemical is represented by more than one study) and then (2) equally sampling across all chemicals. When a chemical is represented by more than one study, then the LP ratio distributions from all studies of that chemical were combined by equally sampling from each LP ratio distribution via Monte Carlo methods to obtain a single

LP ratio distribution for that chemical. (Appendix J describes this in more detail, as well as a sensitivity analysis that included two alternative sampling methods.) Once each chemical is represented by a single LP ratio distribution, then the LP ratio mixture distribution for each early lifestage (prenatal, postnatal, and juvenile) is obtained by equally sampling across all of the chemicals via Monte Carlo methods.

Figure 5. Lifestage Potency Ratio (LPR) distribution.

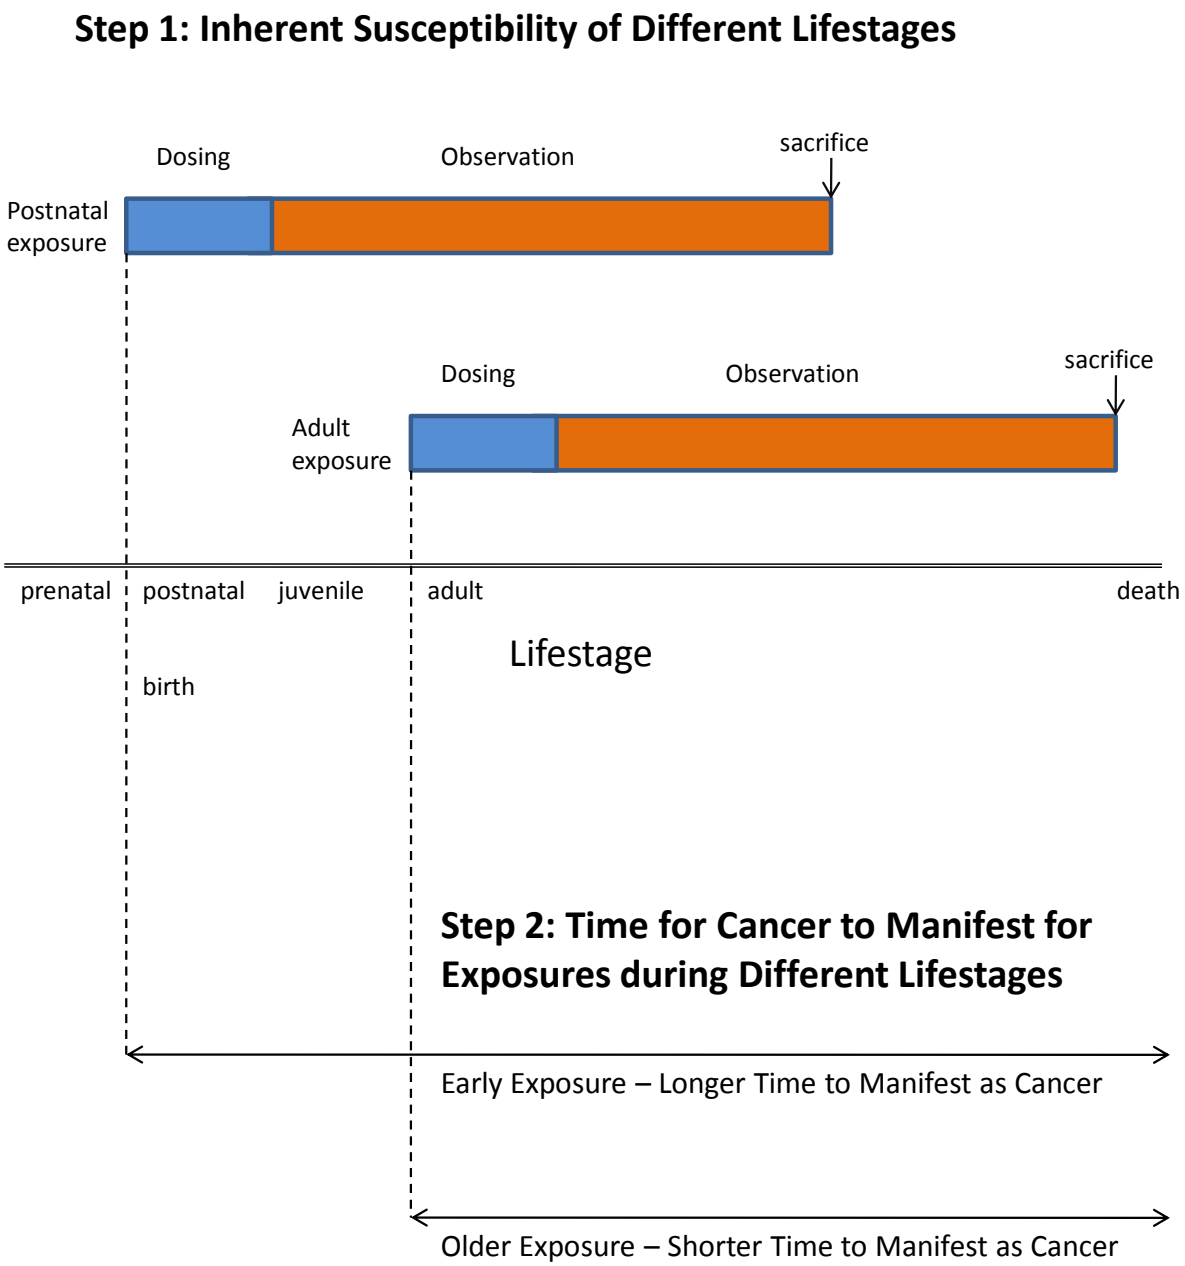


Effect of Longer Time Period for Cancer to Manifest

The LP ratios described above characterize the inherent susceptibility of early lifestages to carcinogen exposure, by comparing potencies for individuals followed for similar periods of time and similarly exposed, but exposed during different lifestages. Age-specific adjustments to the cancer potency must also take into account the longer period of time that carcinogen exposure to the young has to manifest as cancer. Empirical data from studies of both humans and animals demonstrate that, for many cancers, cancer risk increases with age, or time since first exposure. While some cancers have been seen to increase by as much as the sixth power of age, a general approach taken for example by the National Toxicology Program in analyzing tumor incidences in its chronic bioassays is to assume that cancer risk increases by the third power of age. Thus, consistent with the approach used by the NTP in analyzing rodent cancer bioassay data, the longer period of time that exposed young have to develop tumors is addressed by taking into account time-of-dosing. This was done by multiplying the LP ratio by a time-of-dosing factor, to yield an age sensitivity factor (ASF). Specifically, the prenatal LP ratio is multiplied by a factor of 3.0, the postnatal LP ratio is multiplied by a factor of 2.9, and the juvenile LP ratio is multiplied by 2.7. Thus, ASFs were developed for each experiment, by first calculating the LP ratio to address inherent susceptibility of early lifestages relative to adults, and then accounting for the effect of years available to manifest a tumor following carcinogen exposure. (see Figure

6). Note that we are not using the term "sensitivity" in the immunologic sense (*e.g.*, sensitization), but rather are using the term more generically.

Figure 6. Issues addressed by the Age-Sensitivity Factor (ASF)



Application of this approach for risk associated with lifetime exposures would include an ASF of less than 1 for exposures during the latter part of adult life for carcinogens that act on early stages. Therefore, the addition of this adjustment to the younger lifestages but not to the later part of the adult period could overestimate the risk of whole-life exposures. On the other hand, the 70 year "lifetime" used in estimating lifetime cancer risk does not reflect the longer lifespan of the U.S. population. Further, as noted above, the animal bioassays on which potency was based typically exclude pre-weaning dosing and sacrifice animals during their late middle-age. Use of cancer potencies calculated from standard assays can therefore underestimate lifetime cancer risk. The ASF calculated for carcinogens includes both inherent sensitivity of developing animals and the available time since exposure to develop cancer.

Results of OEHHA Analysis

The analyses indicate that both the prenatal and postnatal lifestages can be, but are not always, much more susceptible to developing cancer than the adult lifestage. The analyses also indicated that the ASFs for these age windows vary by chemical, gender and species.

Regarding prenatal lifestage exposure, few cases were indicative of equal inherent adult and prenatal susceptibility, with an LP ratio of unity. The LP ratio distribution was roughly bimodal, with LP ratios for several studies significantly greater than unity and several others significantly less than unity. Figure 7 below shows the ASFs from each of the prenatal multi-lifestage exposure studies, displayed as a cumulative frequency profile. The median of the prenatal ASF mixture distribution was 2.9 (see also Table 6 in Appendix J),

The modality in the prenatal LP ratio distribution was reflected in the DEN and ENU case studies, with results for DEN suggesting inherently less sensitivity than older animals from exposure *in utero*, and for ENU just the opposite. For the DEN and ENU case studies, the referent groups were juvenile rather than adult animals, and the results may have underestimated the LP ratio and ASF, to the extent that some of the apparent sensitivity for DEN and ENU in the prenatal period carries through to the juvenile period. ENU is a direct acting carcinogen that does not require metabolic activation, whereas DEN can not be metabolized to any significant extent by fetal tissues until relatively late in gestation. This may explain the lower fetal susceptibility of DEN. However, prenatal metabolic status is not the sole determinant of prenatal susceptibility; *e.g.*, benzidine and safrole require metabolic activation and exhibit greater susceptibility from prenatal exposure.

The median of the postnatal ASF mixture distribution was 13.5 (see Table 7 in Appendix J). Figure 8 below shows the ASFs from each of the postnatal multi-lifestage exposure studies, displayed as a cumulative frequency profile. Thus, for the chemicals studied, there was generally greater susceptibility to carcinogens during the early postnatal compared to the adult period, particularly when the ASF accounts for the longer period cancer has to manifest when exposure occurs early in life. The DEN and ENU case studies also exhibited substantial extra susceptibility during the postnatal period. To summarize, for most of the carcinogens studied here, rodents are inherently more sensitive in the postnatal period, as indicated by Figure 8.

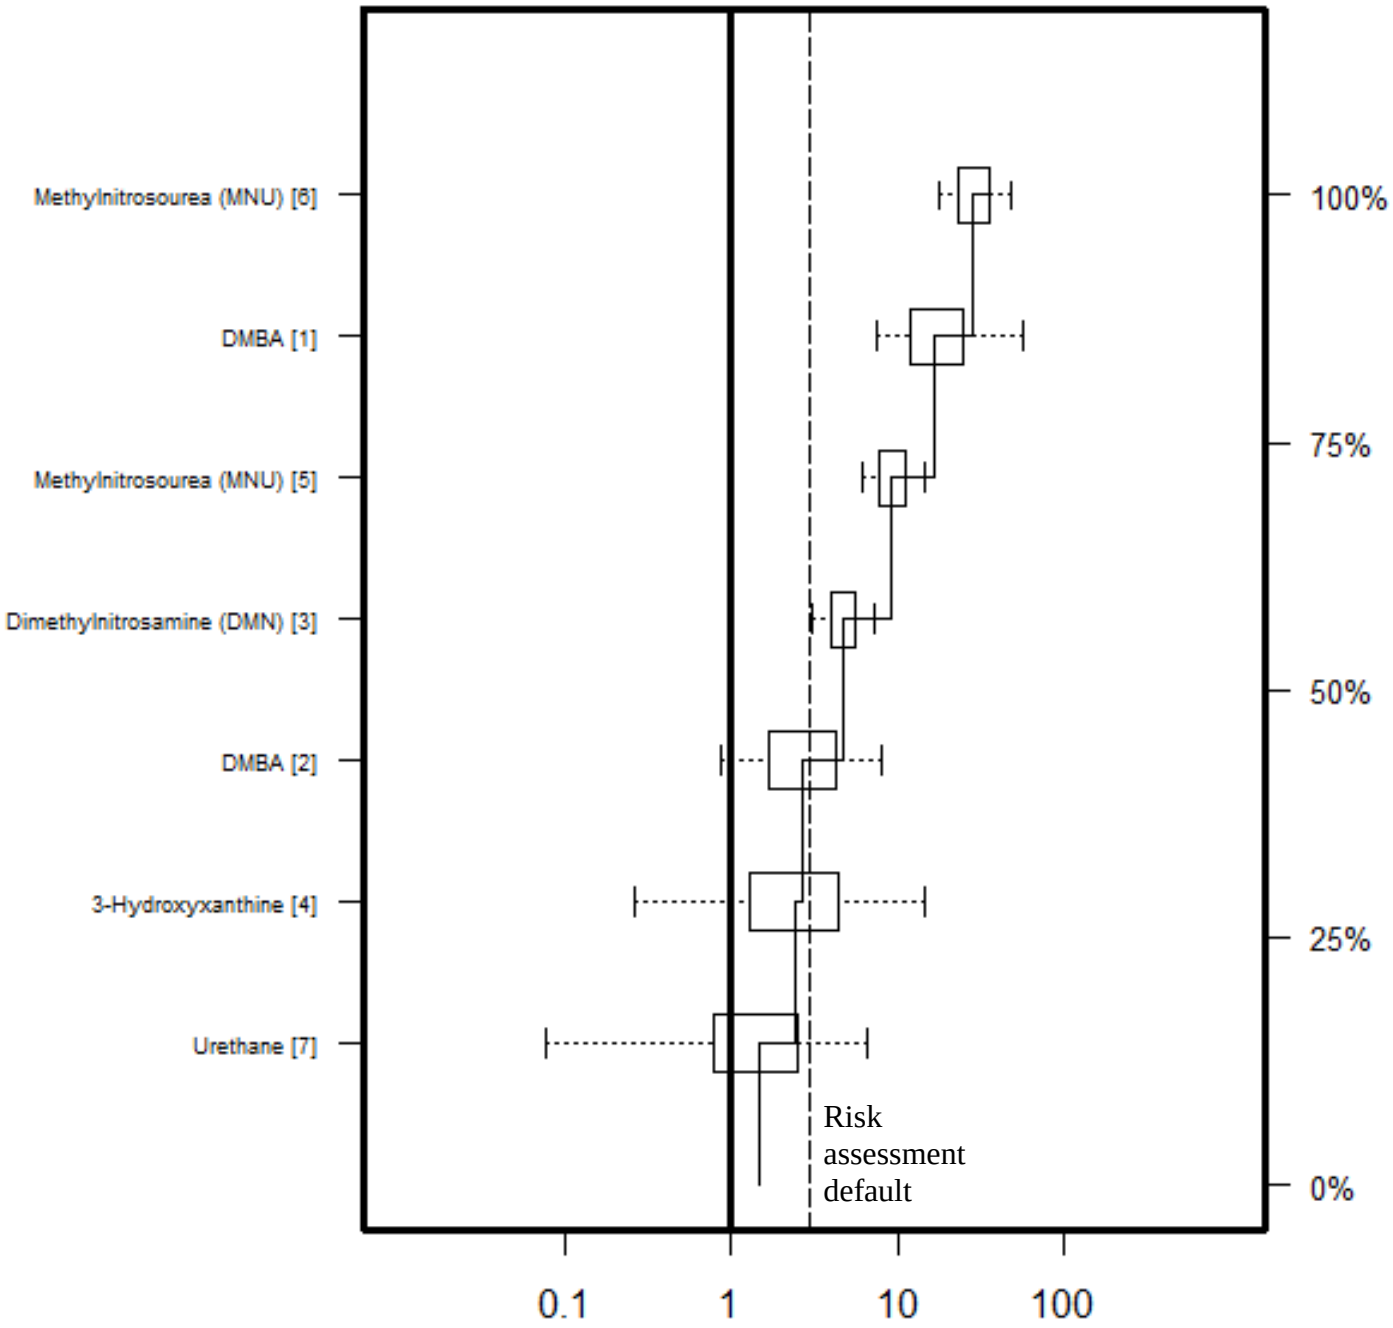
There were only five chemicals and seven studies, two of which were not independent, available to examine susceptibility in the juvenile period. The juvenile LP ratios indicated significantly greater susceptibility in this period for three independent studies, with the remaining studies consistent with equal inherent susceptibility to adult animals (see Figure 16 in Appendix J). Figure 9 below shows the ASFs from each of the juvenile multi-lifestage exposure studies, displayed as a cumulative frequency profile. The median of the juvenile ASF mixture distribution was 4.5 (see Table 8 in Appendix J).

Figure 9. Juvenile ASF Cumulative Frequency Profile



The median of the juvenile ASF mixture distribution is 4.5. The dotted line represents the default value for weighting risk for carcinogen exposures between 2 and 15 years of age (see next section).

The studies that comprise the set of multi-lifestage exposure studies available for these analyses were not homogeneous. That is, they do not represent observations from the same distribution. Sensitivity analyses were conducted to test the robustness of the findings to different procedures for analyzing data and combining results. Of the methods used to combine the LC ratio distributions for underlying studies within each lifestage, the method of equally weighting studies within a chemical appeared to best represent the available data.

In calculating the ASF, to take into account the longer period of time for early carcinogen exposures to result in tumors, the hazard function was assumed to increase with the third power of age. This assumption is standard and has been borne out by a number of observations (Bailer and Portier, 1988). If the true rate of increase with age is greater than that, then the use of these ASFs may result in underestimates of the true sensitivity of these early life stages.

As the multi-lifestage exposure and case studies show, there appears to be considerable variability in age-at-exposure related susceptibility across carcinogens. There is also variability in age-at-exposure related susceptibility among studies of the same carcinogen. The sources of variability evident in the analyzed studies include timing of exposure within a given age window, and gender, strain, and species differences in tumor response. The set of studies identified and analyzed was not sufficiently robust to fully describe the variability quantitatively. This variability raises concerns that selection of the median (the 50^{th} percentile) estimates may considerably underestimate effects for certain agents or population groups. Relatively large variability in humans in response to carcinogens is expected to be common (Finkel, 1995). On the other hand, the numbers of carcinogens represented in the available data are limited and may not be representative of the population of carcinogens to which we are exposed (*e.g.*, greater than 500 on the Proposition 65 list alone). Thus, the size of the weighting factors used to weight risk by age at exposure is a policy decision.

Several of the carcinogens studied induced tumors at multiple sites in the same experiment, and at different sites, depending upon the lifestage during which exposure occurred. For these cases the combined multisite potency distribution referred to above was the basis for the lifestage comparison. This approach differs from other researchers investigating early vs. late in life differences who focused on tumor site-specific measures of carcinogenic activity (*e.g.*, Barton *et al*., 2005; Hattis *et al*., 2004, 2005). OEHHA believes that use of combined multisite potency distributions provides a more complete approach for considering age specific differences in carcinogenic activity. However, the observation that early life is generally a period of increased

susceptibility was similarly found using the tumor site-specific approach by these other researchers.

One limitation of the approach was the focus on lifestages, without attempting to describe changes in susceptibility that occur within a lifestage. Timing of carcinogen exposure within a given age window can affect the cancer outcome. For example, experiments with 1-ethyl-1-nitroso-biuret in prenatal and adult rats showed a three-fold difference in activity between groups exposed on prenatal day -10 versus prenatal day -3. In a second example, female rats exposed early in the adult period were more than three times as sensitive to the breast cancer effects of MNU as females exposed six weeks later. In general, the adult comparison groups in the multi-lifestage exposure studies were fairly young. The extent to which this may result in an overall bias of the results presented here is unclear. Also, for several cases, juvenile animals were used as the later life exposure group. In these cases the ASFs are likely underestimates of the relative sensitivity of the prenatal and postnatal lifestages, compared to that of the adult lifestage.

Excluded from the analysis were early in life studies in which the period of exposure for a specific exposure group crossed multiple lifestages. An example of results from studies of this type is provided by mouse studies for two non-genotoxic carcinogens, diphenylhydantoin (Chhabra *et al*., 1993a) and polybrominated biphenyls (PBBs) (Chhabra *et al*., 1993b), in which exposures began prior to conception, and continued throughout the prenatal, postnatal, and post-weaning period, up to the age of eight weeks. The data demonstrate an increased sensitivity of the early life period. Some studies that crossed multiple lifestages were included in the analyses of Barton *et al*. (2005) (Appendix I), which are consistent with the general conclusions discussed above.

Selection of Default Age-Sensitivity Factors (ASF)

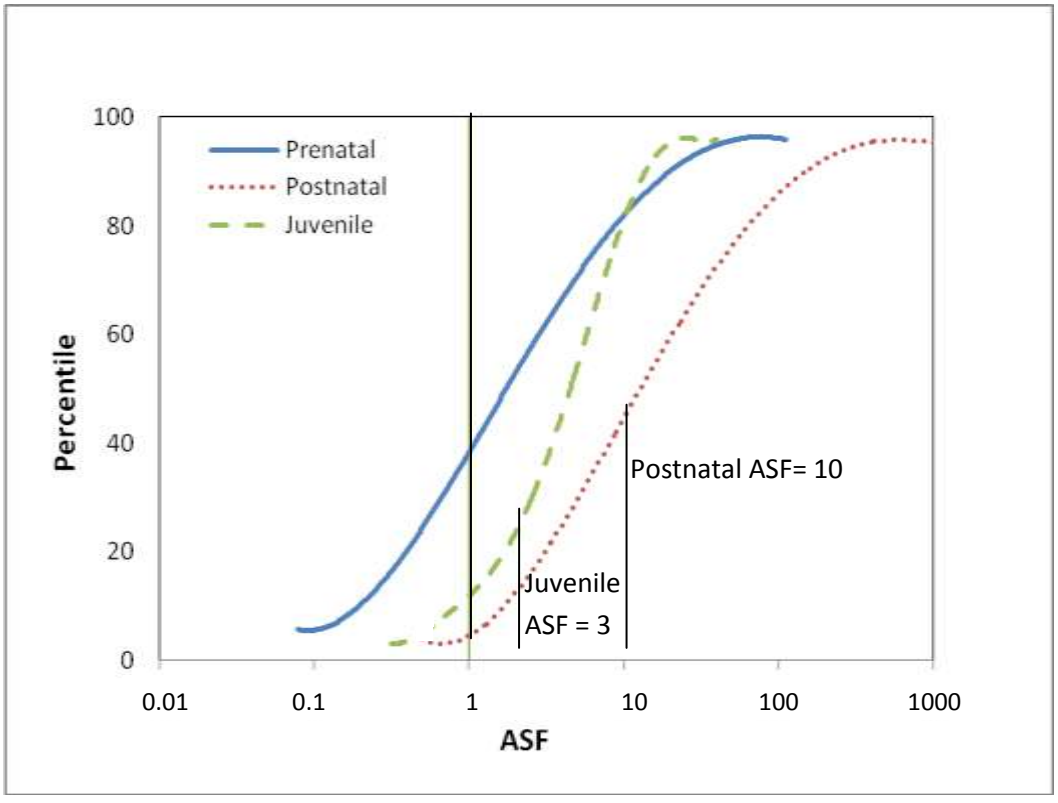
Selection of appropriate values to use to weight exposures that occur early in life using default ASFs for prenatal, postnatal and juvenile exposures is complicated by the limited database of chemicals and studies available for analysis, and the broad distribution of results for different chemicals as is shown in Figure 7, Figure 8, and Figure 9 (see also Appendix J). In view of the variability thus shown, and the considerable uncertainty in applying conclusions from this relatively small set of chemicals to the much larger number of chemicals of concern, it is probably unreasonable to specify a default ASF with greater than half-log precision (*i.e.* values of 1, 3, 10, 30 etc.). Further, rodents are born at a stage of maturity that approximates a third trimester human. Therefore, in the absence of chemical-specific data, OEHHA proposes to apply a default ASF of 10 for the third trimester to age 2 years, and a factor of 3 for ages 2 through 15 years to account for potential increased sensitivity to carcinogens during childhood. A factor of 10 falls just below the median estimate of the ASF for postnatal studies. This is also the value selected by U.S. EPA; while it is consistent with the OEHHA analysis, it may underestimate risk for some chemicals. The broad distribution of observed chemical-specific sensitivity ratios clearly indicates that there are some chemicals for which the sensitivity ratio is much larger than 10. Further research is needed to develop criteria for identifying these cases. Similarly, a factor of 3 for juvenile exposures is consistent with the range of estimates derived from the multi-lifestage exposure studies, and falls close to the median juvenile ASF estimate. It is acknowledged that there are few data available on which to base an estimate for the juvenile period. A factor of 3 adjusts for the longer time available for cancer to manifest, but may not

fully account for some inherent differences in susceptibility to cancer, for example the observed susceptibility of breast tissue of pubescent girls exposed to radiation. For specific carcinogens where data indicate enhanced sensitivity during lifestages other than the immediate postnatal and juvenile periods, or demonstrate ASFs different from the default ASFs, the chemical-specific data should be used in order to adequately protect public health.

The ASFs will be applied to all carcinogens, regardless of the theorized mode of action. While U.S. EPA currently intends to apply weighting factors only to those carcinogens with "a mutagenic mode of action" (U.S.EPA, 2005), OEHHA notes that there is evidence that early life is a susceptible time for carcinogens that are thought to act via non-mutagenic mode of action (DES is a prime example). Defining a mutagenic mode of action may be problematic if approached narrowly (ERG, 2008). Further, carcinogens may have multiple modes of action and one mode may predominate over other modes at different lifestages. The complexity of carcinogenesis argues against restricting the ASF to chemicals acting via a mutagenic mode of action.

Figure 10 provides a visual comparison of the ASF mixture distributions for the three early-life stages, prenatal, postnatal, and juvenile. In this figure, which is in log space, the policy choice of an ASF of 10 for exposures during the third trimester to age 2 years and 3 for the period of life from 2 to 15 years of age are indicated as vertical lines. It is apparent from this figure that weighting risk from exposures to carcinogens early in life is well-supported.

Figure 10. Prenatal, Postnatal, and Juvenile ASF Mixture Distributions and relation to default ASFs



OEHHA recognizes the limitations in the data and analyses presented, as discussed above. However, the analyses do provide some guidance on the extent to which risk may be over or underestimated by current approaches. While there is a great deal of variability across chemicals in the prenatal ASFs, the data indicate that the potency associated with prenatal carcinogen exposure is not zero. A factor of 3 is close to the median ASF, while a factor of 10 falls roughly at the 70th percentile of the prenatal ASF estimate. An ASF could be applied as a default when calculating lifetime cancer risk in humans arising from carcinogen exposures that occur *in utero*. In view of the considerable variability in the data for different carcinogens and the limited database available for analysis, OEHHA is not proposing the application of a specific factor to cancer potency estimates for prenatal exposures in the first and second trimesters as a default position in these Guidelines. However, given that the rodent is born at a stage of maturation similar to a third trimester fetus, it is reasonable to include the third trimester in the 10X potency weighting proposed up to age 2 years. The applicability of a cancer potency adjustment factor for first and second trimester prenatal exposure will be evaluated on a case-by-case basis, and may be used as evidence develops that supports such use. The consideration of prenatal exposures, including application of an appropriate susceptibility factor, would not make a large difference for risk estimates based on continuous lifetime exposures, due to the relatively short duration of gestation. However, risk estimates for short-term or intermittent exposures would be slightly increased by inclusion of the risks to the fetus during the prenatal period. Thus, risk may be underestimated when the first and second trimesters are excluded from the analysis.

Age Bins for Application of ASFs

The choice of human ages to which the ASFs apply is based on toxicodynamic and toxicokinetic considerations. Important toxicodynamic factors related to susceptibility to carcinogens include the rate of cellular proliferation and differentiation, which is quite high during organ maturation. In addition, toxicokinetic differences by age are important, due to impacts on detoxification and clearance of carcinogens (see following section). OEHHA's analysis of the influence of age-at-exposure on carcinogenesis broke the experimental rodent data into age bins that we termed "lifestages" including prenatal, "postnatal" (birth to weaning, about day 21) and "juvenile" (weaning to sexual maturation, or about day 22 to about day 49). Experiments were placed into the lifestage bins if exposure occurred at some time during the experimental rodent age bin.

There is no simple way to compare the rodent age groups used in the OEHHA analysis of available data to equivalent age groups in humans. Complicating factors include variations in organ system structural and functional maturation both within and between species. Further, the rodent age bins were chosen by gross indicators of development namely birth, weaning and sexual maturation, not on the basis of known susceptibility to carcinogenesis. Thus, critical factors relating to carcinogen susceptibility by age are the focus of the choice of human age bins to which the ASFs of 10 and 3 apply, rather than an attempt at exact correlation of rodent lifestage bin with human age.

The investigations used by OEHHA to evaluate the relationship between age at exposure and cancer potency were not conducted by standardized protocol. Further, the windows of susceptibility are quite varied by chemical and organ system, even within the lifestages defined in the OEHHA analysis. This complicates choosing a default ASF and the human age bin to which it applies. Examples from animal studies provided in Appendix J include the chemical

diethylnitrosamine (DEN). The cancer potency varied over several orders of magnitude depending on when during gestation and postnatal life the exposure occurred. A three-fold difference in potency between exposure on prenatal day -3 and prenatal day -10 is noted for 1-ethyl-1-nitrosobiuret in rats. There are also human examples of extensive variation of potency by age at exposure, including radiation, DES, and chemotherapeutic agents. The diversity of responses to different agents obviously underscores uncertainty in the choice of age bins to apply the default ASFs. However, the ASFs are a ***default*** to use when you have no chemical-specific data on influence of age-at-exposure on potency in order to protect public health. There will always be specific chemical examples where the ASF for either the third trimester-<2 yrs or 2-<16 yrs age bin is quite a bit larger or quite a bit smaller than the default.

In the following sections, we discuss our logic in proposing age bins of third trimester to age 2 years, and 2 to age <16 years to which the ASFs of 10 and 3 apply, respectively, and indicate the impact on risk estimates of these age bins.

Toxicokinetic Factors Relevant to Age Bins

Choice of the age-bins to which the default ASFs are applied is based on our understanding of the two primary drivers of age-related sensitivity to carcinogens, namely age-related toxicokinetic factors and toxicodynamic factors. In the case of toxicokinetics, the largest postnatal differences in xenobiotic metabolic capability occur between infants and adults. As noted in OEHHA (2001) and reviewed in detail elsewhere (*e.g.*, Cresteil et al., 1998; Ginsberg et al., 2004), hepatic drug metabolism by the cytochrome P-450 family of enzymes and the Phase II conjugating enzymes undergoes a maturation process during the first few years of life. The hepatic cytochrome P-450 enzymes exist in fetal isoforms at birth, and progressively change to adult isoforms at a relatively early stage of postnatal development. Thus, in humans the metabolic capability towards prototypical substrates develops over the first year of life towards adult levels. Similarly, the largest differences in metabolic capability of Phase II enzymes (conjugation of xenobiotic metabolites prior to excretion) tend to be between infants and adults. Other factors such as renal capability also are most different between neonates and adults. Thus, the first 2 years of life would encompass the increased sensitivity of early life stages due to toxicokinetic differences between early life and adulthood.

Ontogeny of Cytochrome P-450 Enzymes in Humans.

Cresteil (1998) describes three groups of neonatal cytochrome P-450: Cyp3A7 and Cyp4A1 present in fetal liver and active on endogenous substrates; an early neonatal group including Cyp2D6 and 2E1 which surge within hours of birth; and a later developing group, Cyp3A4, Cyp2Cs, and Cyp1A2. Total Cyp 3A protein, a major cytochrome P-450 enzyme responsible for biotransformation of many xenobiotics, is relatively constant in neonates and adults. However, Cyp3A7 is the primary fetal form (Hakkola et al., 1998), while Cyp3A4 is the primary adult hepatic form of the 3A series. At one month Cyp3A4 activity is about one-third of that in the adult liver (Lacroix et al., 1997; Hakkola et al., 1998). Allegaert *et al*. (2007) stated that Cyp3A4 (testosterone-6ß-hydroxylase) activity equaled or exceeded adult activity after 1 year of age. Cyp2E1, which metabolizes benzene, trichloroethylene and toluene, among others, increases gradually postnatally, reaching about one-third of adult levels by one year of age and attains adult levels by 10 years of age (Vieira et al., 1996; Cresteil, 1998). Cyp1A2, and Cyp2C9 and

2C19, the most abundant Cyp2 enzymes in adult human liver, appear in the weeks after birth, and reach 30% to 50% of adult levels at about 1 year of age (Treluyer et al., 1997; Hines and McCarver, 2002). Cyp1A1 is expressed in fetal liver where it can activate such xenobiotics as benzo[a]pyrene and aflatoxin B1 (Shimada et al., 1996), but is less important in adult liver (Hakkola et al., 1998).

Ontogeny of Cytochrome P-450 Enzymes in Rodents.

Hart et al. (2009) report developmental profiles of a number of cytochrome P-450 enzymes (measured as levels of mRNA transcripts of the specific genes) in mice. They identified three groups of isoforms. Group 1 (Cyp3A16 in both sexes; Cyp3A41b in males) appeared rapidly after birth but declined to essentially zero at 15-20 days, which is the period of weaning in mice. A second group (Cyp2E1, Cyp3A11 and Cyp4A10 in both sexes; Cyp3A41b in females) also increased rapidly after birth, but reached a stable maximal level by postnatal day 5. The third group (Cyp1A2, Cyp2A4, Cyp2B10, Cyp2C29, Cyp2D22, Cyp2F2, Cyp3A13 and Cyp3A25) were expressed only at low levels until days 10 to 15, but reached high stable levels by day 20.

ElBarbry et al. (2007) examined the developmental profiles of two toxicologically significant cytochrome P-450 enzymes, Cyp1A2 and Cyp2E1 in rats. mRNA transcripts of these genes were very low postnatally, but thereafter increased to reach a peak at or shortly after weaning (postnatal day 21 - 28 for rats). Immunoreactive Cyp1A2 and Cyp2E1 proteins were first detectable at postnatal day 3 and reached 50% of adult levels at weaning and adult levels at puberty. Differences in profiles between gene expression as mRNA and appearance of specific proteins as determined by immunoassay may reflect changes in the relative importance of transcription and translation control processes at various phases in development. Enzyme activities characteristic of Cyp1A2 and Cyp2E1 were found to parallel gene expression levels (ElBarbry et al., 2007) rather than immunodetectable protein levels, so there may also be issues of cross-reactivity between these two isoenzymes and others for which gene expression was not measured in these experiments.

In summary, the gene expression data in rats and mice show differences in details, but broadly resemble one another in that the main changes occur in the early postnatal period, with the major adjustments completed at or around the time of weaning, although the adult pattern may not be completely established until puberty. There do not appear to be substantive data for experimental species other than rats and mice, although the situation in humans appears similar in general outline and one may conclude that this pattern or some variant of it is characteristic of mammalian species in general.

Ontogeny of Phase II Enzymes

Phase II conjugating enzymes are generally less active in the neonate than the adult (Milsap and Jusko, 1994). Hence, there is concern that detoxification and elimination of chemicals is slower in infants. In humans, expression of some of the UGT enzymes matures to adult levels in two months after birth, although glucuronidation of some drugs by the UGT1A subfamily does not reach adult levels until puberty (Levy et al., 1975; Snodgrass, 1992; McCarver and Hines, 2002). Reduced glucuronidation in neonates slows the clearance of *N*-hydroxyarylamines, phenol, and benzene metabolites. Acetylation by the N-acetyltransferases and sulfation by sulfotransferases

are generally somewhat comparable to adult levels, although it varies by tissue and by specific sulfotransferase (McCarver and Hines, 2002). Human glutathione sulfotransferase (GST) is present as a fetal isoform which decreases postnatally, while GST-alpha and GST-mu increase over the first few years of life to adult levels (McCarver and Hines, 2002). Epoxide hydrolase, important in detoxifying reactive epoxide metabolites, is present in neonatal liver although at much reduced activity relative to adults (McCarver and Hines, 2002).

Clearances of Drugs in Infants and Children *vs.* Adults

Several investigators have evaluated age-related drug disposition (Renwick, 1998; Renwick et al., 2000; Ginsberg et al., 2002; Hattis et al., 2003). Renwick et al. (2000) noted higher internal doses in neonates and young infants versus adults for seven drugs that are substrates for glucuronidation, one with substrate specificity for CYP1A2, and four with substrate specificity for CYP3A4 metabolism. Ginsberg et al (2002) evaluated toxicokinetic information on 45 drugs in children and adults metabolized by different cytochrome P-450 pathways, by Phase II conjugations, or eliminated unchanged by the kidney. These authors noted half-lives 3-9-fold longer in infants than those in adults. It was also shown that the bulk of the elevated child/adult half-life ratios occurred primarily in the 0 to 6 month age range, and that for some compounds the clearance is actually higher in the 6 month to 2 year age grouping. In evaluating the interindividual variability by age, Hattis et al (2003) note that the largest interindividual variability occurs in the youngest children, apparently due to variability in development of critical metabolism and elimination pathways. Anderson and Holford (2008) noted that a comparison of three early-life drug clearance models (surface area, allometric ¾ power and per kilogram scaling) all demonstrated an increase in clearance over the first year of life due to the maturation of metabolic capacity.

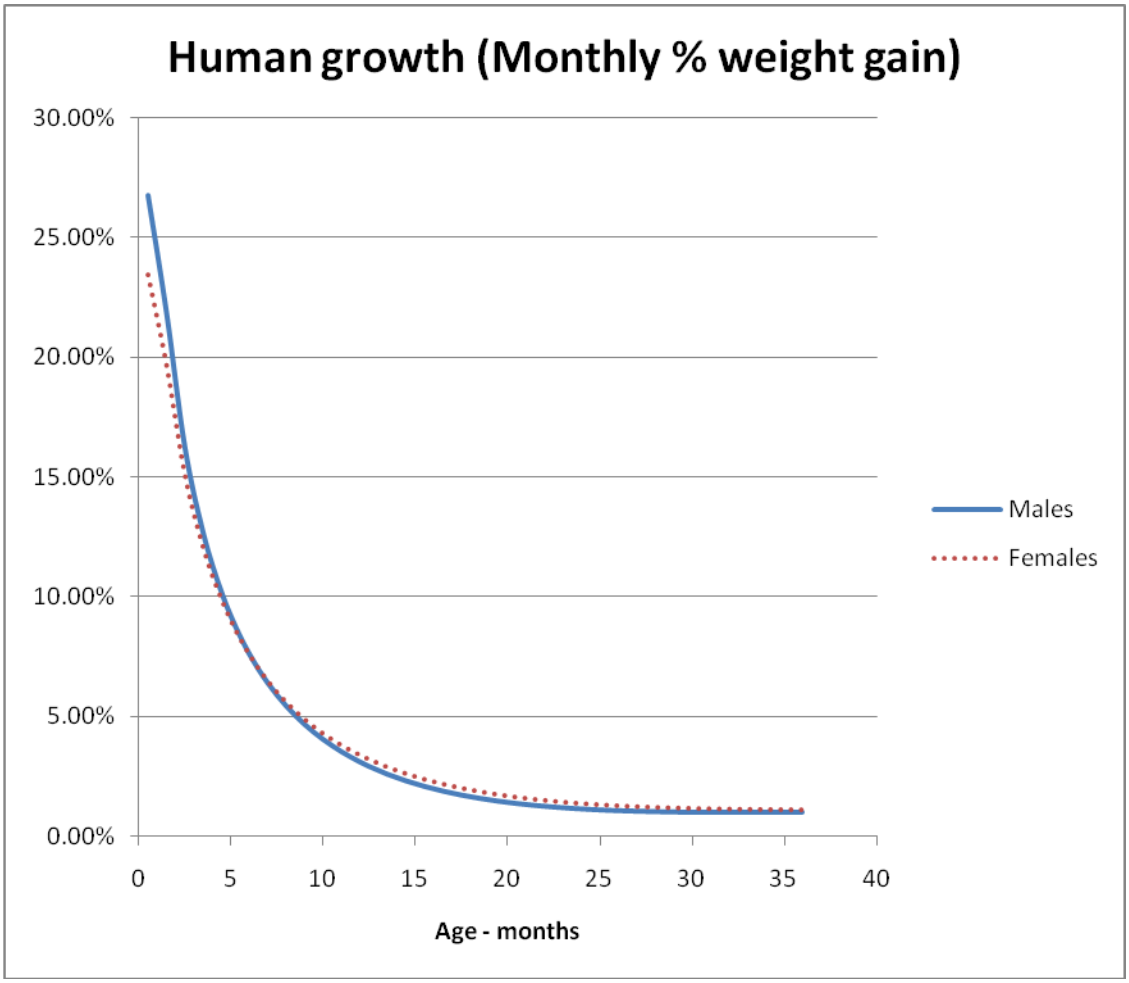
Renal elimination depends on maturity of processes related to tubular reabsorption and secretion, and glomerular filtration rates. At birth, the glomerular filtration rate (GFR) is low (2-4 ml/min), increases in the first few days (8-20 ml/min) and slowly increases to adult values in 8-12 month old infants (Plunkett et al., 1992; Kearns et al, 2003).

Newborn and young animals have less capacity to excrete chemicals into the bile than do adult animals. A number of chemicals are excreted more slowly via bile in neonates than adult rats, including ouabain, the glucuronide conjugate of sulfobromophthalein (Klaassen, 1973), and methyl mercury (Ballatori and Clarkson, 1982), resulting in a longer half-life in neonates.

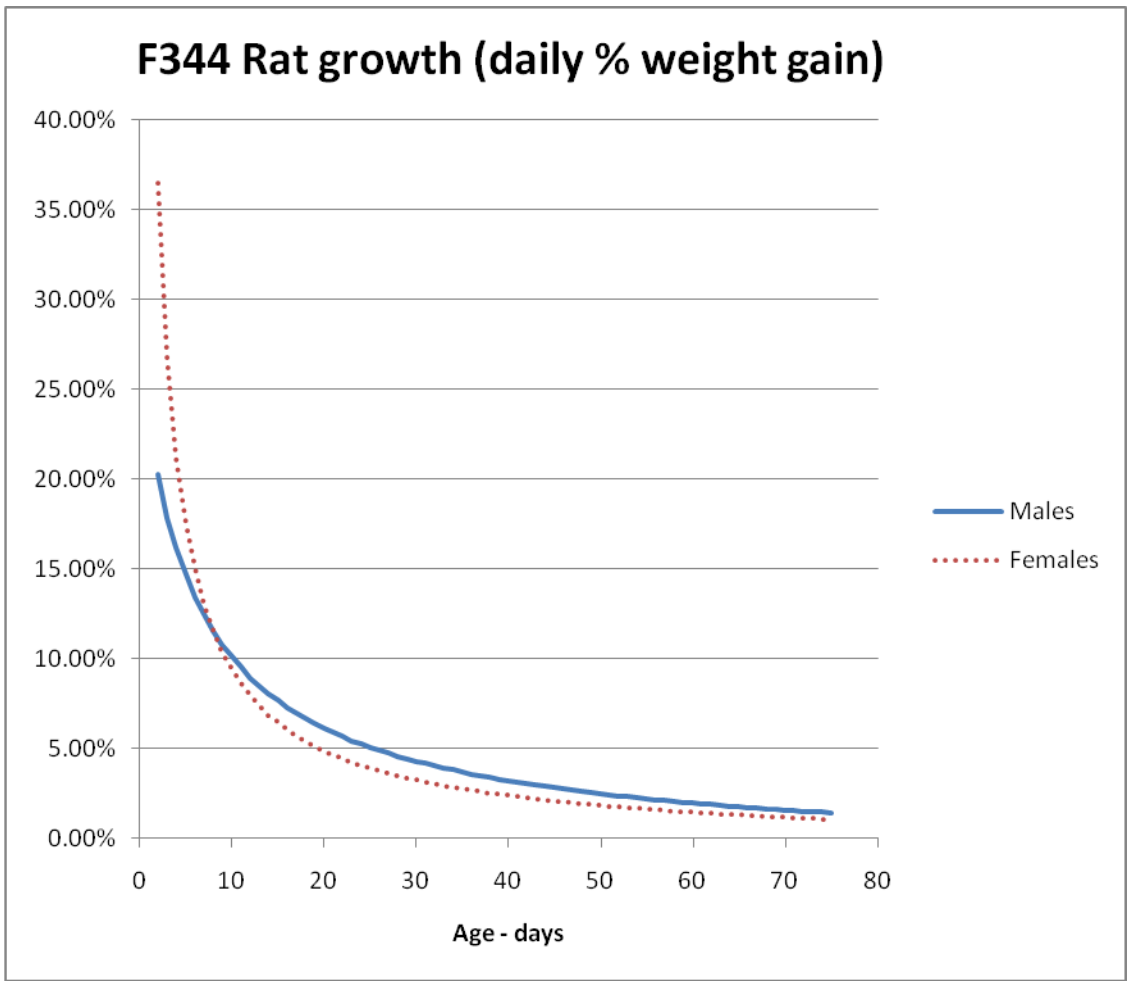
Toxicodynamic Factors Relevant to Age Bins

Important as the developmental changes in toxicokinetics are in determining sensitivity to carcinogens and other toxicants, it is likely that the toxicodynamic differences, *i.e.* intrinsic differences in susceptibility to carcinogenesis at the tissue or cellular level, are even more influential. Changes in cell division rates and differentiation, which are thought to be important toxicodynamic determinants of susceptibility to carcinogenesis, peak in the first 2 years of life for most major organ systems. Cell division continues to accommodate growth throughout childhood and adolescence, extending in some cases even into the young adult period in both humans and experimental animals. Adolescence is an important period for organ cell division and differentiation for the mammary gland and reproductive organs.

As noted above, one of the key factors influencing susceptibility to carcinogenesis is believed to be cell division rate, which acts both by forcing error-prone repair which fixes DNA damage as mutated gene sequences (McLean et al, 1982) and by promoting expansion of mutated clones (Moolgavkar and Knudson, 1981). Actual cell division rates as a function of age are hard to determine for practical and (in the human case) ethical reasons. However, growth curves expressed as the proportional increment in body weight with time may be regarded as a reasonable although not perfect surrogate since for most tissues of the body cell size does not change markedly during growth. Both humans and rodents show remarkably high growth rates in infancy, which then drop steeply to a lower but still significant rate during childhood. A growth spurt at the beginning of adolescence is noticeable in its absolute magnitude, especially in males, but does not approach the proportional growth rate seen in infancy. The time intervals proposed to reflect the period of highest sensitivity to carcinogenesis (up to about 21 days in rodents, up to 24 months in humans) encompass the period of highest growth rate and thus it is assumed the highest cell division rates, as show in the following charts:



Data from CDC NHANES 2000:
http://www.cdc.gov/nchs/about/major/nhanes/growthcharts/datafiles.htm



Data from Tables A3 and A4 of Appendix J

Cell division rates in adult rodents and humans are harder to relate to growth curves since at least some tissues retain active cell division as part of their ongoing functionality and repair. In humans growth in body weight slows to essentially zero at the end of adolescence (and any later increments represent tissue specific changes such as increase in muscle or adipose tissue mass rather than overall growth). On the other hand, rodents continue to increase in body size (at a modest rate compared to that seen in earlier lifestages) throughout the adult period. However, it appears reasonable to conclude from the body weight data that an essentially adult pattern of overall cell division is established by the late adolescent period (age six weeks in rodents; 16 years in humans). However, increased cell division and cell differentiation are seen in the reproductive system and its accessories during puberty.

Organ Development

The age intervals chosen for the ASFs are generally supported by human organ system development data. Examples of supporting data are available for the lung, brain, immune system and liver. Zeltner and Burri (1987) stated that postnatal lung development consists of an alveolar stage, which lasts to about 1-1.5 years of age, and a stage of microvascular maturation, which exists from the first months after birth to the age of 2-3 years. Pinkerton and Joad (2006)

describe alveolar proliferation as occurring most prominently in the 0-2 year age range, with alveolar expansion continuing in the 2-8 year age range. Ballinoti et al. (2008) demonstrated that addition of alveoli rather than expansion is a major mode of lung growth in infants and toddlers by measuring a constant carbon monoxide diffusion capacity to lung volume from 3 through 23 months of age. Kajekar (2007) also considered the 0-2 age range to be the primary period of alveolar development, although there is continued cellular proliferation resulting in lung growth and expansion up to approximately 18 years of age.

Rice and Barone (2000) note that most of the cell proliferation phase of human radial glia and neuronal growth is finished by 2 years of age, based on evidence in Bayer et al. (1993). They note further that numerous studies have shown actively proliferating brain regions are more susceptible to anti-mitotic agents than the same structures after active proliferation ceases. Peak brain growth as a percentage of body weight occurs at birth and around post-natal day (PND) 7-8 in humans and rats, respectively (Watson *et al*., 2006). De Graaf-Peters and Hadders-Algra (2006) reviewed the ontogeny of the human central nervous system and found that a large amount of axon and dendrite sprouting and synapse formation and the major part of telencephalic myelination take place during the first year after birth. While the brain continues to remodel itself throughout life, cellular proliferation in the whole brain peaks by about one year of age and is relatively complete by age 2. Development of the blood-brain barrier (BBB) appears to continue in humans until approximately 6 months of age. Rat BBB functionality is essentially complete by approximately two weeks after birth (Watson *et al*., 2006).

The immune system development occurs in stages, primarily prenatally in primates and both pre- and post-natally in rodents (Dietert et al., 2000). Formation and expansion of hematopoetic stem cells is followed by expansion of lineage-specific stem cells, colonization of bone marrow and thymus, and maturation of cells to immunocompetence. In the primate, this is largely complete by 1 to 2 years of age (Holsapple et al., 2003), although establishment of immune memory develops throughout childhood and beyond. In the rodent, maturation to immunocompetence occurs postnatally from birth to about 30 days of age. In terms of carcinogenesis, perhaps one of the more important immune cells is the NK cell, thought to be responsible for immune surveillance and killing of circulating transformed cells. Based on immunohistochemistry, the principal cell lines including NK cells are present at gestation day 100 in the monkey and are at about 60% of adult values at birth (Holladay and Smialowicz, 2000).

As noted above, renal and hepatic clearance are both lower in humans at birth than in adults. Nephrogenesis is complete by 35 weeks gestation in humans and before birth in the mouse (but after birth in the rat). The ability to concentrate urine and the development of acid-base equilibrium appear in the first few months after birth (Zoetis and Hurtt, 2003). Renal clearance of drugs, a function of a number of processes in the kidney, appears to be comparable to adults within the first few months of life (Hattis et al., 2003; Ginsberg et al., 2002), while glomerular filtration, which rises rapidly over the first few postnatal months, is at adult values by two years of age (Zoetis and Hurtt, 2003). While complete anatomic maturity of the human liver is noted by 5 years of age (Walthall et al, 2005), liver function also appears to mature within the first year of life as seen by drug clearance studies cited above.

Critical Windows of Susceptibility to Carcinogens

It has been shown that there are critical windows during development both pre-and postnatally where enhanced susceptibility to carcinogenesis occurs (Anderson et al, 2000). Some of these observations relate to factors affecting the incidence of cancers in childhood, resulting from prenatal or preconception mutational events. For example, prenatal exposure to ionizing radiation and DES can result in leukemia and vaginal carcinoma, respectively, in childhood. Although obviously a source of great concern, these cancers appearing during childhood are relatively rare compared to cancers appearing later in life. Thus the concern in risk assessment for early in life exposures is to address the lifetime cancer incidence as a result of these exposures, including both cancers appearing during childhood and those appearing later.

OEHHA (see Appendix J) and other investigators (U.S. EPA, 2005; Barton et al, 2005; Hattis et al., 2004) have examined the available rodent data on sensitivity to carcinogenic exposures early in life. All these investigators found substantial increases in sensitivity to carcinogens in animal studies where exposures to young animals were compared to similar exposures to adults. Hattis et al. (2004) reported maximum likelihood estimates for the ratio of carcinogenic potency during the period from birth to weaning to the adult potency of between 8.7 and 10.5, whereas Barton et al (2005) reported a weighted geometric mean of 10.4 for the ratio of juvenile (less than 6-8 weeks) to adult potency in rodents. However, the number of experiments which provide information of this type, and the carcinogenic agents which have been studied, are relatively limited. Hattis examined several different datasets and study designs, but these covered only 13 different chemicals, while the mean value reported by Barton et al. was based on only six of the 18 chemicals which they examined. OEHHA's analysis included data in rodents on 23 chemicals, and found median potency ratios of 13.5 for the postnatal period (birth to day 22) and 4.5 for the juvenile period (postnatal days 22 to ~49) relative to adults (day ~49 to 2 years). These potency ratios include the adjustment for time to manifest tumor (*e.g.*, age to the power of three), unlike the earlier investigations. All these investigations identified variations in the observed lifetime potency ratio depending on the type of experimental design, the sex of the animals, the time of exposure and especially between chemicals. Nevertheless these analyses, although falling far short of a comprehensive evaluation of the age dependence of carcinogenic potency for all the chemicals of interest, do show a consistent overall trend of increasing potency for exposures early in life, especially soon after birth.

An evaluation of cancer induction by ionizing radiation also provides support for the concept of enhanced sensitivity to carcinogenesis at younger ages. Various studies of this phenomenon have been undertaken in animal models, but the important point for the present discussion is that epidemiological data exist which indicate age-dependent sensitivity in humans (U.S. EPA, 1994; 1999). The most extensive data set showing age-dependent effects is that for Japanese survivors of the atomic bomb explosions at Hiroshima and Nagasaki. Analysis of these data shows linear increases in tumor incidence at a number of sites with increasing radiation dose and younger age at exposure. There are other data suggesting humans are more susceptible to chemical carcinogens when exposure occurs in childhood. These data exist for tobacco smoke (Marcus et al., 2000; Wiencke et al., 1999) and chemotherapy and radiation (Mauch et al., 1996; Swerdlow et al., 2000; Franklin et al., 2006).

Proposed Age Bins for Application of Default Age Sensitivity Factors

In developing a default science-based risk assessment policy to address this general conclusion, one key variable to define is the age interval or intervals over which age-dependent sensitivity factors should be applied. Different investigators have considered different age ranges, but in general the more sensitive period has at least been defined as including the time from birth up to mid-adolescence when the major phases of growth and hormonal change are complete. It is also recognized that, apart from the dramatic prenatal developmental events, the earliest postnatal stages represent the greatest differences in physiology and biochemistry from the adult. This reflects the immaturity of many organ systems, extremely rapid growth, and the incomplete maturation of various metabolic capabilities. As noted earlier, the rodent age bins in OEHHA's analysis were based on gross developmental milestones (birth, weaning, sexual maturity). OEHHA's analysis of studies that included exposure sometime between birth and weaning indicated this period as having the highest sensitivity to carcinogenesis. The data for the later juvenile period (postnatal days 22 to ~ 49) are somewhat sparse, covering only three carcinogens and only one where there are corresponding data for both postnatal and juvenile lifestages. However, it appears based on the overall range of potency ratios observed for the juvenile period that sensitivity to many carcinogens is elevated in this period also, but to a lesser extent than during the first 22 days. [Hattis et al. (2005) and Barton et al. (2005) report analyses for exposures at any time during the juvenile period, i.e. up to 6-8 weeks, and do not separate by additional age bins].

Weaning is not such an obvious or consistently timed transition for humans, being subject to a wide range of cultural and economic variables. However, it is generally considered that the human infant period encompasses the first two years of life. This period includes the most rapid periods of cellular division and differentiation for the major organ systems (excluding the breast and reproductive organs). Although there is linear growth between 2 and 8 years of age, the organ development is largely although not entirely complete.

Thus, considering both the development of major organ systems and the associated differences in toxicodynamic and toxicokinetic factors, OEHHA initially proposed to apply the postnatal ASF derived from rodent studies (birth to 21 days) to the human age intervals of birth - < 2 years. Similarly, OEHHA chose to apply the "juvenile" ASF derived from rodent studies (22 - ~49 days) to the human ages 2 - < 16 years. This timetable was also selected by U.S. EPA (2005) in their supplemental guidance for assessing early-life susceptibility to carcinogens. They describe their choice of critical periods as follows:

> "The adjustments described below reflect the potential for early-life exposure to make a greater contribution to cancers appearing later in life. The 10-fold adjustment represents an approximation of the weighted geometric mean tumor incidence ratio from juvenile or adult exposures in the repeated dosing studies (see Table 8). This adjustment is applied for the first 2 years of life, when toxicokinetic and toxicodynamic differences between children and adults are greatest (Ginsberg et al., 2002; Renwick, 1998). Toxicokinetic differences from adults, which are greatest at birth, resolve by approximately 6 months to 1 year, while higher growth rates extend for longer periods. The 3-fold adjustment represents an intermediate level of adjustment that is applied after 2 years of age through <16 years of age. This upper age limit represents middle adolescence following the

period of rapid developmental changes in puberty and the conclusion of growth in body height in NHANES data (Hattis et al., 2005). Efforts to map the approximate start of mouse and rat bioassays (i.e., 60 days) to equivalent ages in humans ranged from 10.6 to 15.1 years (Hattis et al., 2005)."

There is general agreement that rodents are born at a maturational stage approximately equivalent to a third trimester human fetus. Thus, there is good rationale to include the third trimester of pregnancy in the age bin for application of the ASF of 10. Therefore, OEHHA is applying the ASF of 10 for exposures during the third trimester of pregnancy to age 2. The default ASF values used by OEHHA are summarized in Table 2.

While there is strong evidence that growth and therefore cell proliferation rates and cell differentiation are extremely high prior to age 2, and lower (although still elevated relative to the adult) thereafter, there is still residual uncertainty with respect to the cut point for application of the ASFs of 10 and 3. Thus, another possible approach would be to move the cut point for the application of the ASF of 10 to a later age to account for this uncertainty. We present the effect on risk estimates of varying cut points in Table 3 and Table 4.

Table 2. Default Age Sensitivity Factors to be used to estimate cancer risks to infants and children

R (third trimester to age 2yrs)	10
R (age 2 to age 16 yrs)	3
R (age 16 to 70 yrs)	1

Application of ASFs in Risk Assessment

The effect of using the proposed default ASFs in calculating cancer risk over a 70 year lifetime, and for a 9 year exposure common in the Hot Spots program risk assessments is demonstrated in Table 3 and Table 4 below. Ignoring for the moment the increased exposures to carcinogens that children experience, the effect of the weighting factors is to increase the lifetime cancer risk by about 2. For risks from shorter exposures, such as the commonly used 9 year exposure scenario, OEHHA proposes to evaluate risk from exposures starting at the third trimester in the surrounding general population. The weighting factors in this case increase the risk to a larger extent. Depending on the exposure scenario, the use of age-specific distributions for uptake rates for air, food and water would also increase the risk estimates significantly independent of any application of ASFs. This is because the uptake rates for all these media per unit of body weight are higher in children and, especially, infants.

Assessing risks to short-term exposures to carcinogens involves additional uncertainties. The cancer potency factors are generally based on long-term exposures. However, in reality, the local air districts in California are frequently assessing risk from short term activities related to construction, mitigation of contaminated soils, and so forth. OEHHA recommends that when assessing such shorter term projects, the districts assume a minimum of 2 years of exposure and apply the slope factors and the 10 fold ASF to such assessments. Exposure durations longer than 2 years would use the method for the remaining years as noted above.

Table 3. Example of default ASF use for a lifetime exposure (not adjusted for age-specific exposure)

Carcinogen Potency = 1 $(mg/kg\text{-}d)^{-1}$
Exposure = 0.0001 mg/kg-d
No consideration of differences of exposure

No adjustment: Lifetime Risk = potency × dose			Risk
70 year Lifetime risk = 1 × 0.0001			**1.0×10^{-4}**

With proposed default ASF of 10 for third trimester to age 2, and 3 for ages 2 to 16 years: LR = Σ (potency x dose x ASF x fraction of lifetime)	ASF	Duration	Risk
R (third trimester to age 2yrs)	10	2.25/70	0.321×10^{-4}
R (age 2 to age 16 yrs)	3	14/70	0.600×10^{-4}
R (age 16 to 70 yrs)	1	54/70	0.771×10^{-4}
70 year Lifetime Risk			**1.7×10^{-4}**

For comparison, if ASF of 10 were applied to age 5, and ASF of 3 for the ages 5 to 16 years: LR = Σ (potency x dose x ASF x fraction of lifetime)	ASF	Duration	Risk
R (birth to age 5)	10	5.25/70	0.750×10^{-4}
R (age 5 to 16 yrs)	3	11/70	0.471×10^{-4}
R (age 16 to 70 yrs)	1	54/70	0.771×10^{-4}
70 year Lifetime Risk			**2.0×10^{-4}**

Table 4. Example of default ASF use for a 9-year exposure

Carcinogen Potency = 1 $(mg/kg\text{-}d)^{-1}$
Exposure = 0.0001 mg/kg-d
No consideration of differences of exposure

No adjustment: Total Risk = potency × dose x fraction of lifetime		Duration	Risk
9-year Total Risk		9/70	**0.13×10^{-4}**
With default ASF of 10 for third trimester to age 2 and 3 thereafter: LR = Σ (potency x dose x ASF x fraction of lifetime)	ASF	Duration	Risk
R (third trimester to age 2yrs)	10	2.25/70	0.321×10^{-4}
R (age 2 to 9 yrs)	3	7/70	0.300×10^{-4}
9 year Total Risk			**0.62×10^{-4}**
For comparison, if ASF of 10 applied to age 5, and ASF of 3 thereafter: LR = Σ (potency x dose x ASF x fraction of lifetime)	ASF	Duration	Risk
R (birth to age 5 yrs)	10	5/70	0.750×10^{-4}
R (age 5 to 9 yrs)	3	4/70	0.171×10^{-4}
9 year Total Risk			**0.92×10^{-4}**

Special Consideration of Puberty

In addition to the general concerns over increased sensitivity to carcinogenesis during infancy and childhood, there are specific concerns for exposure during the period when hormonal and developmental changes associated with puberty are in process, especially for carcinogens with hormonal modes of action or with impacts on the reproductive system and its accessory organs. At puberty, there is increased development of breast and reproductive organs that clearly involves rapid cellular division and differentiation. Thus, for carcinogens that induce mammary and reproductive organ cancers, puberty represents a time of increased sensitivity. As noted in the section on Selection of Default Age-Sensitivity Factors (page 50), if the risk assessor is evaluating a chemical with the potential for more than usually enhanced potency during this period, such as those which induce mammary or reproductive organ tumors (*e.g.*, a polycyclic aromatic hydrocarbon), then the risk assessment may use a larger ASF to calculate risk from exposure during puberty. OEHHA may recommend chemical-specific ASFs for puberty to the local air quality management districts for use in the Air Toxics Hot Spots program.

U.S.EPA Analysis of the Effect of Age at Exposure on Cancer Potency

U.S. EPA addressed the potential for increased susceptibility to cancer caused by environmental chemicals when the exposure occurs during an early lifestage in "Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens" (U.S. EPA, 2005b) (referred to henceforth as the Supplemental Guidance). This document is intended to be a companion to the revised "Guidelines for Carcinogen Risk Assessment" (U.S. EPA, 2005a). We present a summary of their analysis, which supports the policy decision to weight cancer potency and therefore risk by age-at-exposure. As previously noted, there are several methodological differences between the U.S. EPA analysis and the OEHHA analysis. Of note, in the OEHHA analysis all treatment-related tumors that were observed in a given lifestage exposure experiment were taken into account in estimating cancer potency. Thus in comparing cancer potencies associated with early life vs. adult exposure, OEHHA compared the total cancer risk associated with exposure during a given lifestage, rather than comparing the risk for cancers at one single site in each lifestage, as the U.S. EPA did. In addition, the age groupings are somewhat different in the U.S. EPA analysis from those used by OEHHA in their analysis (described above). For example, prenatal (*in utero*) exposures were not part of the analysis performed by U.S. EPA, and that Agency's analyses did not distinguish between postnatal and juvenile exposures.

U.S. EPA oral exposure cancer risk methodology relies on estimation of the lifetime average daily dose, which can account for exposure factor differences between adults and children (*e.g.*, eating habits and body weight). However, early lifestage susceptibility differences have not been taken into consideration when cancer potency factors were calculated. The Supplemental Guidance document focused on studies that define the potential duration and degree of increased susceptibility that may arise from early-life exposures. An analysis of those studies including a detailed description of the procedures used was published in Barton *et al*. (2005) (included as Appendix I). The criteria used to decide if a study could be included in the quantitative analysis are as follows (excerpted from U.S. EPA, 2005b):

1. Exposure groups at different post-natal ages in the same study or same laboratory, if not concurrent (to control for a large number of potential cross-laboratory experimental variables including pathological examinations),
2. Same strain/species (to eliminate strain-specific responses confounding age-dependent responses),
3. Approximately the same dose within the limits of diets and drinking water intakes that obviously can vary with age (to eliminate dose-dependent responses confounding age-dependent responses),
4. Similar latency period following exposures of different ages (to control for confounding latency period for tumor expression with age-dependent responses), arising from sacrifice at >1 year for all groups exposed at different ages, where early-life exposure can occur up to about 7 weeks. Variations of around 10 to 20% in latency period are acceptable,
5. Postnatal exposure for juvenile rats and mice at ages younger than the standard 6 to 8 week start for bioassays; prenatal (*in utero*) exposures are not part of the current analysis. Studies that have postnatal exposure were included (without adjustment) even if they also involved prenatal exposure,

6. "Adult" rats and mice exposure beginning at approximately 6 to 8 weeks old or older, *i.e.* comparable to the age at initiation of a standard cancer bioassay (McConnell, 1992). Studies with animals only at young ages do not provide appropriate comparisons to evaluate age-dependency of response (*e.g.*, the many neonatal mouse cancer studies). Studies in other species were used as supporting evidence, because they are relatively rare and the determination of the appropriate comparison ages across species is not simple, and
7. Number of affected animals and total number of animals examined are available or reasonably reconstructed for control, young, and adult groups (i.e., studies reporting only percent response or not including a control group would be excluded unless a reasonable estimate of historical background for the strain was obtainable).

Cancer potencies were estimated from a one-hit model (a restricted form of the Weibull time-to-tumor model), which estimates cumulative incidence for tumor onset. U.S. EPA (2005b) compared the estimated ratio of the cancer potency from early-life exposure to the estimated cancer potency from adult exposure. The general form of the equation for the tumor incidence at a particular dose, [P(dose)] is:

$$P(dose) = 1-[1-P(0)]\exp(-\text{cancer potency}*\text{dose})$$

where P(0) is the incidence of the tumor in controls. The ratio of juvenile to adult cancer potencies at a single site were calculated by fitting this model to the data for each age group. The model fit depended upon the design of the experiment that generated the data. Studies evaluated by U.S. EPA had two basic design types: experiments in which animals were exposed either as juveniles or as adults (with either a single or multiple dose in each period), and experiments in which exposure began either in the juvenile or in the adult period, but once started, continued through life.

The model equations for the first study type are:

$$P_A = P_0 + (1-P_0)\,(1-e^{-m_A\delta_A})$$

$$P_J = P_0 + (1-P_0)\,(1-e^{-m_A e^{\lambda}\,\delta_J})$$

where *A* and *J* refer to the adult and juvenile period, respectively, λ is the natural logarithm of the juvenile:adult cancer potency ratio, P_0 is the fraction of control animals with the particular tumor type being modeled, P_x is the fraction of animals exposed in age period *x* with the tumor, m_A is the cancer potency, and δ_x is the duration or number of exposures during age period *x*.

The goal of the model is to determine λ, which is the logarithm of the estimated ratio of juvenile to adult cancer potencies. This serves as a measure of potential susceptibility for early-life exposure.

For the second study type, the model equations take into account that exposures that were initiated in the juvenile period continue through the adult period. The model equations for the fraction of animals exposed only as adults with tumors in this design are the same as in the first study type, but the fraction of animals whose first exposure occurred in the juvenile period is:

$$P_J = P_0 + (1-P_0)\,(1-e^{-m_A e^{\lambda}(\delta_J - \delta_A) - m_A \delta_A})$$

δ_J includes the duration of exposure during the juvenile period and the subsequent adult period.

Parameters in these models were estimated using Bayesian methods and all inferences about the ratios were based on the marginal posterior distribution of λ. A complete description of these procedures (including the potential effect of alternative Bayesian priors that were examined) was published in Barton *et al*. (2005) (Appendix I). This method produced a posterior mean ratio of the early-life to adult cancer potency, which is an estimate of the potential susceptibility of early-life exposure to carcinogens. Ratios of greater or less than one indicate greater or less susceptibility from early-life exposure, respectively.

U.S. EPA reviewed several hundred studies reporting information on 67 chemicals or complex mixtures that are carcinogenic via perinatal exposure. Eighteen chemicals were identified which had animal study designs involving early-life and adult exposures in the same experiment. Of those 18 chemicals, there were overlapping subsets of 11 chemicals involving repeated exposures during early postnatal and adult lifestages and 8 chemicals using acute exposures (usually single doses) at different ages. Those chemicals are listed in Table 5.

Table 5 Chemicals having animal cancer study data available with early-life and adult exposures in the same experiment.

Chemical	Study Type
Amitrole	repeat dosing
Benzidine	repeat dosing
Benzo[a]pyrene (BaP)	acute exposure
Dibenzanthracene (DBA)	acute exposure
Dichlorodiphenyltrichloroethane (DDT)	lifetime exposure, repeat dosing
Dieldrin	lifetime exposure, repeat dosing
Diethylnitrosamine (DEN)	acute exposure, lifetime exposure
Dimethylbenz[a]anthracene (DMBA)	acute exposure
Dimethylnitrosamine (DMN)	acute exposure
Diphenylhydantoin, 5,5-(DPH)	lifetime exposure, repeat dosing
Ethylnitrosourea (ENU)	acute exposure
Ethylene thiourea (ETU)	lifetime exposure, repeat dosing
3-Methylcholanthrene (3-MC)	repeat dosing
Methylnitrosourea (NMU)	acute exposure
Polybrominated biphenyls (PBBs)	lifetime exposure, repeat dosing
Safrole	lifetime exposure, repeat dosing
Urethane	acute exposure, lifetime exposure
Vinyl chloride (VC)	repeat dosing

U.S. EPA calculated the difference in susceptibility between early-life and adult exposure as the estimated ratio of cancer potency at specific sites from early-life exposure over the cancer potency from adult exposure for each of the studies that were determined qualitatively to have appropriate study designs and adequate data. The results were grouped into four categories: 1) mutagenic chemicals administered by a chronic dosing regimen to adults and repeated dosing in the early postnatal period (benzidine, diethylnitrosamine, 3-methylcholanthrene, safrole, urethane and vinyl chloride); 2) chemicals without positive mutagenicity data administered by a chronic dosing regimen to adults and repeated dosing in the early postnatal period (amitrole, dichlorodiphenyltrichloroethane (DDT), dieldrin, ethylene thiourea, diphenylhydantoin, polybrominated biphenyls); 3) mutagenic chemicals administered by an acute dosing regimen (benzo[*a*]pyrene, dibenzanthracene, diethylnitrosamine, dimethylbenzanthracene, dimethyl-nitrosamine, ethylnitrosourea, methylnitrosourea and urethane); 4) chemicals with or without positive mutagenicity data with chronic adult dosing and repeated early postnatal dosing.

The acute dosing animal cancer studies were considered qualitatively useful by U.S. EPA because they involve identical exposures with defined doses and time periods demonstrating that differential tumor incidences arise exclusively from age-dependent susceptibility. However, they

were not used to derive a quantitative cancer potency factor age adjustment, primarily because most of the studies used subcutaneous or intraperitoneal injection as a route of exposure. These methods have not been considered quantitatively relevant routes of environmental exposure for human cancer risk assessment by U.S. EPA, for reasons including the fact that these routes of exposure are expected to have a partial or complete absence of first pass metabolism which could affect potency estimates. Additionally, U.S. EPA decided that cancer potency estimates are usually derived from chronic exposures, and therefore, any adjustment to those potencies should be from similar exposures.

The repeated dosing studies with mutagenic chemicals using exposures during early postnatal and adult lifestages were used to develop a quantitative cancer potency factor age adjustment. Studies with repeated early postnatal exposure were included in the analysis even if they also involved earlier maternal and/or prenatal exposure, while studies addressing only prenatal exposure were not used in the analysis. The weighted geometric mean susceptibility ratio (juvenile to adult) for repeated and lifetime exposures in this case was 10.4 (range 0.12 – 111, 42% of ratios greater than 1).

USEPA suggests the use of age-dependent-adjustment factors (ADAF) for chemicals acting through a mutagenic mode of action., based on the results of the preceding analysis, which concluded that cancer risks generally are higher from early-life exposure than from similar exposure doses and durations later in life:

1. For exposures before 2 years of age (i.e., spanning a 2-year time interval from the first day of birth until a child's second birthday), a 10-fold ADAF.

2. For exposures between 2 and <16 years of age (i.e., spanning a 14-year time interval from a child's second birthday until their sixteenth birthday), a 3-fold ADAF.

3. For exposures after turning 16 years of age, no adjustment (ADAF=1).

The ADAF of 10 used for the 0 – 2 years of age range is approximately the weighted geometric mean cancer potency ratio from juvenile versus adult exposures in the repeated dosing studies. U.S. EPA considered this period to display the greatest toxicokinetic and toxicodynamic differences between children and adults. Data were not available to calculate a specific dose-response adjustment factor for the 2 to <16-year age range, so EPA selected an ADAF of 3 because it was half the logarithmic scale difference between the 10-fold adjustment for the first two years of life and no adjustment (*i.e.*, 1-fold) for adult exposure. The ADAF of 3 represents an intermediate level of adjustment applied after 2 years of age through <16 years of age. The upper age limit (16 years of age) reflects the end of puberty and the attainment of a final body height. U.S. EPA recognizes that the use of a weighted geometric mean of the available study data to develop an ADAF for cancer potencies may either overestimate or underestimate the actual early-life cancer potency for specific chemicals, and therefore emphasizes in the Supplemental Guidance that chemical-specific data should be used in preference to these default adjustment factors whenever such data are available.

U.S. EPA is recommending the ADAFs described above only for mutagenic carcinogens, because the data for non-mutagenic carcinogens were considered to be too limited and the modes

of action too diverse to use this as a category for which a general default adjustment factor approach can be applied. OEHHA considers this approach to be insufficiently health protective. There is no obvious reason to suppose that the toxicokinetics of non-mutagens would be systematically different from those of mutagens. It would also be inappropriate to assume by default that non-mutagenic carcinogens are assumed to need a toxicodynamic correction factor of 1. Most if not all of the factors that make individuals exposed to carcinogens during an early-lifestage potentially more susceptible than those individuals exposed during adulthood also apply to non-mutagenic carcinogen exposures (*e.g.*, rapid growth and development of target tissues, potentially greater sensitivity to hormonal carcinogens, differences in metabolism). It should also be noted that carcinogens that do not cause gene mutations may still be genotoxic by virtue of causing chromosomal damage. Additionally, many carcinogens do not have adequate data available for deciding on a specific mode of action, or do not necessarily have a single mode of action. For these reasons, OEHHA will apply the default cancer potency factor age adjustments described above to all carcinogens unless data are available which allow for the development of chemical-specific cancer potency factor age adjustments. In those cases, an agent-specific model of age dependence (based on observational or experimental data) might be used, or alternative (larger or smaller) adjustment factors and age ranges may be applied where understanding of the mechanism of action and target tissues makes this appropriate.

Other Source Documents for Cancer Risk Assessment Guidance

As noted previously, the cancer potencies and unit risks tabulated in this technical support document have been developed by various programs over a number of years. The methods used therefore necessarily varied according to the date of the assessment and the program responsible. The following section summarizes the sources and procedures most commonly applied, and their historical context where this is apposite.

United States Environmental Protection Agency (U.S. EPA)

The U.S. EPA was one of the first regulatory agencies to develop and apply cancer risk assessment methodology. Their guidance documents and technical publications have been influential for many programs, including the California Air Toxics (Toxic Air Contaminants and Hot Spots) programs.

Guidelines for Carcinogen Risk Assessment (U.S. EPA, 1986)

Prior to the more recent guidelines updating project which, after nearly ten years of internal and public review drafts culminated in the 2005 final revision (see below), U.S. EPA carcinogen risk assessment procedures were generally as described in Anderson *et al*. (1983) and "Guidelines for Carcinogen Risk Assessment" (U.S. EPA, 1986). These methods, which are outlined below, were used to calculate the Integrated Risk Information System (IRIS) cancer potency values, some of which are cited in this document. U.S. EPA has always indicated that cancer risk estimates based on adequate human epidemiologic data are preferred if available over estimates based on animal data. Although the newer guidelines offer alternative methods for dose-response analysis of animal bioassays, and updated consideration of specific topics such as lifestage-related differences in sensitivity, and mechanism of action for some types of carcinogen, the underlying principles and many of the specific procedures developed in these original guidelines are still applicable and in use.

U.S. EPA Calculation of Carcinogenic Potency Based on Animal Data

In extrapolating low-dose human cancer risk from animal carcinogenicity data, it is generally assumed that most agents that cause cancer also damage DNA, and that the quantal type of biological response characteristic of mutagenesis is associated with a linear non-threshold dose-response relationship. U.S. EPA stated that the risk assessments made with this model should be regarded as conservative, representing the most plausible upper limit for the risk. The mathematical expression used by U.S. EPA in the 1986 guidelines to describe the linear non-threshold dose-response relationship at low doses is the linearized multistage procedure developed by Crump (1980). This model is capable of fitting almost any monotonically increasing dose-response data, and incorporates a procedure for estimating the largest possible linear slope at low extrapolated doses that is consistent with the data at all experimental dose levels. A description of the linearized multistage procedure has been provided above (page 29). U.S. EPA used an updated version (GLOBAL86, Howe *et al*., 1986) of the computer program GLOBAL79 developed by Crump and Watson (1979) to calculate the point estimate and the 95% upper confidence limit of the extra risk $A(d)$.

U.S. EPA separated tumor incidence data according to organ sites or tumor types. The incidence of benign and malignant tumors was combined whenever scientifically defensible. U.S. EPA considered this incidence combination scientifically defensible unless the benign tumors are not considered to have the potential to progress to the associated malignancies of the same histogenic origin. The primary comparison in carcinogenicity evaluation is tumor response in dosed animals as compared to contemporary matched control animals. However, U.S. EPA stated that historical control data could be used along with concurrent control data in the evaluation of carcinogenic responses, and notes that for the evaluation of rare tumors, even small tumor responses may be significant compared to historical data. If several data sets (dose and tumor incidence) are available (different animal species, strains, sexes, exposure levels, exposure routes) for a particular chemical, the data set used in the model was the set where the incidence is statistically significantly higher than the control for at least one test dose level and/or where the tumor incidence rate shows a statistically significant trend with respect to dose level. The data set generating the highest lifetime cancer risk estimate (q_1^*) was chosen where appropriate. An example of an inappropriate data set would be a set which generates an artifactually high risk estimate because of a very small number of animals used. If there are 2 or more data sets of comparable size for a particular chemical that are identical with respect to species, strain, sex and tumor sites, the geometric mean of q_1^* estimated from each of those data sets was used for risk estimation. U.S. EPA assumed that mg/surface area/day is an equivalent dose between species. Surface area was further assumed to be proportional to the 2/3 power of the weight of the animal in question. Equivalent dose was therefore computed using the following relationship:

$$\mathrm{d} = \frac{1_e * m}{L_e * W^{2/3}}$$

where L_e = experimental duration, l_e = exposure duration, m = average dose (mg/day) and W = average animal weight. Default average body weights for humans, rats and mice are 70, 0.35 and 0.03 kg, respectively.

Exposure data expressed as ppm in the diet were generally converted to mg/day using the relationship m = ppm * F * r, where ppm is parts per million of the chemical in the diet, F is the weight of the food consumed per day in kg, and r is the absorption fraction (assumed to be 1 in the absence of data indicating otherwise). The weight of food consumed, calories required, and animal surface area were generally all considered to be proportional to the 2/3 power of the animal weight, so:

$$m \propto \text{ppm} * W^{2/3} * r, \text{ or } \quad \frac{m}{rW^{2/3}} \propto \text{ppm}$$

The relationship could lead to the assumption that dietary ppm is an equivalent exposure between species. However, U.S. EPA did not believe that this assumption is justified, since the calories/kg food consumed by humans is significantly different from that consumed by laboratory animals (primarily due to differences in moisture content). An empirically derived food factor, $f = F/W$ was used, which is the fraction of a species' body weight consumed per day as food. U.S. EPA (1986) gave the f values for humans, rats and mice as 0.028, 0.05 and 0.13, respectively.

Dietary exposures expressed as concentrations in ppm were converted to mg/surface area using the following relationship:

$$\frac{m}{r * W^{2/3}} = \frac{\text{ppm} * F}{W^{2/3}} = \frac{\text{ppm} * f * W}{W^{2/3}} = \text{ppm} * f * W^{2/3}$$

Exposures expressed as mg/kg/day ($m/Wr = s$) were converted to mg/surface area using the relationship:

$$\frac{m}{rW^{2/3}} = s * W^{2/3}$$

The calculation of dose when exposure is via inhalation was performed for cases where 1) the chemical is either a completely water-soluble gas or aerosol and is absorbed proportionally to the amount of inspired air, or 2) where the chemical is a partly water-soluble gas which reaches an equilibrium between the inspired air and body compartments. After equilibrium is attained, the rate of absorption is proportional to metabolic rate, which is proportional to the rate of oxygen consumption, which is related to surface area.

Exposure expressed as mg/day to completely water-soluble gas or aerosols can be calculated using the expression $m = I * v * r$, where I is the inspiration rate/day in m^3, v is the concentration of the chemical in air (mg/m^3), and r is the absorption fraction (assumed to be the same for all species in the absence of data to the contrary; usually 1). For humans, the default inspiration rate of 20 m^3 has been adopted. Inspiration rates for 113 g rats and 25 g mice have been reported to be 105 and 34.5 liters/day, respectively. Surface area proportionality can be used to determine inspiration rate for rats and mice of other weights; for mice, $I = 0.0345\ (W / 0.025)^{2/3}$ m^3/day; for rats, $I = 0.105\ (W / 0.113)^{2/3}$ m^3/day. The empirical factors for air intake/kg/day (i) for humans, rats and mice are 0.29, 0.64 and 1.3, respectively. Equivalent exposures in mg/surface area can be calculated using the relationship:

$$\frac{m}{W^{2/3}} = \frac{Ivr}{W^{2/3}} = \frac{iWvr}{W^{2/3}} = iW^{1/3}vr$$

Exposure expressed as mg/day to partly water-soluble gases is proportional to surface area and to the solubility of the gas in body fluids (expressed as an absorption coefficient r for that gas). Equivalent exposures in mg/surface area can be calculated using the relationships $m = kW^{2/3} * v * r$, and $d = m/W^{2/3} = kvr$. The further assumption is made that in the case of route-to-route extrapolations (*e.g.*, where animal exposure is via the oral route, and human exposure is via inhalation, or vice versa), unless pharmacokinetic data to the contrary exist, absorption is equal by either exposure route.

Adjustments were made for experimental exposure durations shorter than the lifetime of the test animal; the slope q_1^* was increased by the factor $(L/L_e)^3$, where L is the normal lifespan of the experimental animal and L_e is the duration of the experiment. This assumed that if the average dose d is continued, the age-specific rate of cancer will continue to increase as a constant function of the background rate. Since age-specific rates for humans increase by at least the 2nd power of the age, and often by a considerably higher power (Doll, 1971), there is an expectation

that the cumulative tumor rate, and therefore q_1^*, will increase by at least the 3rd power of age. If the slope q_1^* is calculated at age L_e, it would be expected that if the experiment was continued for the full lifespan L at the same average dose, the slope q_1^* would have been increased by at least $(L/L_e)^3$.

U.S. EPA Calculation of Carcinogenic Potency Based on Human Data

U.S. EPA stated that existing human epidemiologic studies with sufficiently valid exposure characterization are always used in evaluating the cancer potency of a chemical. If they showed a carcinogenic effect, the data were analyzed to provide an estimate of the linear dependence of cancer rates on lifetime cancer dose (equivalent to the factor q_1^*). If no carcinogenic effect was demonstrated and carcinogenicity had been demonstrated in animals, then it was assumed that a risk does exist, but it is smaller than could have been observed in the epidemiologic study. An upper limit of cancer incidence was calculated assuming that the true incidence is just below the level of detection in the cohort studied, which is largely determined by the cohort size. Whenever possible, human data are used in preference to animal data. In human epidemiologic studies, the response is measured as the relative risk of the exposed cohort of individuals compared to the control group. The excess risk ($R(X)$ - 1, where $R(X)$ is relative risk) was assumed to be proportional to the lifetime average exposure X, and to be the same for all ages. The carcinogenic potency is then equal to $[R(X) - 1]/X$ multiplied by the lifetime risk at that site in the general population. According to this original procedure, the confidence limit for the excess risk was not usually calculated. This decision was ascribed to the difficulty in accounting for inherent uncertainty in the exposure and cancer response data. More recent assessments have taken the opposite view and attempted to calculate and characterize this uncertainty by determining confidence limits, *inter alia*.

Guidelines for Carcinogen Risk Assessment (U.S. EPA, 2005a)

U.S. EPA revised its "Guidelines for Carcinogen Risk Assessment" (referred to henceforth as the "U.S. EPA Guidelines") in 2005. Compared to the 1986 version of this document, more emphasis is placed on establishing a "mode of action" (MOA). The following excerpt provides a definition of this term:

> "The term "mode of action" is defined as a sequence of key events and processes, starting with interaction of an agent with a cell, proceeding through operational and anatomical changes, and resulting in cancer formation. A "key event" is an empirically observable precursor step that is itself a necessary element of the mode of action or is a biologically based marker for such an element. Mode of action is contrasted with "mechanism of action," which implies a more detailed understanding and description of events, often at the molecular level, than is meant by mode of action".

Cancer risk assessments performed under the prior U.S. EPA Guidelines sometimes included a MOA description. However, the 1986 U.S. EPA Guidelines did not explicitly mandate the development of a MOA description in cancer risk assessments.

The MOA information is then used to govern how a cancer risk assessment shall proceed. Tumor incidence data sets arising from a MOA judged to be not relevant to humans are not used

to extrapolate a cancer potency factor. If an MOA cannot be determined or is determined to have a low-dose linear dose-response and a nonmutagenic MOA, then a linear extrapolation method is used to develop a cancer potency factor. The same linear extrapolation is used for all lifestages, unless chemical specific information on lifestage or population sensitivity is available. Carcinogens that act via an MOA judged to have a nonlinear low-dose dose response are modeled using MOA data, or the RfD/RfC risk assessment method is used as a default. Adjustments for susceptible lifestages or populations are to be performed as part of the risk assessment process.

If a carcinogen is deemed to act via a mutagenic MOA, then the data from the MOA analysis is evaluated to determine if chemical-specific differences between adults and juveniles exist and can be used to develop a chemical-specific risk estimate incorporating lifestage susceptibility. If this cannot be done, then early-life susceptibility is assumed, and age-dependent adjustment factors (ADAFs) are applied as appropriate to develop risk estimates. In cases where it is not possible to develop a toxicokinetic model to perform cross-species scaling of animal tumor data sets which arise from oral exposures, the U.S. EPA Guidelines state that administered doses should be scaled from animals to humans on the basis of equivalence of $mg/kg^{3/4}$-d (milligrams of the agent normalized by the 3/4 power of body weight per day). This is a departure from the 1986 U.S. EPA guidelines, which used a 2/3 power of body weight normalization factor. Other adjustments for dose timing, duration and route are generally assumed to be handled in similar fashion to that described for the 1986 guidelines, although of course updated parameter values would be used where available.

The 2005 U.S. EPA Guidelines also use benchmark dose methodology (described above, page 27) to develop a "point-of departure" (POD) from tumor incidence data. For linear extrapolation, the POD is used to calculate a cancer potency factor, and for nonlinear extrapolation the POD is used in the calculation of a reference dose (RfD) or reference concentration (RfC).

It should be noted that none of the cancer potency factors listed in this document were obtained from U.S. EPA risk assessments performed under the 2005 U.S. EPA Guidelines. All U.S. EPA IRIS cancer potency values contained in this document were obtained from risk assessments using the 1986 U.S. EPA Guidelines.

Office of Environmental Health Hazard Assessment (OEHHA), California Environmental Protection Agency

The cancer risk assessment procedures originally used by the Office of Environmental Health Hazard Assessment (OEHHA) are outlined in "Guidelines for Chemical Carcinogen Risk Assessments and their Scientific Rationale" (referred to below as the Guidelines) (CDHS, 1985). These procedures were generally used in generating Toxic Air Contaminant (TAC) cancer potency values, standard Proposition 65 cancer potency values and Public Health Goal (PHG) cancer potency values. Expedited Proposition 65 cancer potency values depart somewhat from those procedures and are discussed separately below.

OEHHA cancer risk assessment methodology as described by CDHS (1985) generally resembled that used at that time by U.S. EPA (Anderson *et al*., 1983; U.S. EPA, 1986). OEHHA risk

assessment practice similarly reflects the evolution of the technical methodology (*e.g.*, as described in U.S. EPA, 2005a) since the original guidelines were published. The basic principles and procedures described below are still considered applicable. More recent additions to OEHHA cancer risk assessment methods such as the use of benchmark dose methodologies and early-lifestage cancer potency adjustments are discussed above. The Guidelines state that both animal and human data, when available, should be part of the dose-response assessment.

OEHHA Calculation of Carcinogenic Potency Based on Animal Data

The procedures used to extrapolate low-dose human cancer risk from animal carcinogenicity data assumed that a carcinogenic change induced in a cell is transmitted to successive generations of cell descendants, and that the initial change in the cell is an alteration (*e.g.*, mutation, rearrangement, etc.) in the cellular DNA. Non-threshold models are used to extrapolate to low-dose human cancer risk from animal carcinogenicity data.

Several models were proposed for extrapolating low-dose human cancer risk from animal carcinogenicity data in the original Guidelines. These models include the Mantel-Bryan method (log-probit model), the one-hit model, the linearized multistage procedure, the gamma multihit model, and a number of time-to-tumor models. The Guidelines stated that time-to-tumor models (i.e., a Weibull-in-time model) should be used for low-dose extrapolation in all cases where supporting data are available, particularly when survival is poor due to competing toxicity. However, the Guidelines also noted the difficulty of determining the actual response times in an experiment. Internal tumors are generally difficult to detect in live animals and their presence is usually detected only at necropsy. Additionally, use of these models often requires making the determination of whether a tumor was the cause of death, or was found only coincidentally at necropsy when death was due to other causes. Further, competing causes of death, such as chemical toxicity, may decrease the observed time-to-tumor for nonlethal cancers by allowing earlier necropsy of animals in higher dose groups. The linearized multistage (LMS) procedure was noted as being an appropriate method for dose extrapolation in most cases, with the primary exception being a situation in which sufficient empirical data are available to indicate a dose-response curve of a "quasi-threshold" type (*e.g.*, flat for two or three dose levels, then curving sharply upwards). In this case, the LMS procedure may underestimate the number of stages and overestimate the low-dose risks. In this case, the gamma multihit model was suggested as being a potential alternative. The Mantel-Bryan model was described as having little biological basis as applied to carcinogenesis, and being likely to underestimate risks at low doses. The Guidelines stated that this model should not be used for low dose extrapolation. More recent practice has departed from these original guidelines in some respects, for instance by experimenting with cell-proliferation based models in a few cases. However, the LMS model remained the preferred extrapolation model for most purposes. Some of the difficulties in achieving a satisfactory fit to tumor incidence data were found to be alleviated by application of toxicokinetic models and use of an internal rather than applied dose metric with the LMS model. This has resulted in the alternative models originally advocated (Gamma multihit, Mantel-Bryan) being mostly abandoned. As noted above (Dose-Response Assessment, page 23), the use of allegedly biologically based statistical models such as LMS has fallen from favor in recent years, and benchmark dose methodology has become the preferred method for extrapolating cancer potency values from animal cancer incidence data. However, it should also be noted that results

generated by the LMS model and benchmark dose methodology from the same data set are often quite similar.

The 1985 Guidelines stated that both animal and human data, when available, should be part of the dose-response assessment. Although preference was given to human data when these were of adequate quality, animal studies may provide important supporting evidence. Low-dose extrapolation of human cancer risk from animal carcinogenicity data was generally based on the most sensitive site, species and study demonstrating carcinogenicity of a particular chemical, unless other evidence indicates that the data set in question is not appropriate for use. Where both benign and malignant tumors are induced at the same site and the benign tumors are considered to have the potential to progress to malignant tumors, the incidence data for both types of tumors could be combined to form the basis for risk assessment. Pharmacokinetic data on chemical metabolism, effective dose at target site, or species differences between laboratory test animals and humans were considered in dose-response assessments when available. In performing exposure scaling from animals to humans, the "surface area" correction (correcting by the 2/3 power of body weight) was used unless specific data indicate that this should not be done. The Guidelines assumed that in the absence of evidence to the contrary, chemicals that cause cancer after exposure by ingestion will also cause cancer after exposure by inhalation, and vice versa. These original proposals have continued in use with little change except that currently, TAC and PHG cancer potency factor calculations use a 3/4 power of body weight correction for interspecies scaling, in line with current U.S. EPA practice. The standard Proposition 65 cancer potency factor calculations still use a 2/3 power correction because the cancer potency calculation method is specified in regulation (California Health and Safety Code 25249.5 *et seq.*).

Cancer unit risk factors [in units of $(\mu g/m^3)^{-1}$] have been calculated from cancer potency factors [in units of $(mg/kg\text{-}day)^{-1}$] using the following relationship:

$$UR = \frac{CPF * 20\ m^3}{70\ kg\ *\ CV}$$

where UR is the cancer unit risk, CPF is the cancer potency factor, 70 kg is the reference human body weight, 20 m^3 is the reference human inspiration rate/day, and CV is the conversion factor from mg to µg (= 1000). The cancer unit risk describes the excess cancer risk associated with an inhalation exposure to a concentration of 1 $\mu g/m^3$ of a given chemical; the cancer potency factor describes the excess cancer risk associated with exposure to 1 mg of a given chemical per kilogram of body weight.

It should be noted that although this default method is still used in deriving published cancer unit risk values, for site-specific risk assessments age-appropriate distributions and percentile values are used in the current version of the Hot Spots exposure assessment document. Where exposure to children occurs (as it does in most exposures to the general population surrounding a source site) it is also necessary to apply the age-specific adjustment factors for the appropriate durations in accordance with the guidance offered above (Page 30 *et seq.*).

OEHHA Calculation of Carcinogenic Potency Based on Human Data

Human epidemiologic studies with adequate exposure characterization are used to evaluate the cancer potency of a chemical. If they show a carcinogenic effect, the data are analyzed to provide an estimate of the linear dependence of cancer rates on lifetime cancer dose. The 1985 Guidelines stated that with continuous exposure, age-specific incidence continues to increase as a power function (*e.g.*, t^3 or t^4) of the elapsed time since initial exposure. Lifetime risks can be estimated by applying such a power function to the observed data and extrapolating beyond the actual followup period. OEHHA has generally undertaken the calculation of study power and confidence bounds on the potency estimate as important tools to establish the credibility of the estimate obtained and in comparing this with other estimates (from other human studies or from animal data). Due to the diversity in quality and type of epidemiological data, the specific approaches used in OEHHA risk assessments based on human epidemiologic studies vary on a case by case basis rather than following explicit general guidelines. Examples of the methods used can be observed in the Toxic Air Contaminant documents (these documents are listed in Appendix D: the methods used are described in the compound summaries provided in Appendix B).

Expedited Proposition 65 Cancer Risk Assessment Methodology

Expedited cancer potency values developed for several agents listed as carcinogens under Proposition 65 (California Health and Safety Code 25249.5 *et seq*.) were derived from selected animal carcinogenicity data sets of the Carcinogenic Potency Database (CPDB) of Gold *et al.* (1984, 1986, 1987, 1989, 1990, 1997) using default procedures specified in the administrative regulations for Proposition 65 (Title 22 California Code of Regulations [CCR] 12703). OEHHA hazard assessments usually describe all relevant data on the carcinogenicity (including dose-response characteristics) of the chemical under examination, followed by an evaluation of any pharmacokinetic and mechanistic (*e.g.*, genotoxicity) data. An evaluation of the data set for the chemical may indicate that adjustments in target dose estimates or use of a dose response model different from the default are appropriate. The procedure used to derive expedited Proposition 65 cancer potency values differs from the usual methodology in two ways. First, it relies on cancer dose response data evaluated and extracted from the original literature by Gold *et al.* Second, the choice of a linearized multistage procedure for generating cancer potency values is automatic, and pharmacokinetic adjustments are not performed. The methods used to develop expedited cancer potency values incorporate the following assumptions:

1. The dose response relationship for carcinogenic effects in the most sensitive species tested is representative of that in humans.
2. Observed experimental results can be extrapolated across species by use of the interspecies factor based on "surface area scaling."
3. The dose to the tissue giving rise to a tumor is assumed to be proportional to the administered dose.
4. The linearized multistage polynomial procedure can be used to extrapolate potency outside the range of experimental observations to yield estimates of "low" dose potency.
5. Cancer risk increases with the third power of age.

The Carcinogenic Potency Database of Gold *et al.* (1984, 1986, 1987, 1989, 1990) contains the results of more than 4000 chronic laboratory animal experiments on 1050 chemicals by combining published literature with the results of Federal chemical testing programs (Technical Reports from the Carcinogenesis Bioassay Program of the National Cancer Institute (NCI)/National Toxicology Program (NTP) published prior to June 1987). The published literature was searched (Gold *et al*., 1984) through the period December 1986 for carcinogenicity bioassays; the search included the Public Health Service publication "Survey of Compounds Which Have Been Tested for Carcinogenic Activity" (1948-1973 and 1978), monographs on chemical carcinogens prepared by the International Agency for Research on Cancer (IARC) and Current Contents. Also searched were Carcinogenesis Abstracts and the following journals: British Journal of Cancer, Cancer Letters, Cancer Research, Carcinogenesis, Chemosphere, Environmental Health Perspectives, European Journal of Cancer, Food and Chemical Toxicology, Gann, International Journal of Cancer, Journal of Cancer Research and Clinical Oncology (formerly Zeitschrift fur Krebsforschung und Klinische Onkologie), Journal of Environmental Pathology and Toxicology, Journal of Toxicology and Environmental Health, Journal of the National Cancer Institute, and Toxicology and Applied Pharmacology. Studies were included in the database if they met the following conditions:

1. The test animals were mammals.
2. Chemical exposure was started early in life (100 days of age or less for hamsters, mice and rats).
3. Route of administration was via the diet, drinking water, gavage, inhalation, intravenous injection or intraperitoneal injection.
4. The test chemical was administered alone (not in combination with other chemicals).
5. Chemical exposure was chronic (*i.e*. duration of exposure was at least one-fourth the standard lifespan for that species), with not more than 7 days between exposures.
6. The experiment duration was at least half the standard lifespan for the species used.
7. The study design included a control group and at least 5 animals/exposure group.
8. No surgical interventions were performed.
9. Pathology data were reported for the number of animals with tumors (not total number of tumors).
10. All results reported were original data (not analysis of data reported by other authors).

Included in their data set tabulations are estimates of average doses used in the bioassay, resulting tumor incidences for each of the dose levels employed for sites where significant responses were observed, dosing period, length of study and histopathology. Average daily dose levels were calculated assuming 100% absorption. Dose calculations follow procedures similar to those of Cal/EPA and U.S. EPA; details on methods used and standard values for animal lifespans, body weights, and diet, water and air intake are listed in Gold *et al.* (1984). OEHHA (1992) reviewed the quality assurance, literature review, and control procedures used in compiling the data and found them to be sufficient for use in an expedited procedure. Cancer potency estimates were derived by applying the mathematical approach described in the section below to dose response data in the Gold *et al.* database.

The following criteria were used for data selection:

1. Data sets with statistically significant increases in cancer incidence with dose ($p \leq 0.05$) were used. (If the authors of the bioassay report considered a statistically significant result to be unrelated to the exposure to the carcinogen, the associated data set was not used.)
2. Data sets were not selected if the endpoint was specified as "all tumor-bearing animals" or results were from a combination of unrelated tissues and tumors.
3. When several studies were available, and one study stood out as being of higher quality due to numbers of dose groups, magnitude of the dose applied, duration of study, or other factors, the higher quality study was chosen as the basis for potency calculation if study results were consistent with those of the other bioassays listed.
4. When there were multiple studies of similar quality in the sensitive species, the geometric mean of potencies derived from these studies was taken. If the same experimentalists tested two sexes of the same species/strain under the same laboratory conditions, and no other adequate studies were available for that species, the data set for the more sensitive sex was selected.
5. Potency was derived from data sets that tabulate malignant tumors, combined malignant and benign tumors, or tumors that would have likely progressed to malignancy.

Cancer potency was defined as the slope of the dose response curve at low doses. Following the default approach, this slope was estimated from the dose response data collected at high doses and assumed to hold at very low doses. The Crump linearized multistage polynomial (Crump *et al.*, 1977) was fit to animal bioassay data:

$$\text{Probability of cancer} = 1 - \exp[-(q_0 + q_1 d + q_2 d^2 + ...)]$$

Cancer potency was estimated from the upper 95% confidence bound on the linear coefficient q_1, which is termed q_1^*.

For a given chemical, the model was fit to a number of data sets. As discussed in the section above, the default was to select the data for the most sensitive target organ in the most sensitive species and sex, unless data indicated that this was inappropriate. Deviations from this default occur, for example, when there are several bioassays or large differences exist between potency values calculated from available data sets.

Carcinogenicity bioassays using mice and/or rats will often use an exposure duration of approximately two years. For standard risk assessments, this is the assumed lifespan for these species. Animals in experiments of shorter duration are at a lower risk of developing tumors than those in the standard bioassay; thus potency is underestimated unless an adjustment for experimental duration is made. In estimating potency, short duration of an experiment was taken into account by multiplying q_1^* by a correction factor equal to the cube of the ratio of the assumed standard lifespan of the animal to the duration of the experiment (T_e). This assumes that the cancer hazard would have increased with the third power of the age of the animals had they lived longer:

$$q_{animal} = q_1^* * (104 \text{ weeks}/T_e)^3$$

In some cases excess mortality may occur during a bioassay, and the number of initial animals subject to late occurring tumors may be significantly reduced. In such situations, the above described procedure can, at times, significantly underestimate potency. A time-dependent model fit to individual animal data (i.e., the data set with the tumor status and time of death for each animal under study) may provide better potency estimates. When Gold *et al.* indicated that survival was poor for a selected data set, a time-dependent analysis was attempted if the required data were available in the Tox Risk (Crump *et al.*, 1991) data base. The Weibull multistage model (Weibull-in-time; multistage-in-dose) was fit to the individual animal data.

To estimate human cancer potency, q_{animal} values derived from bioassay data were multiplied by an interspecies scaling factor (K; the ratio of human body weight (bw_h) to test animal body weight (bw_a), taken to the 1/3 power (Anderson *et al.*, 1983)):

$$K = (bw_h/bw_a)^{1/3}$$

Thus, cancer potency = $q_{human} = K * q_{animal}$

Chemical-specific Descriptions of Cancer Potency Value Derivations

Unit Risk and potency values for chemicals whose cancer potency values were obtained from Toxic Air Contaminant documents, standard or expedited Proposition 65 documents, U.S. EPA's Integrated Risk Information System (IRIS) documents and Health Effects Assessment Summary Table (HEAST) entries, or from other documents prepared by OEHHA's Air Toxicology and Epidemiology Branch or Pesticide and Environmental Toxicology Branch are presented in Appendix A. Information summaries for these chemicals are presented in Appendix B.

Disclaimer

The statements and conclusions in this report are those of the contractor and not necessarily those of the South Coast Air Quality Management District or other participating organizations and their employees. The mention of commercial products, their source, or their use in connection with material reported herein is not to be construed as actual or implied endorsement of such products.

Acknowledgments

This report was prepared at the University of California, Riverside, and Bourns College of Engineering-Center for Environmental Research and Technology (CE-CERT). The primary contributors to this report include Drs. Wayne Miller, Kent C. Johnson, Thomas D. Durbin, and Ms. Poornima Dixit. The authors thank the following organizations and individuals for their valuable contributions to this project. We acknowledge Messrs. Don Pacocha, Edward O'Neil, and Joe Valdez of CE-CERT for their assistance in carrying out the experimental program.

Also, we would like to thank the following: Mr. Scott Monday, Alfredo Ortiz, and the rest of the support team at the Air Resources Board for N_2O analysis and technical guidance. Scott was very helpful in coordinating samples and Alfredo was patient in performing the analysis with short notice.

Also, we would like to thank the following: T. J. Rafel at Western Truck Center and Steve South at EDCO disposal for the use of their SCR equipped diesel refuse haulers. Patrick McGuruk at Container Freight/EIT., LLC for the use of two class 8 diesel powered vehicles. John Vondriska at Moreno Valley Unified School District for the use of a propane powered school bus. David Chiu at Krisda Inc for the use of a Class 8 LPG vehicle. Doug Kollmyer from A to Z Bus Sales for the use of a DPF equipped diesel school bus. Ed Hardiman, Rudy Raya and their support team at Caltrans for the use of two diesel Navistar refuse haulers. Jonathan Evans and Mark Yragui at Cummins Cal Pacific for their assistance in locating SCR equipped diesel refuse haulers in California. Bennie Anselmo for his assistance in locating an SCR equipped diesel refuse hauler in Northern California.

Executive Summary

Heavy-duty diesel vehicles are a major contributor to diesel emissions in the South Coast Air Basin. While emission measurements of these vehicles in engine dynamometer certification laboratories are showing nitrogen oxides (NO_x) and particulate matter (PM) emissions meeting the U.S. Environmental Protection Agency's (EPA's) and California Air Resources Board's (CARB's) emissions standards, some values from in-use conditions are showing increased emissions of ammonia from liquefied natural gas (LNG) trucks and of NO_x from diesel trucks. As such, additional studies are required to assess the impact of technology on emissions from heavy-duty engines used in variety of heavy-duty applications. The objective of this study was to carry out chassis dynamometer testing of heavy-duty natural gas and diesel vehicles using near-certification and in-use driving cycles while measuring: 1) regulated emissions; 2) unregulated emissions such as ammonia and formaldehyde; 3) greenhouse gas levels of carbon dioxide (CO_2) and nitrous oxide (N_2O); and 4) ultrafine PM emissions.

In December 2010 and October 2011, the SCAQMD Board awarded contracts to University of California, Riverside (UCR) and West Virginia University (WVU) to conduct chassis dynamometer testing of twenty-four model year (MY) 2007-2012 heavy-duty vehicles from different vocations and fueling technologies, and if necessary, to evaluate emission-reduction potential of retrofit technology for ammonia emissions from a natural gas heavy-duty engine. The test vehicle vocations included goods movement, refuse, transit and school bus applications, and the test cycles used for the specific vocations were port drayage truck cycles for goods movement, SCAQMD refuse truck cycles for the refuse applications, and Orange County Transportation Authority (OCTA) and Central Business District (CBD) cycles for transit applications. The Heavy Duty Urban Dynamometer Driving Schedule (HD-UDDS) was a common cycle for all vocations. The test matrix involved five natural gas and four dual-fuel vehicles to be tested on a chassis dynamometer by WVU, eight diesel and two propane vehicles tested by UCR, and five diesel vehicles tested by both WVU and UCR for inter-laboratory comparison. The heavy-duty natural gas engines were both stoichiometric fueled and three-way catalytic converter (TWC) equipped; lean burn high-pressure direct injection (HPDI) engines were equipped with diesel particulate filters DPFs and selective catalytic reduction (SCR) technology. Diesel engines tested in were either U.S. EPA 2007 emissions compliant or U.S. EPA 2010 emissions compliant. The U.S. EPA 2007 emissions compliant engines were equipped with exhaust gas recirculation (EGR) technology and DPFs, while the U.S. EPA 2010 emissions compliant engines were of two types: a) with EGR and DPF only b) with DPF and SCR.

The emission results for PM and NO_x are summarized below:

- PM emissions from the diesel test vehicles were below 0.01 grams per brake horsepower-hour (g/bhp-h) measured over port drayage, CBD, and UDDS drive cycles. Cold start PM emissions were relatively high for two diesel vehicles; one was a port SCR equipped vehicle and the other was a refuse SCR equipped vehicle. The port vehicle was 17 times higher (22.9 mg/mi vs 1.33 mg/mi) and the refuse vehicle was 8 times higher (18.4 mg/mi vs 2.75 mg/mi). In both cases the high cold start emission factors were below the certification standard. PM emissions were well below the certification for all diesel tests, thus suggesting DPF-based solutions are robust and reliable in meeting targeted standards. In addition, PM emissions from a liquefied petroleum gas (LPG) test vehicle was approximately 0.14 g/bhp-hr measured over the UDDS cycle, which is above the certification standard.

- NO_x results covered a wide range of emission factors, where the emissions depended on the certification standard, vehicle application, driving cycle, and manufacturer. For example, NO_x emissions were lowest for goods movement vehicles powered by diesel engines equipped with SCR technology; however, increases from 0.112 g/mi (0.028 g/bhp-h) during high speed cruise operation to 5.36 g/mi (1.34 g/bhp-h) for low speed transient operation were measured. Unique to the high NO_x emissions was a condition in which the temperature of the SCR was less than 250°C. Advanced EGR 2010 certified engines showed higher NO_x emissions compared to SCR equipped engines, and pre-2010 certified engines were higher than the 2010 certified engines.
- The NO_x impact of SCR equipped diesel engines depends on the vehicles' duty cycles and manufacturers' implementation for low temperature SCR performance. For the near dock port cycle, the SCR was below 250°C approximately 80% of the time, 65% of the time for the local port cycle, and approximately 45% of the time for the regional port cycle. The percentage of time below 250°C varied significantly between manufacturers, from 8% to 30% for the near dock cycle, and from 41% to 64% for the regional cycle. The difference in time below 250°C suggests some manufacturers have better strategies for maintaining high exhaust temperatures than others.
- The SCR equipped engines were within their certification standards and were typically below 0.2 g/bhp-h. Only during low SCR temperature were the emissions found to be higher than the certification standard. In-use compliance testing does not enforce the emissions standards when the SCR is below 250 °C, thus the SCR equipped vehicles were typically compliant based on the results presented in this report.

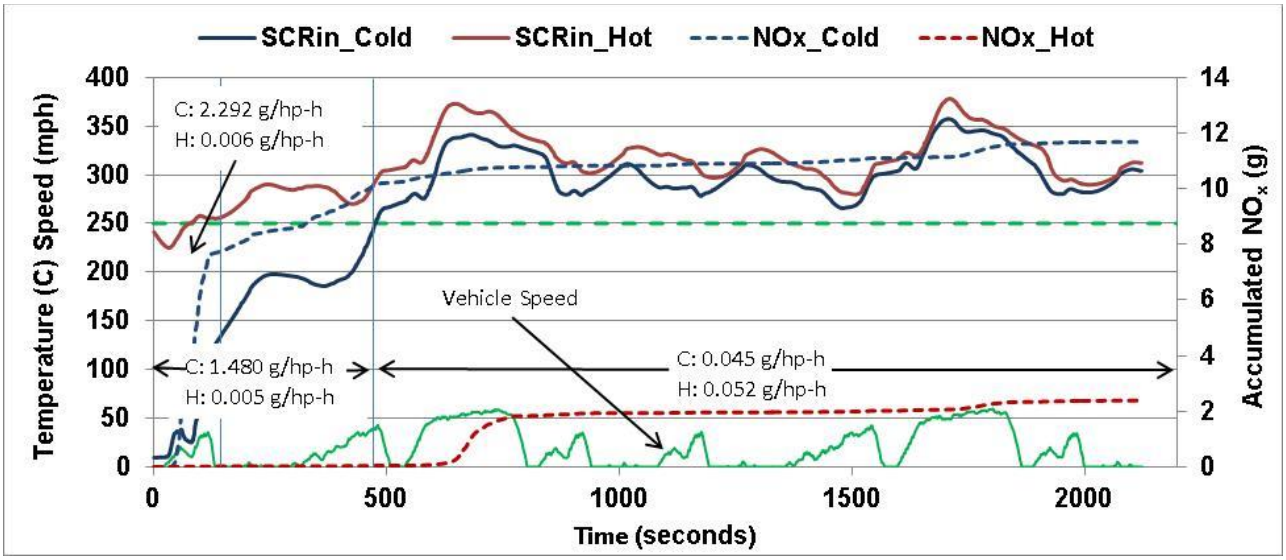

Figure ES-1: Accumulated NOx emissions during hot and cold start UDDS testing

- Figure ES-1 shows the cumulative NO_x emissions, instantaneous SCR inlet temperature and vehicle speed for a class 8 Freightliner equipped with a Cummins 11.9 liter 2011 engine. The figure is typical for SCR equipped diesel engines, where cold start NO_x emissions can be as high as 2.3 g/bhp-hr compared to an equivalent warm test of 0.006 g/bhp-h. Although cold start emissions do not contribute to the inventory, it is important to consider the extreme nature of cold start emissions if vehicles are allowed to cool frequently. The NO_x emissions

accumulated in 1 mile after a cold start were equivalent to emissions accumulated during 32 miles of running hot.

- The 2010 certified diesel engines with advanced cooled EGR and no SCR were tested. These vehicles operated utilizing a lug curve with peak torque starting as low as 1000 revolutions per minute (RPM), where the driver was instructed to operate the vehicle down to 900 RPM before shifting. The truck behavior was unusual, and both UCR and WVU trained drivers commented on the strange operation. Additionally, the certified emissions had a family emission limit (FEL) of 0.5 g/bhp-hr for 2010 MY, but the measured NO_x emissions were around 1 g/bhp-hr (0.25 g/mi) for the UDDS cycle, which represents a certification-like cycle. Even the port cycles showed brake specific emissions higher than 1 g/bhp-hr and as high as 2 g/bhp-hr for the near dock cycle.
- Pre-2010 certified diesel engines exhibited regulated emissions that were very close to the standard and were found to be repeatable for randomly selected models tested. This suggests that pre-2010 emissions inventories may be more reliable than SCR-equipped diesel engines due to SCR performance variability.
- Most NO_x emissions from SCR equipped diesel refuse vehicles were produced during the compaction portion of the in-use test cycle. The high NO_x emissions corresponded with a low SCR exhaust temperature, where the emissions increased from 0.27 g/bhp-hr NO_x for the transient and curbside cycles to 3.8 g/bhp-hr NO_x for the compaction cycle.
- The percentage of NO_x as NO_2 ranged from 10% to near 90%, with the highest levels of NO_2 emissions from non-SCR-equipped diesel vehicles. NO_2 was highest for the pre-2010 certified engines (averaging 1.15 ± 0.48 g/mi for the UDDS cycle). In general NO_2 ratios were similar for all tests at around 45%±8%, except for the SCR equipped diesel vehicles, which showed high variability with a NO_2 ratio of 47%±36%.

The emission results for ammonia, hydrocarbons, toxics, and fine particles are summarized below:

- Ammonia (NH_3) emissions from the vehicles tested ranged from about 0.01 to 0.1 g/mi. The diesel vehicles' NH_3 emissions averaged 0.04±0.03 g/mi (0.01±0.01 g/hp-h), where the port vehicle emissions were similar (0.03±0.02 g/mi), but the propane school bus had relatively higher NH_3 emissions (0.48±0.04 g/mi) over the CBD test cycle. All the diesel vehicles showed cycle averaged raw NH_3 emission concentrations less than 10ppm. Of the 54 diesel tests conducted, only 2 vehicles had NH_3 emissions over 5 parts per million (ppm). Half of the tests were below 2 ppm. Five of seven propane vehicle tests had NH_3 emissions greater than 5 ppm and two were over 50 ppm, suggesting that relatively higher NH_3 emissions exist for the propane vehicles compared to the diesel vehicles.
- The emission factors for total hydrocarbon (THC), methane (CH_4), non-methane hydrocarbon (NMHC) and toxics were very low for all diesel vehicles tested. This agrees with other research from the Advanced Collaborative Emissions Study (ACES) project that showed a 98% reduction from diesel engines with catalytic exhaust systems. THC, NMHC, and CH_4 emissions were at or below 0.09 g/mi, 0.06 g/mi, and 0.04 g/mi, respectively, for all vehicles (except the LPG vehicle) for both the UDDS and port regional cycles. Slightly higher THC, CH_4, and NMHC emissions were found for the lower power near dock port cycle (0.36 g/mi, 0.10 g/mi, and 0.29 g/mi, respectively). Toxic emissions were low and near the

detection limits of the method where 75% of the measured carcinogenetic species (benzene, toluene, ethylbenzene, and xylenes - BTEX) were below the average ambient background concentration pulse one standard deviation (< 10 mg/mi and typically < 2 mg/mi background corrected). Carbonyl emissions were also low relative to the measurement method, where more than 75% of the measured species were below the same threshold except for formaldehyde. Formaldehyde showed a relatively higher emission concentration, with 75% of the measurements above the threshold. Even though the formaldehyde samples were relatively high, their absolute contribution were below 72 mg/mi, with an average of 18±19 mg/mi. Acetaldehyde was the next largest carbonyl with maximum emissions of 18 mg/mi and an average of 1.5±4 mg/mi. The rest of the carbonyls were below 2 mg/mi. Cold start UDDS emissions were similar to the hot start UDDS emissions for THC, CH_4, NMHC, and toxics (note the UDDS was performed as a 2xUDDS cycle, which may have minimized the cold start effect for the HCs and toxics).

- The LPG goods movement vehicle showed higher THC, NMHC, CH_4, and toxic emissions than the diesel vehicles tested. THC, NMHC and CH_4 were 22.4 g/mi, 1.43 g/mi, and 21.4 g/mi respectively for the UDDS hot cycle. BTEX and formaldehyde samples were more than 10 times the average ambient background concentration plus one standard deviation. The propane vehicle averaged 6.5±9.3 mg/mi, 9.7±12 mg/mi, and 22.4±19 mg/mi for 1,3-butadiene, n-butane, and benzene respectively for the BTEX sample. The Carbonyls were high for formaldehyde and acetaldehyde (241±253 mg/mi and 42±48 mg/mi respectively) with the remaining aldehydes below 2 mg/mi. These results should be confirmed with additional testing on LPG port vehicles.

- Real-time PM measurements suggest the reported reference PM emission rate may be lower due to low filter weights for DPF equipped vehicles. The PM mass of the gravimetric method averaged 0.78±1.57 mg/bhp-hr for selected diesel vehicles. The average PM mass from the real-time measurement method averaged 0.05±0.09 mg/bhp-hr for the same vehicles. The average filter weight for these selected vehicles ranged from 10-20 µg, where UCR's CVS tunnel blank averages were 5µg with a 5µg single standard deviation. Thus, there is speculation that some of the uncertainty may be artifacts on the filter. As such, real-time PM measurements are useful for identifying low level PM mass in addition to real-time analysis.

- Elemental carbon (EC) and organic carbon (OC) PM was very low for all the vehicles tested and was typically below 0.2 mg/mi and 2.2 mg/mi respectively. More than half (69%) of the measured EC and OC emissions were below the average ambient background concentration plus one standard deviation. The propane vehicles had the highest organic PM contribution (>10 mg/mi for the near dock port cycle).

- Fine-particle emissions were typically higher during the first 200 seconds of the cold start UDDS cycle compared to the hot stabilized UDDS cycle ($5x10^5$ #/cc vs $1x10^3$ #/cc, respectively). The fine particle emissions appear to be higher for the regional port cycle compared to the near dock, local, and UDDS cycles ($8x10^4$ #/cc vs $1x10^3$ #/cc, respectively). The higher concentration of the regional port cycle may be a result of higher ATS temperatures and possible passive regenerations.

The results for greenhouse gas emissions and fuel economy are summarized below:

- The greenhouse gases (GHG) and fuel economy are characterized by CO_2 emissions for the diesel vehicle, but with the LPG truck, methane emissions represented approximately 8% of the GHG. The diesel fuel economy averaged 3.5 mi/gal (Port 1, 2 and UDDS) to 5.06 mi/gal (Port 3) for the port vehicles, 7.0 mi/gal for the school buses, and 4.2 mi/gal (UDDS) to 2.0 mi/gal (RTC) for the refuse haulers. The regional cycle (Port 3) showed 20% higher fuel economy than the more transient Port 1, 2, and UDDS cycles. The fuel economy from the refuse trash cycle (with integrated compaction phase) was about 50% lower than the transient UDDS cycle. The propane port vehicle showed 19% lower fuel economy than the diesel vehicles (3.3 mi/gal).
- The project measured N_2O greenhouse gases on selected tests. For those vehicles measured more than half (64%) of the N_2O emissions were below 0.4 ppm, which is the average ambient background concentration plus one standard deviation. The emission factors averaged 3.6±1.9 mg/mi with a maximum of 18 mg/mi (Cum_11.9 near dock port cycle).

The results for cross laboratory check are summarized below:

- The work comparison averaged around 3% negative bias (-3%), where UCR's laboratory was slightly lower than WVU's, with a spread of -9% to +4% on average. Both WVU and UCR show very low test-to-test variability, with a coefficient of variation (COV) less than 2% for all tests.
- The bsCO_2 was close and averaged around 5% positive bias, where UCR's laboratory was slightly higher than WVU's with a spread of 0% to 10% overall. Both WVU and UCR show very low test-to-test variability, with a COV less than 3% for all tests.
- The bsNO_x correlation was also good, but the comparison varied for the SCR equipped vehicles due to the low emission levels and the variable conditions of the SCR. For the non-SCR equipped vehicles, the deviation averaged about 3% positive bias, where UCR's laboratory was slightly higher than WVU's, with an average of -2% to 8%. The NO_x correlation was poor for the cold start SCR equipped vehicles and for two refuse haulers due to variability in the aftertreatment systems.

In summary, the data from this study suggests that 2010 compliant SCR-equipped HDD vehicles are exhibiting high in-use NO_x emissions that can be as high as 2 g/hp-h under low load conditions represented by short trips or frequent stops. The cause of the high NO_x emissions appears to be low load exhaust temperatures and, thus, low SCR aftertreatment temperatures. For SCR-equipped diesel engines, some accounting of vehicle duty cycle and SCR exhaust temperature is needed to properly characterize NO_x inventories. Additionally, there were differences in SCR performance that varied between manufacturers, suggesting future performance will continue to vary. The ratio of NO_2 in the NO_x has been demonstrated to be about 45% for all diesel vehicles tested, where there is more variability with the SCR equipped diesels. Both NO_x emission factors and NO_2 ratios suggest NO_x emissions are more variable for SCR equipped diesels compared to non-SCR equipped diesel vehicles. This also suggests activity studies are needed to assess the impact of SCR performance on NO_x inventories. Other results showed the diesel PM, CO, THC, and selected toxics were all very low, well below certification limits, and near the limits of the measurement method for all the tests performed. The low PM, CO, THC, and selected toxics for all the diesel vehicles tested suggest these emissions are well controlled. Looking ahead, the overall results suggest NO_x emissions are still a concern for selected activities, and SCR performance needs to be investigated during wide in-use, on-road operation to characterize its impact on local inventories.

1 Introduction

1.1 Background

Emissions from heavy-duty trucks and buses accounted for about one-third of NOx emissions and one-quarter of PM emissions from mobile sources when stringent emission standards were introduced by the EPA on December 21, 2000 and by CARB in October 2001. The new standards, shown below, further reduced PM by 90% and NOx by 95% from existing standards.

- PM—0.01 g/bhp-hr
- NOx—0.20 g/bhp-hr
- NMHC—0.14 g/bhp-hr

The PM emission standard took effect in the 2007. However, the NO_x and NMHC standards were phased in for diesel engines between 2007 and 2010 based on the percent-of-sales basis: 50% from 2007 to 2009 and 100% in 2010. The regulation contained other provisions for meeting the NOx requirement so very few engines actually met the stringent standard of 0.20 g/bhp-hr before 2010. In addition to transient Federal Test Procedure (FTP) testing, the emission certification requirements included: 1) the 13-mode steady-state engine dynamometer test Supplemental Emissions Test (SET) test, with limits equal to the FTP standards, and 2) the not-to-exceed (NTE) emission testing with limits of 1.5 × FTP standards for engines meeting a NOx FEL of 1.5 g/bhp-hr or less and 1.25 × FTP standards for engines with a NOx FEL higher than 1.5 g/bhp-hr.

The implementation of the more stringent standards for heavy-duty highway engines was a key strategic element of the plan for improving air quality in the South Coast Air Quality Management District (AQMD). While measurements in laboratories were showing NOx and PM emissions meeting the stringent certification standards, some values from in-use conditions were showing increased emissions of ammonia from LNG trucks and of NOx from diesel trucks. Since there was a question about whether the in-use engines were meeting the stringent emission standards the AQMD Board authorized issuance of RFP #P2011-06 to assess the in-use emissions.

The RFP's objectives were to carry out chassis dynamometer testing of heavy-duty natural gas and diesel vehicles using near-certification and in-use driving cycles while measuring: 1) regulated emissions; 2) unregulated emissions such as ammonia and formaldehyde; 3) greenhouse gas levels of CO_2 and N_2O and 4) ultrafine PM emissions. The study would test about twenty-five heavy-duty vehicles used for transit, refuse and goods movement applications with engines fueled with natural gas, propane, diesel, and a combination of diesel and natural gas fuels. The engine fleet was sub-divided by emission standards and technology.

1.2 Objectives

The University of California, Riverside (UCR) was contracted to test 16 heavy-duty vehicles, mainly diesel fueled engines, used for goods movement, refuse and for transient applications. The testing protocol involved measuring the emissions identified in the RFP while the vehicles operated following driving cycles that better represented the in-use conditions rather than just certification conditions. For example, the trucks used in goods movement were tested on three port driving cycles; refuse haulers tested on the AQMD refuse hauler cycle and buses were tested on the central business district cycle. The contract involved cross-laboratory testing of some common vehicles with West Virginia University as part of the quality assurance program.

1.3 Technology Used for Meeting Low-Emission Limits

Meeting the very strict emission standards was a challenge for engine manufacturers and required them to develop technology solutions that looked at the integrated system of engine and after treatment. Furthermore the solutions for a diesel engine were not the same for an engine fueled by natural gas.

For control of PM from diesel engines, the engine manufacturers relied on Diesel Particulate Filters (DPF). In general, DPF control system consists of four sections: 1) an inlet, 2) a Diesel Oxidation Catalyst (DOC), 3) a DPF and 4) an outlet. Exhaust flows out of the engine and through a DOC before entering the DPF where PM is collected on the walls of the DPF. The collected carbon is oxidized to remove it from the DPF during the regeneration process. When operating conditions maintain high exhaust temperatures, the DPF is self-regenerating. Otherwise, an active regeneration is required to remove a build-up of PM and pressure drop in the DPF by adding diesel fuel upstream of the DOC. The chemical reaction over the DOC raises the exhaust gas temperature high enough to oxidize the carbon from the filter.

The control of NOx from diesel engines from 2007 to 2009 was met with the use of cooled exhaust gas recirculation (EGR) and a redesign of engine operating conditions. For the 2010 engines, EGR was continued for all manufacturers and all but one manufacturer, Navistar, adopted the use of Selective Catalytic Reduction (SCR)[1]. In the SCR process NOx is converted into nitrogen by the reaction with ammonia over a special catalyst. When operating temperatures are >250°C, an aqueous solution of urea is injected into the exhaust upstream of the SCR catalyst. The heat converts the urea into ammonia and water, which is the reactant to convert NOx to nitrogen. At temperatures <250°C, urea is not injected so the full engine out NOx emissions are emitted. SCR technology has a long history of successful operation in stationary sources.

Another path for meeting the stringent 2010 emissions limits was to design engines based on either natural gas or liquefied propane gas (LPG). Gaseous fueled engines meet the strict PM limits without a DPF. However, gaseous-fueled engines require technology for control of NOx. When designed and operated at stoichiometric conditions, then the engine can use three-way catalyst (TWC) technology, like that on gasoline vehicles. However, many engines operate as lean burn so NOx is higher than the 2010 limit and must be controlled with EGR and SCR technologies as used in the diesel engines.

1.4 Vehicle/Engine

The overall project included twenty-five on-road heavy-duty vehicles (test vehicles) used in the goods movement, refuse, and transit applications. Some are powered by diesel fuel and others by gaseous fuels. Some vehicles were added later to the matrix. The complete vehicle matrix is shown in Table 1-1 with a summarized view by technology in Table 1-2. The “Test Lab” column in Table 1-1 and the shaded portion of the matrix of Table 1-2 identify the vehicles contracted to UCR. The total vehicles contracted to UCR were 16 vehicles, nine port vehicles, five refuse haulers, and two school busses.

[1] On October 23, 2012 Navistar and Cummins announced deal on SCR emissions technology.

1.5 Test Cycles

Five driving cycles were chosen for this project and details are provided in Appendix A. While certification of an engine is carried out with an engine dynamometer these cycles were run with the engine installed in a chassis; hence a chassis dynamometer was used. Furthermore some of the selected driving cycles were to be more representative of in-use activity rather than certification. The matrix of selected driving schedules for each engine application is shown in Table 1-3. Table 1-4 summarizes the test matrix and unique vehicle ID for quick reference.

[1] Grey sections are shared vehicles between UCR and WVU

1.5.1 EPA Urban Dynamometer Driving Schedule (UDDS)

The EPA Urban Dynamometer Driving Schedule (UDDS) was a basis for the development of the Federal Test Procedure (FTP) transient engine dynamometer cycle for heavy-duty engines. While not the FTP, values from the UDDS on a chassis dynamometer are often compared with the values from a “certification test” run on an engine dynamometer. A comparison of the two test cycles is shown in Table 1-5. In this study the values from the UDDS were used to confirm that the selected engine was representative of the emission values for that technology.

The AQMD test program also included a cold-start UDDS as that is similar to the cold start FTP used in the certification testing. In a final certification procedure, the cold start values are weighted at 14% of the final number.

Table 1-5 Basic Parameters of the Cycle

	UDDS	FTP
Duration, seconds	**1060**	**1200**
Distance, km	**8.9**	**10.3**
Average speed, km/h	**30.4**	**30**
Dynamometer	**Chassis**	**Engine**

1.5.2 Port Drayage Cycles

Three port cycles were developed by TIAX for the Ports of Long Beach and Los Angeles based on the analysis of activity for over 1,000 Class 8 drayage trucks. Five characteristic operating parameters -- average speed, maximum speed, energy per mile, distance, and number of stops – were mapped to driver behavior. The driving behaviors are associated with specific activities such as queuing or on-dock movement, near-dock, local or regional movement, and highway movements. The final driving schedules, called the drayage port tuck (DPT) cycle, is represented by three distinct driving cycles, each composed of three phases. Some details are provided in Table 1-6.

Table 1-6 Drayage Truck Port Cycles

Drayage Truck Port cycles	Phase 1	Phase 2	Phase 3
Near-dock (2 to 6 miles)	Creep	Low Speed Transient	Short High Speed Transient
Local (6 to 20 miles)	Creep	Low Speed Transient	Long High Speed Transient
Regional (20+ miles)	Creep	Low Speed Transient	High Speed Cruise

1.5.3 AQMD refuse truck cycle (AQMD-RTC)

The refuse haulers will be tested using the AQMD refuse truck cycle (AQMD-RTC) that was developed by West Virginia University to simulate waste hauler operation in the AQMD District. The AQMD cycle is a modification of the William H. Martin Refuse Truck Cycle consisting of a transport segment (Phase 1), a curbside pickup segment (Phase 2), and a compaction segment (Phase 3).

1.5.4 Buses: Central Business District and Orange County Cycles

The Central Business District (CBD) Cycle is a chassis dynamometer testing procedure for heavy-duty vehicles. The graph of CBD cycle looks like a “sawtooth” driving pattern that is composed of idle, acceleration, cruise, and deceleration modes. The CBD is representative of the activity of in-use bus service.

The Orange County Bus Cycle (OCTA) is a chassis dynamometer test for heavy-duty vehicles developed by the West Virginia University (WVU) based on the driving patterns of urban transit buses in the Los Angeles, California area.

1.6 Fuel Selection

Commercial grade #2, ultra-low sulfur diesel fuel was used for the testing rather than fuel used for certification. Street fuel was more representative of what in-use vehicles would be using. Similarly, for the propane vehicles, locally supplied propane fuel was used in the testing as this was more representative of an in-use fuel.

For automotive propane usage Autogas is used for propane, Autogas is a mixture of propane with various contributions from other gasses. As such, locally supplied propane fuel meets the HD-5 specification for propane. As such it consist of at least 90% propane, no more than 5% propylene, and 5% other gases, primarily butane and butylene[2].

1.7 Emission Measurements

The contract specified the measurements of certain properties of the exhaust stream. These included:

- Regulated emissions: nitric oxides (NOx), particulate mass (PM), carbon monoxide (CO) and non-methane hydrocarbons (NMHC).
- Non-regulated emissions: ammonia (NH_3), benzene, toluene, butadiene, carbonyls (like formaldehyde).
- Greenhouse gases: nitrous oxide (N_2O), methane (CH_4), and carbon dioxide (CO_2)
- Ultrafine PM concentration and particle size distribution.

1.8 Engine Power Measurement

Engine break power was calculated using ECM broadcast J1939 standardized information. These signals are the same signals used for in-use compliance testing for the not-to-exceed standards in the 40 CFR Part 1065. A brief description is provided to describe the calculation and the results from the calculation. Equation 1 below shows the formula to calculate brake power:

$$bhp = \frac{RPM*(T_{actual}-T_{friction})*T_{reference}}{5252} \qquad \text{Eq 1}$$

Where:

bhp – is the brake power in units of (hp)

RPM – engine speed in revolutions per minute (rpm)

T_{actual} – ECM broadcast actual torque in (%)

[2] Alternative Fuels Data Center, US Department of Energy "Propane Fuel Basics, Office of Energy Efficiency and Renewable Energy, http://www.afdc.energy.gov/fuels/propane_basics.html

$T_{friction}$ – ECM broadcast friction torque in (%)

$T_{reference}$ – ECM broadcast reference torque in (ft-lb)

The engine speed, actual torque, and friction torque are real time second by second signals. The reference torque is a constant value and is fixed for each engine under test. Sometimes the reference torques is provided from the OEM and other times they can be downloaded from the ECM. Table 1-7 below lists all the reference torques used for this testing program. Two of the vehicles did not report a reference torque due to the ECM not supporting the latest J1939 data signals. The older format may be a result of the two vehicles being propane. As such, an estimated power was determined for these from the chassis dynamometer and previous tests for similar sized vehicles.

Table 1-7 Reference Torques Used for the Various Test Vehicles

Vocation	Mfg/Model/Yr	SN	Catalyst Type	RefTorque ftlb

[1] this vehicle did not report a reference torque because it utilized an older ECM interface since it was powered by propane fuel.

2 Vehicle and Chassis Testing Procedures

This section describes the vehicle inspection that covers safety, maintenance, emissions, and fault codes. UCR worked with WVU and the AQMD project manager to generate a common vehicle acceptance program, as described in the following section.

2.1 Vehicle Selection

Selecting a vehicle meeting the emissions and control technology shown on Table 1-2 was the first step in starting a vehicle on the process of evaluating its emissions from near in-use conditions. The vehicle selection process included a number of steps, shown below. All the vehicles selected by UCR were discussed with the AQMD project manager before any testing was initiated.

2.1.1 Safety inspection

Vehicles were first inspected for safety as part of UCR's routine vehicle inspection and acceptance practices. This involved reviewing recent vehicle maintenance records for brakes, steering, fluids, and tires. These records were usually in good shape with fleets due to California Highway Patrol requirements. In addition to the records of the vehicle owner, UCR independently inspected brakes, tires, and other items as shown in Appendix D.

2.1.2 Maintenance and usage history

The maintenance and vehicle usage history were documented in this study. Appendix D shows the list of maintenance and usage history information that were recorded. This includes mileage, rebuilds information, oil maintenance records and other details. A list of some ECM downloads and other records can be found in Appendix C.

2.1.3 On-site emissions inspection

On site emissions inspections were performed to ensure that the vehicles emission systems were operating as designed. These inspections included a snap and idle test to look for visible smoke, wiping the tail pipe for diesel soot with a clean cloth, and visually inspecting the EGR, aftertreatment system components and other details that could affect the emissions.

2.1.4 Fault codes

The final inspection was to connect an electronic tool to the engine ECM and identify active fault codes. If fault codes were active then the AQMD project manager and the owner were contacted before testing the vehicle. ECM readings and fault codes were documented at the end of the testing program to capture both the as-received and as-left condition of the vehicles. There were a few vehicles that UCR did not have the appropriate vehicle interface tools to download the ECM information. For these vehicles the leasing agency or other parties were utilized for the vehicle ECM downloading. In addition to ECM downloads, all vehicle dashboards were monitored for visual vehicle/engine faults. A list of all the downloaded and observed information for each vehicle tested is summarized in Appendix D.

There were no fault codes for any of the vehicles tested. The LPG vehicle also did not generate a fault code, but UCR felt the vehicle ran with a higher than usual coolant temperature and the

engine size seemed small relative to the chassis application. Unfortunately there was only one LPG port vehicle identified and available at the time of the study.

2.2 Chassis Dynamometer

In 2010, UCR installed a state-of-art heavy-duty chassis dynamometer that is capable of performing all of the cycles listed in the RFP. The new dynamometer handles buses and trucks at on-road driving conditions. The dynamometer includes a 48" Electric AC Chassis Dynamometer with dual, direct connected, 300 horsepower motors attached to each roll set. The dynamometer applies appropriate loads to a vehicle to simulate factors such as the friction of the roadway and wind resistance, as would be experienced under typical in-use driving conditions. A driver accelerates and decelerates following a driving trace while on the dynamometer. As the on-road driving conditions are simulated, emissions measurements will be collected with UCR's Center for Environmental College of Engineering Research and Technology's (CE-CERT's) Mobile Emissions Laboratory (MEL) that is described in subsequent sections.

2.3 Chassis Test Procedures

Testing on a chassis dynamometer was ideal for evaluating the effect of the in-use driving cycle on tail pipe emissions. To improve measurement accuracy, a repeatable test procedure was developed to reduce variability in the data due to: 1) the engine, 2) aftertreatment system (ATS), 3) the Mobile Emissions Laboratory (MEL) and 4) dynamometer conditions. For example, it was important to define an amount of time between tests, the so-called soak time. This section describes UCR's approach to pre-test conditioning to minimize variability and to maximize the quality of the comparison test data.

2.3.1 Setting up the dynamometer

The first activity with the dynamometer was adjustments for the coast down coefficients and for the load. The road load coefficients were calculated based on parameters; for example, the frontal area of the vehicle and a factor accounting for is general shape. The road load and associated coast down coefficients were verified with chassis dynamometer coast downs prior to testing. The targeted vehicle weights for each application varied for each application, as listed in Table 2-1.

Table 2-1 Test vehicle application weight selections

Vehicle Weights (lb)			
Transit	School Bus	Refuse	Goods Movement
34,500 [1]	20,000 [2]	56,000 [3]	69,500

[1] Typical weight of an average transit bus with passengers of 150 lb

[2] A school bus with a capacity of 64 passengers at 100 lb. The weight accounted here is the sum of the vehicle weight with school kids.

[3] Typically loaded refuse hauler in the SC AQMD district

2.3.2 Vehicle and dynamometer preconditioning

After adjusting the loads on the dynamometer, it was ready for the warm-up cycle. For test days with cold starts of either the UDDS or CBD tests, the cold start test was used as the

conditioning and warm-up cycle for the dyno. For test days without planned cold starts; for example the port and refuse cycles, the vehicle was warmed up using a preconditioning drive cycle representative of the application. Thus the preconditioning cycle was the AQMD Refuse for the refuse truck cycle, the OCTA for the OCTA cycle, and a modified version of the DTP cycle for the DTP cycle. Due to the length of the DTP cycles only the final phase of the DTP cycles was used and this is about 30 minutes.

The preconditioning cycles warm up both the vehicle and dynamometer to the conditions of the test configuration, thus reducing emissions variability between tests. This approach is commonly used for certification testing, fuels evaluations, and other repeatable test evaluations.

2.3.3 After treatment system (ATS) preconditioning (regenerations)

There were several discussions with committee members about whether or not to control regenerations from the DPF equipped test vehicles. Regenerations are known to cause variability in measured emission levels due to systems that are statistically not under control; for example, back pressure on the DPF, after treatment catalyst temperature, and DPF cleaning that involved adding and combusting raw diesel fuel in the exhaust line. If uncontrolled, each of these parameters will significantly affect the measured emissions so in this work regenerations were performed on a regular basis prior to or in between test to improve the repeatability of the test data.

Given that the nature of this study is targeting in-use emissions, it was decided to allow regenerations to occur while testing following the in-use cycles. If DPF cleaning/regeneration occurred during the test, that test was repeated and the data were treated as a unique sample and not averaged with the other non-regeneration data. The regeneration data were analyzed and reported separately to characterize emissions with regeneration. Several regenerations occurred during the test project. In the case of one refuse hauler, regeneration occurred on every test cycle so those emission results include regeneration since that was the norm.

2.3.4 Soak time between tests

Soak time or the time between tests is known as an important factor that needs to be standardized to ensure test repeatability. Practically speaking, time is needed between each test to load new filter and sorption media, check instrument calibrations, and give the driver a break. For reference, EPA protocol certification tests use a 20 minute engine off soak period to return the engine to stabile operating condition prior to the next test. As the EPA's recommended 20 minute interval proved sufficient to prepare all media and checks before subsequent tests, UCR used 20 minutes as the standard soak period for all cycles during this project.

3 Emissions Laboratory Setup and Checks

This section describes the measures performed for the mobile emissions laboratory (MEL) to ensure accuracy (trueness and precision) of the emissions data.

3.1 Emissions Measurement Laboratory

As the on-road driving conditions are simulated, emissions measurements were collected with *UCR's* Mobile Emissions Laboratory (MEL). UCR's Mobile Emission Lab[3,4] (MEL) measures criteria pollutants, particulate matter (PM), and toxics with a CVS system, all meeting federal requirements. As discussed in the previous section, MEL will be located next to the UCR heavy-duty chassis dynamometer and measure emissions from vehicles on the dynamometer. The MEL was the second HDD lab in the United States to meet 40CFR Part 1065 specifications and has successfully carried out cross laboratory comparisons of both gaseous and PM emissions with Southwest Research Institute in 2007 and 2009. Earlier cross correlation measurements were carried out with NREL in Denver in 2005, as well as with the ARB lab in Los Angeles. Results from UCR's mobile lab are recognized by the engine manufacturers and regulatory groups, including the US EPA and CARB, and the data are often used to support regulation.

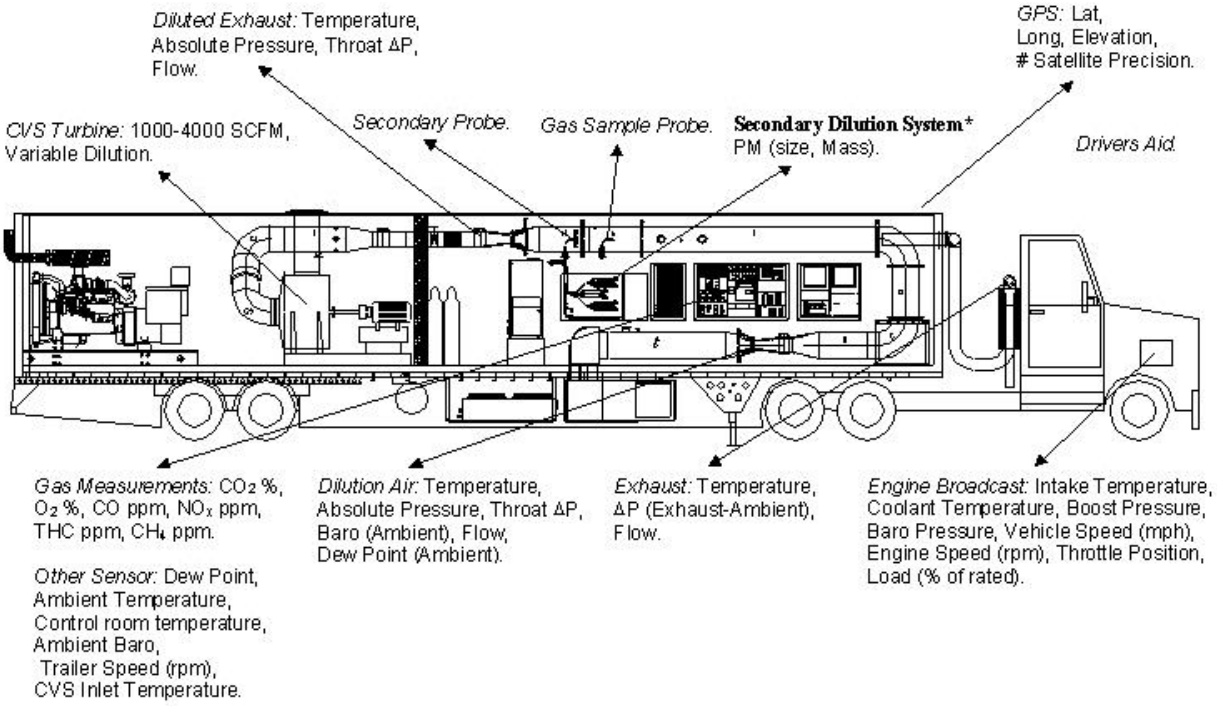

Figure 3-1 UCR's Mobile Emissions Lab (MEL)

---

[3] Cocker III, D. R., Shah, S., Johnson, K., Miller, J. W., Norbeck, J., *Development and Application of a Mobile Laboratory for Measuring Emissions from Diesel Engines. I Regulated Gaseous Emissions*, Environ. Sci. & Technology.,**2004**, 38,2182-2189

[4] Cocker, D.R.; Shah, S.D.; Johnson, K.J.; Zhu, X; Miller, J.W.; Norbeck, J.M., *Development and Application of a Mobile Laboratory for Measuring Emissions from Diesel Engines. 2. Sampling for Toxics and Particulate Matter,* Environ. Sci. & Technology, **2004**, 38, 6809-6816

The first research carried out in the new combined HDD chassis-MEL facility involved a comparison of emissions from federally mandated diesel fuel with those from the stricter California formulation. The project successfully tested 15 heavy-duty trucks over a 75-day period, and so can easily handle the 22 vehicles within the time period specified for this RFP.

Instruments within MEL continuously measure emissions of NOx, CO, CO_2, NMHC, and $PM_{2.5}$ with one-second resolution. The Dekati Mass Monitor (DMM) was used for real-time PM sampling. Ultrafines were monitored using UCR's unique fast-Scanning Mobility Particle Spectrometer (f-SMPS) analyzer[5], which is specifically designed for ultrafines. Integrated PM samples, such as PM mass and speciated PM, were collected on Teflo® and Quartz filters respectively.

The DMM measures PM mass concentrations through a combination of an electrical mobility diameter via particle charging and an aerodynamic diameter via inertial impaction over six stages of electrometers[6]. The combination of mobility diameter and number averaged aerodynamic particle diameter allows estimation of particle mass with the assumption of a log normal distribution. The aerodynamic diameters are estimated from six impactor electrometers that range from 0.030 um to 0.532 µm. The mobility diameter estimates the sub 30 nm particle diameters. If the distribution is bimodal, the DMM assumes an average density of 1 g/cm3. The DMM also has an inlet precut classifier set around 1.32 µm. The DMM was operated on the faster response option, as opposed to the lower detection option. The faster response setting is more typical for transient emission testing.

The f-SMPS is a key tool for measuring particle size distribution; however, use for transient cycles was limited to gathering data from steady state cycles as use was limited by the time resolution of the SMPS. For this study a unique instrument designed at UCR[7] was used to measure the near real time particle size distribution (PSD) with an emphasis on the ultrafine (<100nm) mass. The f-SMPS instrument utilizes a Radial Differential Mobility Analyzer (rDMA) and a Mixing Condensation Particle Counter (mCPC). The combination of these two components allowed the acquisition of particle size distributions range of 5–98 nm at rates of up to 0.4 Hz. For this research program the f-SMPS was setup for a 9 second scan time where typical SMPS's utilize a 90 second scan time.

Ammonia (NH_3) concentration was continuously measured using a Tunable Diode Laser (TDL) unit that is part of MEL. Data in Figure 3-2 show the very rapid release of NH_3 on acceleration and the quick response of the TDL used in UCR's earlier research. Other measurement

methods for ammonia, such as the dilute FTIR or a chemiluminescent analyzer, do not provide the needed response and accuracy during transient operation, as seen in other research[8].

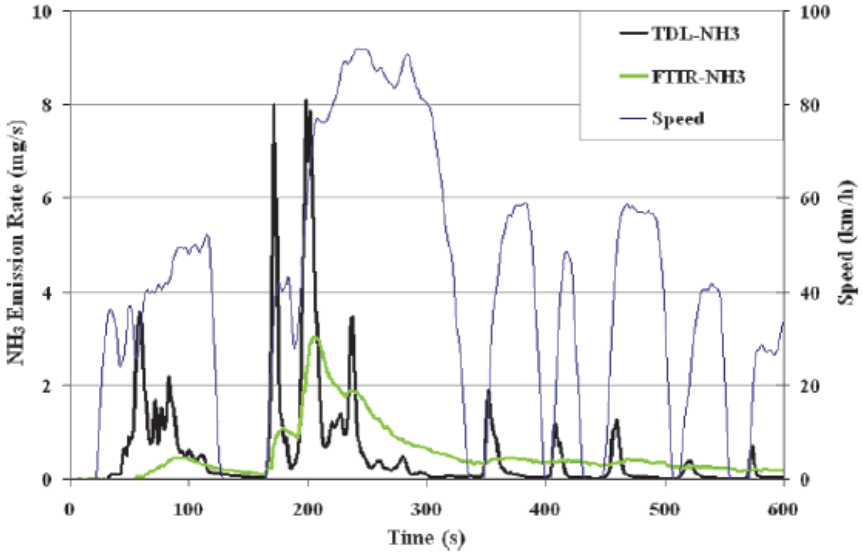

Figure 3-2 Comparison of FTIR & TDL Measurements of Ammonia Concentrations

3.2 Laboratory Setup for the Emissions Bench (MEL)

Prior to testing a number of steps were undertaken for the emissions lab (MEL) to ensure the testing was carried out according to CFR Part 1065 protocols. In addition to the real-time analyses in MEL, some samples, like PM Teflon filters, were moved to UCR labs for subsequent analysis. Those steps are described in this section

3.2.1 MEL dilution tunnel cleaning

Due to the low level of PM mass emissions expected from DPF equipped vehicles, the dilution tunnel in MEL was cleaned using a burn-out procedure developed at UCR. This procedure is used prior to testing any vehicle expected to have <5 mg/bhp-hr PM mass emissions and ensures that the measured PM is from the engine and not from materials desorbed from the tunnel walls. UCR's studies showed the procedure allowed PM measurements at the sub 1 mg/bhp-hr level and the main source of error is filter handling and not tunnel contamination.

In addition to reliance on experience of the burn-out procedure, UCR has carried out a routine check of the effectiveness by taking tunnel blanks. Summary data are available for MEL's tunnel blank and other blank reference checks as part of this research project.

3.2.2 MEL laboratory steps prior to test

This section summarizes the MEL's analyzers and support systems as per 40 CFR Part 1065 prior to, in between, and after testing for this program. The results from the pre-tests show successful linearity for all the MEL analyzers, chassis load cell, micro balance, humidity, and

[8] Huai, T., T.D. Durbin, J.W. Miller, J.T. Pisano, C.G. Sauer, S.H. Rhee, and J.M. Norbeck. **2003**. *Investigation of NH_3 Emissions from New Technology Vehicles as a Function of Vehicle Operating Condition*. Environ. Sci. & Technol., vol. 37, 4841-4847.

other integrated systems. Steps prior to test and startup are included in a checklist as part of the SOP for MEL.

3.3 Laboratory Setup for the Off-line Analyses

This section provides information about the various analyses that were carried out in the UCR labs after the chassis test. Each of these test methods follows a Standing Operating Procedure created according to the EPA protocol guidance document[9].

3.3.1 Filter weighting for PM mass

The mass concentrations of $PM_{2.5}$, metals and ions were acquired by analysis of particulates collected on 47mm diameter 2µm pore Teflo filters (Whatman brand). The filters were measured for net gains using a UMX2 ultra precision microbalance with buoyancy correction following the weighing procedure guidelines of the Code of Federal Regulations (CFR) (2). Before and after collection, the filters were conditioned for 24 hours in an environmentally controlled room (*Tdry* = 22 C and *Tdew* = 9.5C or 45%RH at *Tdry* 22C) and weighed daily until two consecutive weight measurements were within 3µg.

3.3.2 Measurement of Elemental and Organic Carbon (EC-OC)

OC/EC analysis was performed on samples collected on 2500 QAT-UP Tissuquartz Pall (Ann Arbor, MI) 47 mm filters that were preconditioned at 600°C for 5 h. A 1.5 cm_2 punch is cut out from the quartz filter and analyzed with a Sunset Laboratory (Forest Grove, OR) Thermal/Optical Carbon Aerosol Analyzer according to the NIOSH 5040 reference method.

3.3.3 Measuring Carbonyls

Carbonyls are collected on 2,4-dinitrophenylhydrazine (DNPH) coated silica cartridges (Waters Corp., Milford, MA) after a Teflon filter. A critical flow orifice controls the flow to 1.0 LPM through the cartridge and the sample time is adjusted to draw a known volume of exhaust sample through the DNPH cartridge so that the amount of formaldehyde on the cartridge is at the mass level recommended by Waters. Sampled cartridges are extracted using 5 mL of acetonitrile and injected into an Agilent 1100 series high performance liquid chromatograph (HPLC) equipped with a diode array detector. The column is a 5µm Deltabond AK resolution (200cm x 4.6mm ID) with upstream guard column. The HPLC sample injection and operating conditions are set up according to the specifications of the SAE 930142HP protocol. Samples from the dilution air are collected for background correction.

3.3.4 Measuring volatile toxic compounds

Traditional air monitoring methods for direct measurement of very-volatile and volatile organic compounds (VVOC/VOC) are insensitive at the low levels found in exhaust from lean burn engines. Accordingly, UCR uses selective adsorbents for concentrating the molecules of interest after diluted exhaust gas passes through a Teflon filter. After collection, adsorbents are returned to the laboratory where the adsorbed molecules are flashed into a

[9] United States Office of Environmental Protection Agency Information Bulleting EPA/600/B-07/*001 Guidance for Preparing Standard Operating Procedures (SOPs)* EPA QA/G-6, April 2007

concentrator/reservoir at low temperature, and then controllably vaporized into a gas chromatograph with a field ionization detector (GC/FID).

Molecules starting at approximately C_4 (butadiene) to C_6 (benzene) to C_{12} are effectively collected and concentrated on an adsorbent column composed with a multi-bed carbon bed including molecular sieve, activated charcoal, and carbotrap resin; each adsorbent has a specific selectivity towards certain boiling ranges or polarity. The adsorbent material first contacted in the column adsorbs the most volatile compounds, while the remaining compounds adsorb sequentially in relation to their volatility. The GC sample injection, columns, and operating conditions are set up according to the specifications of SAE 930142HP Method-2 for C_4-C_{12} hydrocarbons. Samples from the dilution air are collected for background correction

3.3.5 Measuring nitrous oxide (N_2O)

N_2O emissions were collected in a Tedlar bags and analyzed using an outside laboratory equipped with a MKS Fourier Transform Infrared (FTIR) system. The absorption cell for the FTIR has a volume of 5 liters, and the residence time in the cell is approximately 10 seconds. UCR's N_2O FTIR was not available at the time of testing, thus, off-site analyses were carried out by the California Air resources Board and West Virginia University. Since the analysis of N_2O was performed off-site UCR did not measure all vehicles in the test program due to logistics. Thus the analysis of N_20 only reflects those vehicles sampled.

4 Quality Control/Quality Assurance

This section covers some of the quality control/assurance planning that was taken to assure the accuracy of the data.

4.1 Cross-laboratory Correlation

Five diesel vehicles were tested at both UCR and WVU. Although six laboratories are required for a statistically significant comparison, the data obtained from this study still allow a comparison of values from two independent laboratories and create a measure of the confidence in the accuracy of the data since the two laboratories would presumably not have the same bias in the data sets. Three port vehicles and two refuse haulers were jointly tested and comparative data for engine work and brake specific emissions are presented. The vehicles tested represent three different emission level categories from less than 0.2 g/bhp-hr to 1.2 g/bhp-hr NO_x emission levels.

This cross-laboratory correlation task serves as a quality check for the emissions data that were collected independently by each laboratory. This correlation attempts to compare the emissions testing procedure of both laboratories that will include both the chassis dynamometer loading of the vehicle and the associated emissions measurement system. Although both WVU and UCR may adopt different procedures to conduct an emissions measurement campaign, the resulting data should be within an acceptable tolerance for real-world representativeness in each laboratory. Both UCR and WVU conducted the emissions measurement within immediate succession to prevent test vehicles going back into service. This procedure ensured the vehicle condition remained the same between WVU and UCR with no engine faults or maintenance conducted between the test intervals. Both laboratories tested the vehicle during day time conditions in Riverside Ca (as WVU was located only 5 miles away from UCR with their mobile laboratory setup)

Table 4-1 through Table 4-5 show the UCR and WVU engine work and selected emissions for five different shared vehicles including the cycle to cycle averaged coefficient of variation (COV). The emissions comparison is on a brake specific basis and includes $bsCO_2$, $bsNO_x$, bsPM, and $bsNH_3$ with units of g/bhp-hr for all species. Chassis dynamometer data is traditionally reported as distance-specific. However, for laboratory comparison purposes, changes in vehicle loading procedure and dynamometer setup can result in differences in distance-specific emissions. Therefore, brake-specific emissions were chosen as metric for comparison as components such as CO_2 are linear with work done by the engine.

Engine Work:

Five diesel vehicles were tested by both UCR and WVU for cross-laboratory comparison. Although six laboratories are required for a statistically significant comparison, the data obtained from this study still allow a comparison of values from two independent laboratories and create a measure of confidence in the accuracy of the data since the two laboratories would presumably not have the same bias in the data sets. Three port vehicles and two refuse haulers were jointly tested and comparative data for engine work and brake specific emissions are presented. The vehicles tested represent three different emission level categories from less than 0.2 g/bhp-hr to 1.2 g/bhp-hr NOx emission levels.

This cross-laboratory correlation task serves as a quality check for the emissions data that were collected independently by each laboratory. This correlation attempts to compare the emissions testing procedures of both laboratories, including the chassis dynamometer loading of the test vehicle and the associated emissions measurement system. Although both WVU and UCR may adopt different procedures to conduct an emissions measurement campaign, the resulting data should be within an acceptable tolerance for real-world representativeness in each laboratory. Both UCR and WVU conducted the emissions measurement within immediate succession before returning test vehicles back into their regular revenue service. This procedure ensured the vehicle condition remained the same between WVU and UCR with no engine faults or maintenance conducted between the test intervals. Both laboratories tested the vehicle during day time conditions in Riverside CA (as WVU was located only 5 miles away from UCR with their mobile laboratory setup).

Tables 1-5 show the UCR and WVU engine work and selected emissions for five different shared vehicles including the cycle to cycle averaged coefficient of variation (COV). The emissions comparison is on a brake specific basis and includes bsCO2, bsNOx, bsPM, and bsNH3 in g/bhp-hr. Although chassis dynamometer data is traditionally reported as distance-specific, for laboratory comparison purposes, changes in vehicle loading procedure and dynamometer setup can result in differences in distance-specific emissions. Therefore, brake-specific emissions were chosen as metric for comparison as components such as CO2 are linear with work done by the engine.

ENGINE WORK

Engine work was calculated from ECU reported actual engine percent torque, nominal friction torque, engine speed and reference torque. Although the design of the two chassis dynamometers are vastly different, with, WVU absorbing power directly at the wheel and hub and UCR absorbing power using rollers, the work comparison averaged around 3% negative bias (-3%) where UCR's laboratory was slightly lower than WVU's with a spread of -9% to +4% on average. Both WVU and UCR show very low test to test variability with coefficient of variation (COV) less than 2% for all tests.

There were a few test vehicles that showed small absolute work biases and others with relatively large biases. Typically the work differences were around ±5% (5 hp), but for two port regional cycles the power difference was as higher with one at 9 hp difference (#2 vehicle) and another at 14 hp difference (#3 vehicle). Both UCR and WVU investigated their power numbers with chassis dyno wheel torque and other power metrics and found all the measurements presented were valid. Interesting for both UCR and WVU most of the vehicles on the port cycles generated the same amount of work (107 bhp-hr) except for these two vehicles. On these two vehicles, UCR was high by 13 bhp-hr for the #2 vehicle and WVU was low for the by 25 bhp-hr for the #3 vehicle.

CARBON DIOXIDE

The $bsCO_2$ is the most suitable metric for cross-laboratory comparison, since CO_2 is an accurate indicator of both fueling and work. Fueling of the engine is highly liner with engine work, and therefore a similar work between the two laboratories should result in a similar $bsCO_2$. This

metric will provide the comparison of the emissions measurement system of the two laboratories. This comparison also normalizes chassis dynamometer setup differences to evaluate the ability to measure engine conditions. The bsCO_2 was very close and averaged around 5% positive bias where UCR's laboratory was slightly higher than WVU's with a spread of 0% to 10% overall. Both WVU and UCR show very low test to test variability with COV less than 3% for all tests.

OXIDES OF NITROGEN

For SCR equipped diesel engines the efficiency of control is highly dependent on temperature; in fact, conversion of NOx increases exponentially with temperature. As a consequence, small temperature differences during a test will lead to different NOx emissions from one laboratory to another. The importance of temperature is evident in the test data in that the COV results for CO_2 can be approximately 1% and can be as high as 10% for NOx. Given this backdrop the observed differences between the two laboratories in the NOx levels for the SCR-equipped vehicles are reasonable.

The cold start NOx variability between UCR and WVU is expected due to different catalyst conditions for the testing. Differences at low emission levels for the SCR-equipped vehicles are not a significant difference, but represent an expected variability for aftertreatment systems and NOx emissions.

The Navistar engine in Vehicle #2 was 0.7 g/bhp-hr different in brake specific NOx emissions for UCR and WVU during the regional port cycle. Since both showed very good agreement for bsCO2 (0% difference) the higher NOx may be a result of higher sustained loads for the UCR test compared to the WVU test. The Navistar engine utilized an advanced NOx system to approach a 0.5 g/bhp-hr certification level. If UCR had a slightly higher load then Vehicle #2 results could be related to the DPF regeneration and NO_2 used in that process.

Test vehicle #4 (advanced EGR refuse vehicle) shows a significant difference in NOx emissions measured over the SCAQMD-RTC cycle and not the UDDS cycle. The two laboratories showed a NOx emission factor ranging from 0.25 g/bhp-hr to 0.29 g/bhp-hr for the UDDS cycle, but 0.28 g/bhp-hr to 1.56 g/bhp-hr for the SCAQMD-RTC cycle. Figure 4-1 shows the accumulated NOx for two of UCR refuse cycles. The NOx emissions, from 0 to 2000 seconds, were around 0.29 g/bhp-hr (almost a perfect match with WVU). After 2000 seconds, the UCR measured NOx emission increases dramatically to 3.6 g/bhp-hr for the end of the curbside portion of the cycle and all of the compaction part of the cycle. WVU did not measure the same high NOx during the compaction part of the cycle.

To further understand the NOx emissions from these higher EGR engines during partial regeneration and non-regeneration operation, WVU had instrumented the vehicle with pre DPF and post DPF tailpipe NOx sensors. These sensors are installed by WVU for internal sanity check of the measured data. Figure 4-2 and Figure 4-3 show the pre and post DPF NOx concentrations during a test in which no DPF regeneration was detected and during a test in which a partial regeneration was detected. It can be observed that the DPF in these vehicles are contributing to a significant reduction in NOx concentrations during vehicle operation. This can be attributed to the continuous passive regeneration of the catalyzed DPF to utilize NO_2 to light-off soot

accumulation. On an average the DPF contributes to 68% reduction in engine-out NOx during normal vehicle operation. However, in some instances when passive soot light-off is insufficient, the engine strategy employs one or more different approaches to improve soot light off. The approaches included an in-cylinder increase in NOx concentration together with exhaust fuel injection. Figure 4-3 shows a partial active regeneration event during which a significant increase in NOx emissions is observed followed by a return to normal vehicle operation towards the end of the test.

UCR data for the refuse truck cycle could be characterized by such an event, which is beyond the control of the test laboratory and hence could have resulted in a significant difference in brake-specific NOx emissions.

Test vehicle #5 (SCR equipped refuse vehicle) showed a difference in NOx between 0.18 g/bhp-hr and 0.25 g/bhp-hr on the UDDS cycle. This difference is small considering the test to test variably was high. The high variability is again related to stability of the SCR.

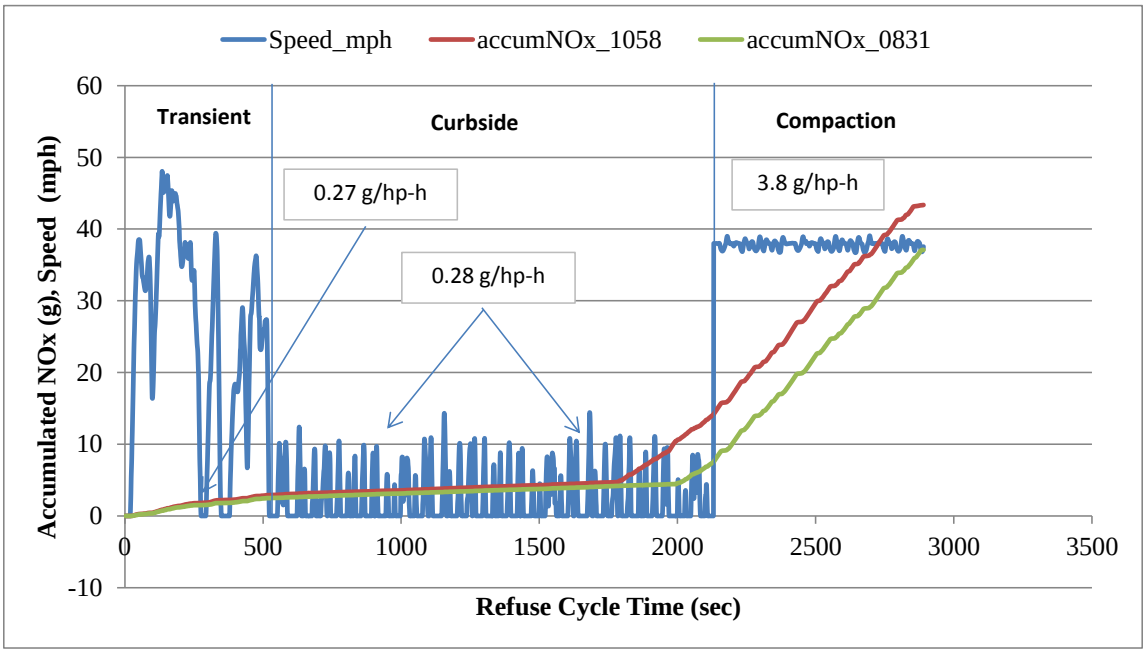

Figure 4-1 Refuse hauler shared vehicle #4 (Navistar A260 2011)

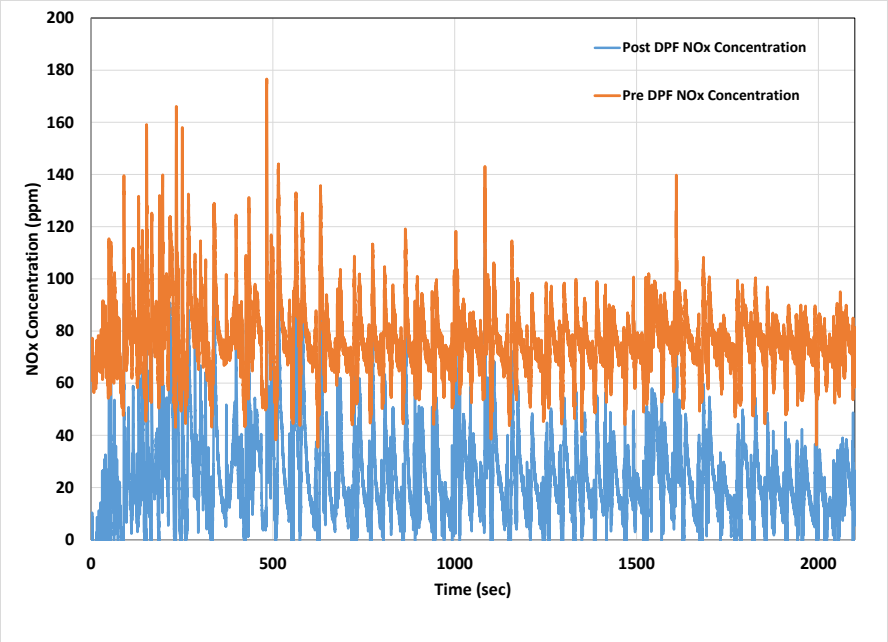

Figure 4-2 Pre and Post DPF NO_x concentration for a non-regeneration vehicle operation

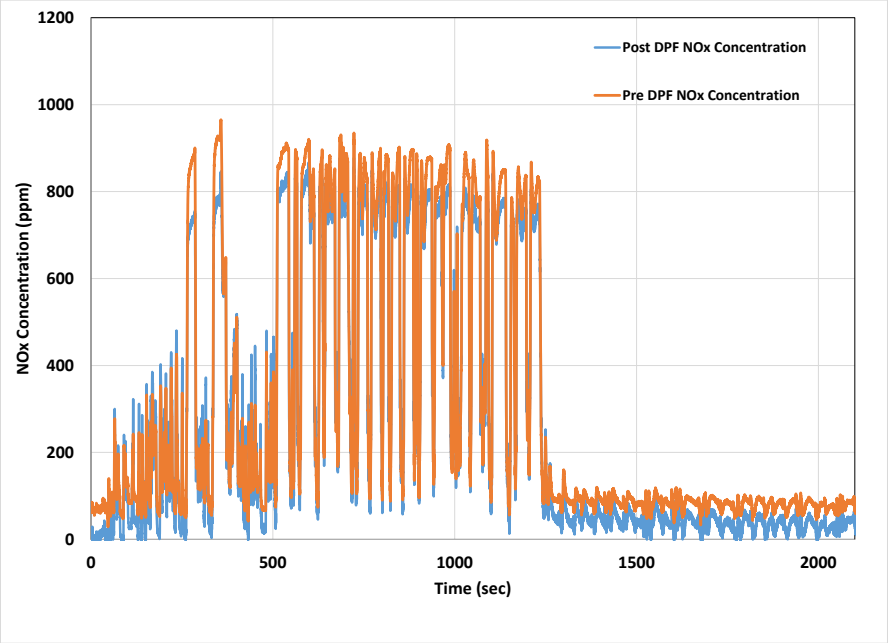

Figure 4-3 Pre and Post DPF NO_x during partial active regeneration during refuse truck cycle

Particulate Matter:

The bsPM emission levels were low for both UCR and WVU and were below the PM certification value for all tests and typically around 10% of the standard (< 1 mg/bhp-h) as expected for a properly functioning DPF. The PM emissions were thus similar between both laboratories and no significant outliers were identified.

Ammonia:

The bsNH_3 emissions were very low where there was no statistical difference between the different vehicles. As suggested for UCR, see Section 8.6, most of the NH_3 measurements were at or just above the lower detection limits of UCR's NH_3 measurement method. WVU also suggested several of the vehicles showed no quantifiably NH_3 emissions. The NH_3 emissions were thus similar between both laboratories and no significant outliers were identified.

Report Summary:

[1] The COV is the coefficient of variation defined as one standard deviation divided by the averaged measured value. For PM and NH_3 the measurements were small and thus the COV was calculated as Stdev/10mg/bhp-hr for PM was used and Stdev/60mg/bhp-hr for NH_3.PM = 10 mg/bhp-hr was used based on the 10 mg/bhp-hr certification standard and 60 mg/bhp-hr is used based on an average of 10 ppm flow weighted limit for the raw exhaust.

[2] Blank values represent only one value or no data available. For example there were only single cold start tests and thus no COV was calculated. The dashes for NH_3 indicate no COV was practical.

[2] Blank values represent only one value or no data available. For example there were only single cold start tests and thus no COV was calculated. The dashes for NH_3 indicate no COV was practical. WVU did not have a cold start test on this vehicle due to vehicle availability.

4.2 Post-test QC Procedures

4.2.1 MEL carbon balance

Mass balances are a standard engineering check. For selected vehicles, UCR compared the carbon balance between the fuel flow rate reported by the ECM and the carbon measured in MEL's analytical instruments. An example of this comparison is shown in Figure 4-4.

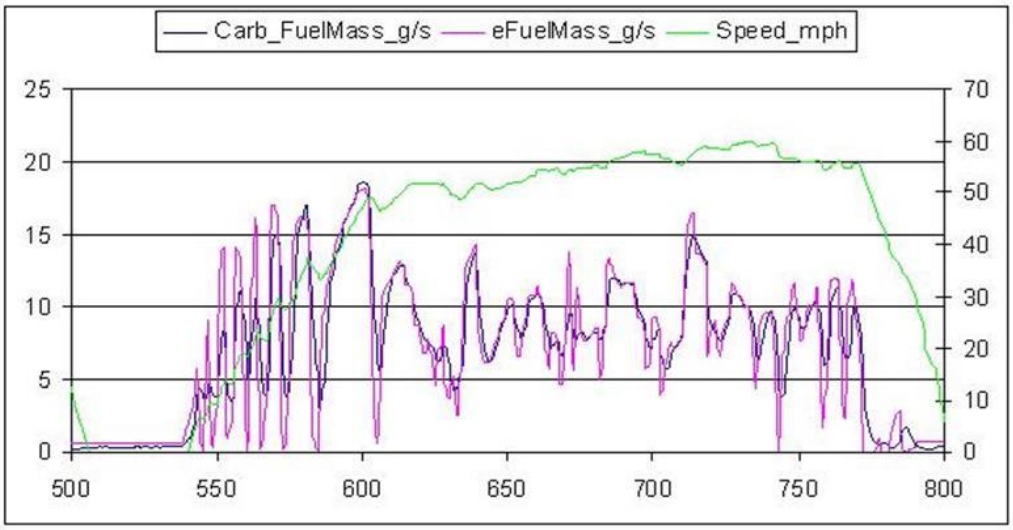

Figure 4-4: Real time second by second ECM and carbon balance fuel rate (port cycle)

While the visual agreement between ECM and measured fuel flow is good, a more quantitative measure of the closeness of fit is a parity chart of all data for a typical regional port cycle, as shown in Figure 4-5. The coefficient of determination, denoted R^2, is 91% and while generally considered quite acceptable, there appeared to be a greater deviation at the low values for

carbon flow. It appeared as though the ECM flow was less than that measured. Further investigation was warranted.

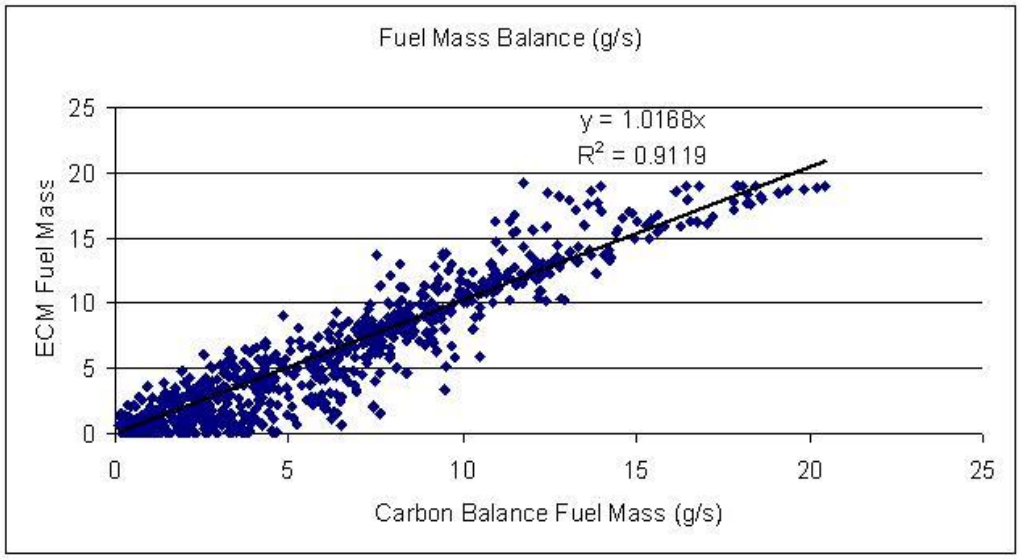

Figure 4-5: Parity Plot of Data from ECM and Exhaust Measurements (port cycle)

The further investigation compared the mass balances of selected engines for various engine manufacturers and test cycles. For example, Figure 4-6 shows plots of the UDDS, near dock, local port, and regional port cycles for a Navistar, Cummins and Volvo engine. For high loads and fuel flow rates, the coefficient of determination was 99% for all three manufacturers and the relative error ranged from +6% to -2%, excellent agreement. The same data were re-plotted in Figure 4-7 with the parameter being the test cycle. Phase 1 of the port cycle has the lowest load/fuel rates and this portion of the port cycle showed the highest uncertainty, ranging from -20% to + 60%, or 10-times that found at high flow/power rates. On the other hand, data for the UDDS cycle with relatively high power and fuel flow rates showed an excellent mass balance comparing MEL and the ECM. Data from this research confirms the findings of previous research that showed fuel rate is inaccurate below 30% load

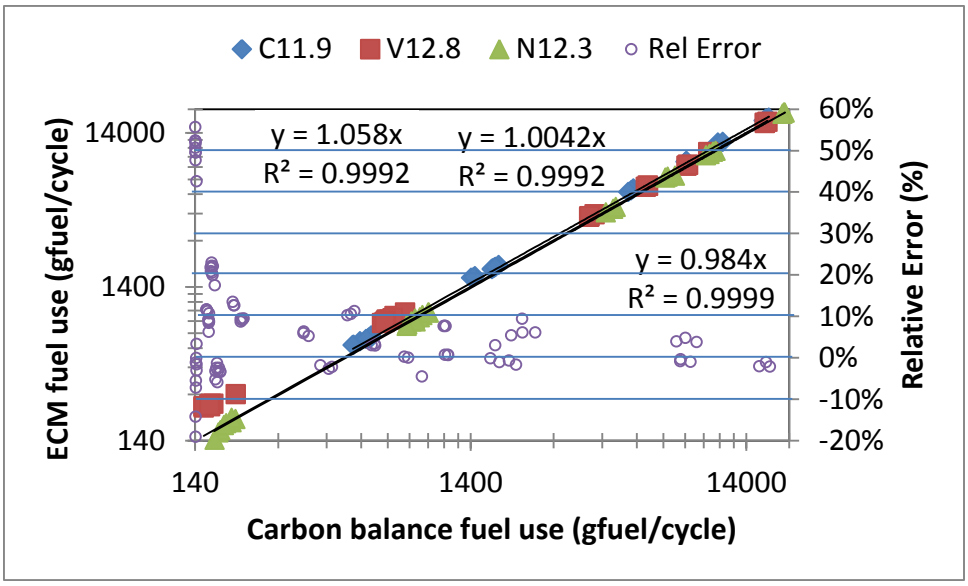

Figure 4-6: Carbon balance for all three port cycles and the UDDS cycle

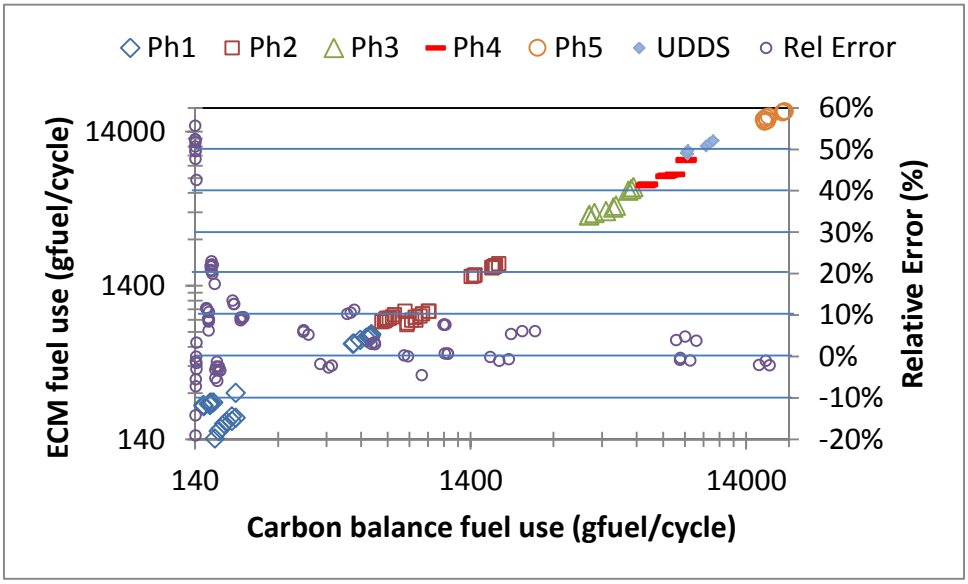

Figure 4-7 Carbon Balance Correlation on a test cycle basis

4.3 MEL quality control NTE

NTE data was calculated for selected vehicles to show representativeness of the cycles relative to in-use compliance NTE calculation methods. The NTE data presented does not include the measurement allowance since a reference laboratory was used and not PEMS. The following results provide perspective on the emissions generated by the vehicles and the type of cycle selected for this in-use study. The true emissions impact for this project should be drawn from the emissions results section.

Figure 4-8, Figure 4-9, and Figure 4-10 show the bsNOx NTE emissions for a 2009 Navistar, 2011 Navistar, and a 2010 SCR equipped Cummins engine. All three NTE method calculations are provided in the figures and show that all NTE data pass the in-use requirements for both the Navistar 2011 and Cummins 2010 vehicles. Only the 2009 Navistar vehicle showed bsNOx emissions that exceeded the in-use NTE standard during the regional port cycle.

For the Cummins SCR equipped engine, only one point exceeded the in-use NTE standard and it was excluded due to temperature exclusions as per 1065. No NTE's were generated for the near dock and local port cycles except for two with the 8.3 liter Cummins engine. Only the UDDS and regional port cycles generated NTE values as defined by 1065.

4.4 MEL quality control checks

During the data analysis phase of this project the repeated tests were evaluated for consistency. This includes analyzing the variability between replicates by plotting the single standard deviation. All tests identified as greater than 2-3 times the standard deviation were viewed as outliers and investigated. Below are the following test points that were investigated for this project.

Table 4-6: Tests investigated for repeatability and consistency

ID	Cycle	Species	Issue	Action
Cummins/ISX11.9/2011	PDT_1	PM	stdev	valid

5 Results and Discussion for Goods Movement Vehicles

The results are reported in several sections, according to application. This first section focuses on the heavy, heavy-duty gas trucks and is followed by buses. This order can be justified from data in SCAQMD's 2012 AQMP as show in Table 5-1 where the HHD trucks are about 80% of truck/bus emissions in 2014 and about 70% in 2023. Focusing on the vehicle category with the greatest emissions contribution to the inventory provides the AQMD with the most likely path to achieving their goal of reducing NO_x.

Table 5-1 Data from the SCAQMD's 2012 AQMP (tons NO_x/day)

Code	Source Category	2014	2023
736	Heavy Heavy Duty Gas Trucks ((HHD)	1.02	0.96
746	**Heavy Heavy Duty Diesel Trucks (HHD)**	**76.43**	**32.63**
760	Diesel Urban Bus (UB)	13.4	11.03
762	Gas Urban Bus (UB)	0.76	0.70
772	Diesel School Buses (SB)	2.15	1.81
777	Gas Other Buses (OB)	0.86	0.53
	Total	94.62	47.66

Emission factors for all cycles are presented on the basis of grams per mile and for the UDDS cycle as grams per brake-hp-hr in order to compare with FTP values and. The emission factor in grams/mile is more useful for inventory purposes.

5.1 Test Trucks

Nine trucks used for good movement were tested on a number of chassis cycles. Selected information for the trucks were identified and listed in Table 1-1. The LPG vehicle in Category VI was the only one found to be available in the Los Angeles area so we presume the market share is very small for such vehicles. LPG truck odometer reading was 103,608 but the truck owner said the engine was installed in an existing chassis and the engine mileage was <20,000 miles.

5.2 Test Conditions

Vehicles were tested on the UDDS cycle and on three port cycles that more closely represented in-use activities for a goods movement vehicle. The loads for the goods movement vehicles were set at 69,500 lb. load and street #2 CARB diesel fuel was used. Both load and fuel matched in-use conditions. The emission values represent the average of triplicate runs and the graphs show the confidence limits to one standard deviation.

5.3 Emissions from the UDDS Cycle

As mentioned earlier, the brake specific emissions values from the UDDS chassis dyno test are often compared with the values measured in the heavy-duty FTP certification test on an engine dyno. This comparison provides some indication that the selected vehicle is representative of

the desired FEL and technology. This section focuses on NOx emissions given the interest in the original RFP.

5.3.1 Brake-specific emissions from Hot UDDS Cycle

Figure 5-1 shows the UDDS values for NOx in Category IV ranged from 1.6 to 2.7 g/bhp-hr versus a certification standard of about 1.2 so values for the hot UDDS are on the high side. Category VI has the only LPG Class 8 truck that we were able to find in the Los Angeles area. Although there were no fault codes on the vehicle, it was difficult to test (engine near overheating) and the emissions were higher than anticipated. The engine did not appear to be sized properly for the chassis and perhaps was leaner than expected. Future evaluations of LPG vehicles are needed to confirm these high results. For Category VII, emissions for the non-SCR or Navistar trucks were >0.2 g/bhp-h as expected as they were using solely using EGR, a unique shifting strategy and NOx emission credits. Values were about 1g/bhp-hr for the Navistar. Finally the Category VII with SCR had the lowest NOx emissions. The UDDS values ranged from 0.06 to 0.27 and were close to the certification values.

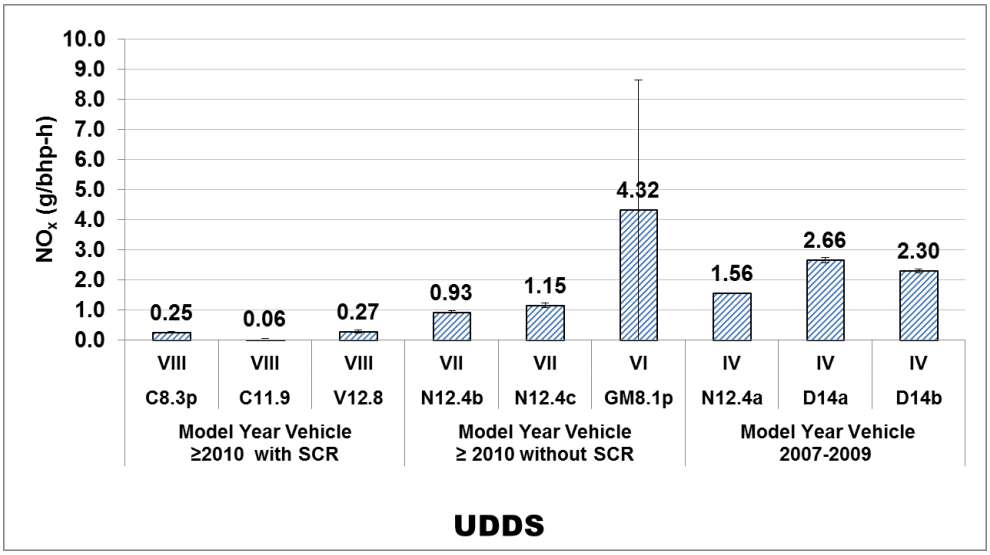

Figure 5-1 Brake Specific NOx Emissions for UDDS Cycle

5.3.2 Brake-specific emissions from Cold UDDS Cycle

Brake-specific emissions from cold UDDS cycle are shown in Figure 5-2 and values for the emission factors are increased significantly, about double for Category VII with SCR. Smaller increases were observed for Category IV with just EGR technology but then the emissions levels are about 10x those of systems with an SCR. For example the Navistar increased from about 1.6 to 1.7 and the DDC from 2.7 to 3.0. When the SCR is cold, raw engine out emissions are headed to the atmosphere.

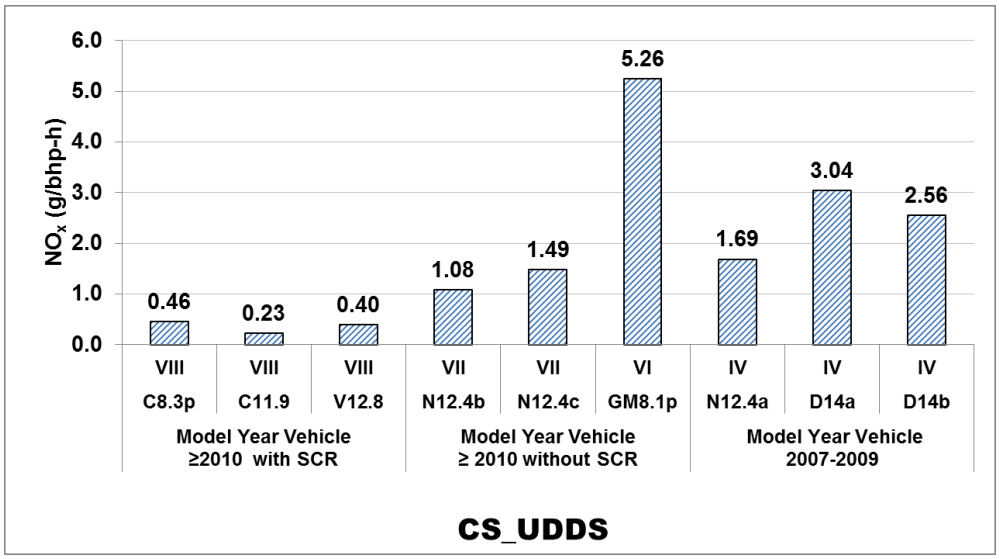

Figure 5-2 Brake Specific NOx Emissions for a Cold Start UDDS Cycle

[1] No error bars for the cold start tests because on only one test was performed

5.3.3 Emissions in g/mile for the UDDS cycle

Results were also analyzed and calculated on the basis of the emissions being expressed in grams per mile, the figure needed for calculating the inventory. These data are shown in Figure 5-6.

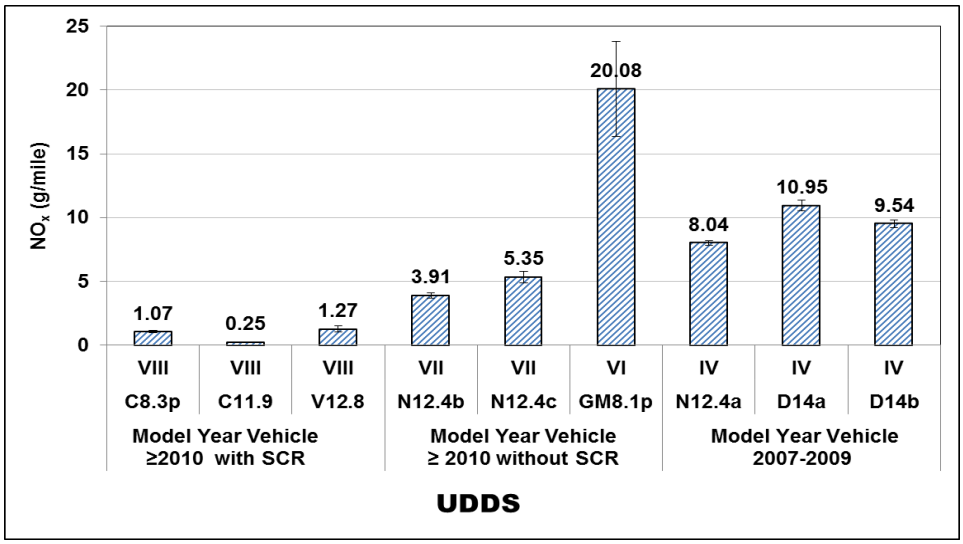

Figure 5-3: NO_x Emission Factors for hot UDDS cycle (g/mile)

Many have asked whether there is a relationship and a single factor to convert g/bhp-hr to g/mile. The answer to this question is presented in Table 5-2. The average factor is 4.45 with a coefficient of variation of 7.9%. This seems like a rather good fit considering the emission control technology varies widely. The value 4.5 compares with 3.5 used in earlier work.

Table 5-2 Relationship Between g/mile & g/bhp-hr for the Hot UDDS

Units									
g/mi	1.07	0.25	1.27	3.91	5.35	20.08	8.04	10.95	9.54
g/bkhp-hr	0.25	0.06	0.27	0.93	1.15	4.36	1.56	2.66	2.3
ratio	4.28	4.17	4.70	4.20	4.65	4.61	5.15	4.12	4.15

NOx emissions in g/mile for a cold UDDS cycle are presented in Figure 5-4. Values were a multiple of the values for the hot UDDS cycle, as expected. Note that NOx emissions 1 mile after cold start equal 2 miles after hot start.

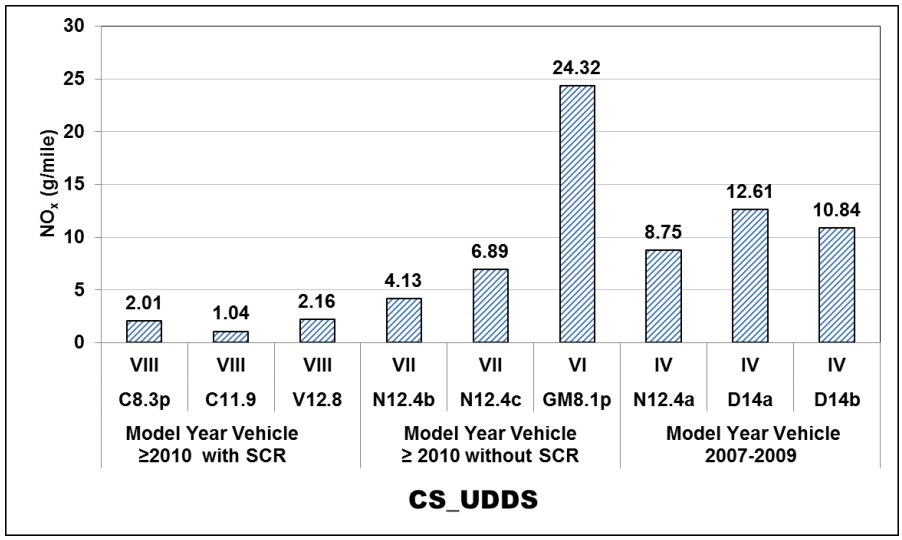

Figure 5-4: NO_x Emission factors for Cold Start UDDS Cycle (g/mile)

[1] No error bars for the cold start tests because on only one test was performed

Apportioning the NOx emissions into NO and NO_2 was part of the analysis. These data are shown in Table 5-3. Excluding the LPG truck, the percentage of NO_2 ranges from 24% to 59% and most values are >50%. These values are reminiscent of the early retrofit data and the subsequent rule that limited the increase above baseline to a 20% increase. Thus if the baseline was 10%, then the control technology was limited to 30%,

Table 5-3: Fraction of NO_2 to total NO_x for the Vehicles on the UDDS cycles

Vehicle			Port UDDS			Port UDDS_CS		
Category	Engine	MY	NO_2	NO_x	$\%NO_2$	NO_2	NO_x	$\%NO_2$
VIII	C8.3p	2010	0.54	1.07	50%	0.51	2.01	25%
VIII	C11.9	2011	0.15	0.25	58%	0.24	1.04	23%
VIII	V12.8	2011	0.30	1.27	24%	0.17	2.16	8%
VII	N12.4b	2011	2.19	3.91	56%	1.82	4.13	44%
VII	N12.4c	2011	2.18	5.35	41%	2.16	6.89	31%
VI	GM8.1	2009	0.05	20.08	0%	0.07	24.32	0%
IV	N12.4a	2009	3.08	8.04	38%	2.83	8.75	32%
IV	D14a	2008	6.13	10.95	56%	6.25	12.61	50%
IV	D14b	2008	5.60	9.54	59%	5.33	10.84	49%

Figure 5-5 shows the NOx emissions for the cold and hot start UDDS cycles for the port vehicles. In general NOx increased for the cold start and varied by a factor of 3 higher for the Cummins 11.9 SCR equipped vehicle (C11.9) to only a 6% increase for the Navistar 12.4 liter non SCR equipped vehicle (N12.4b). The cold start NOx emissions were much higher (160%) for the SCR equipped vehicles compared to the non-SCR equipped vehicles (only 15% higher). This shows that non-SCR cold start NOx emissions are not as big an impact as SCR equipped engines.

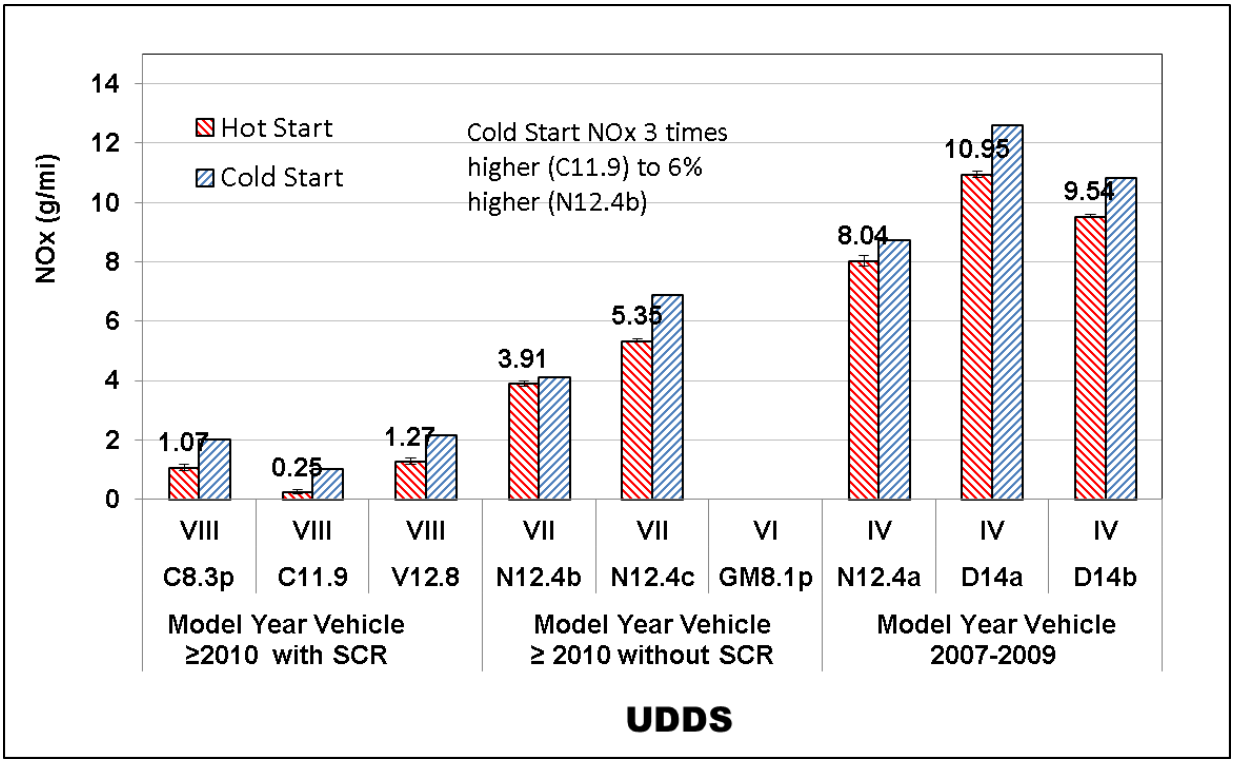

Figure 5-5 NOx emissions compared between cold and hot start UDDS cycles

5.4 Regulated Emissions from Port Cycles in grams/mile

Goods leaving the ports on HDD trucks travel over many routes and distances, few of which resemble the federal FTP driving schedule. Accordingly, the ports contracted TIAX to data log

and create driving schedules that better represented the in-use activity of trucks entering and leaving the ports. Based on travel distance, TIAX developed three driving schedules: 1) near dock; 2) local and 3) regional. Data are presented for each of the driving schedules.

5.4.1 NO_x emissions

The NO_x emission results in g/mile for the different port cycles are presented in Figure 5-6, Figure 5-7 and Figure 5-8. Clearly the single LPG truck remains an outlier and data suggest the engine is running lean or not properly configured for the chassis. Additional LPG vehicle testing is needed to confirm these results. That truck is not further discussed.

Trucks with SCR and EGR technology had the lowest NOx emissions with the observation that the longer the truck drove; that is the regional cycle, the lower the overall emissions. Presumably longer distances raise average catalyst temperature resulting in lower overall emissions.

Trucks with EGR and an active DPF showed a similar pattern with longest driving times resulting in the lowest emissions. Since nitrogen and oxygen in air react to form NOx, one suspects that the concentration of oxygen is higher for the near dock cycle. This hypothesis is being confirmed. In-use data did show excellent repeatability of the DDC product in the field.

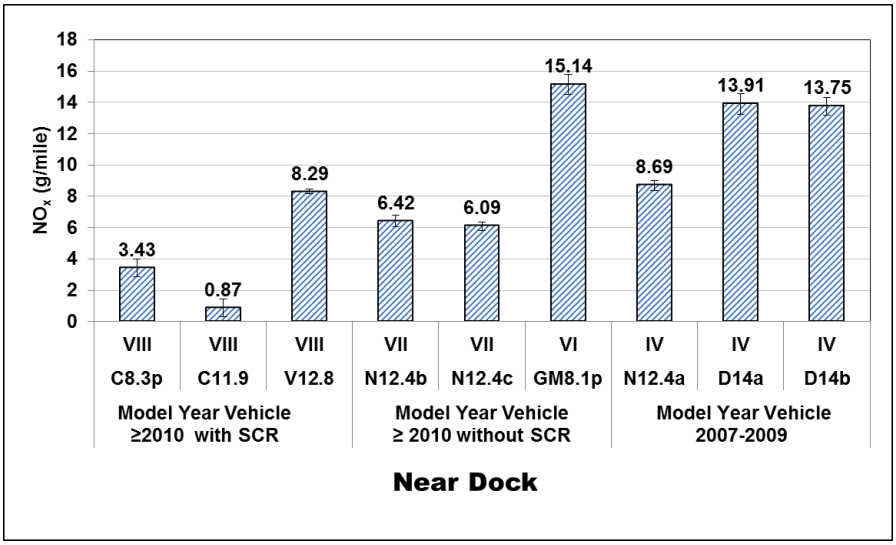

Figure 5-6: NO_x Emission factors for Near Dock Cycle (g/mile)

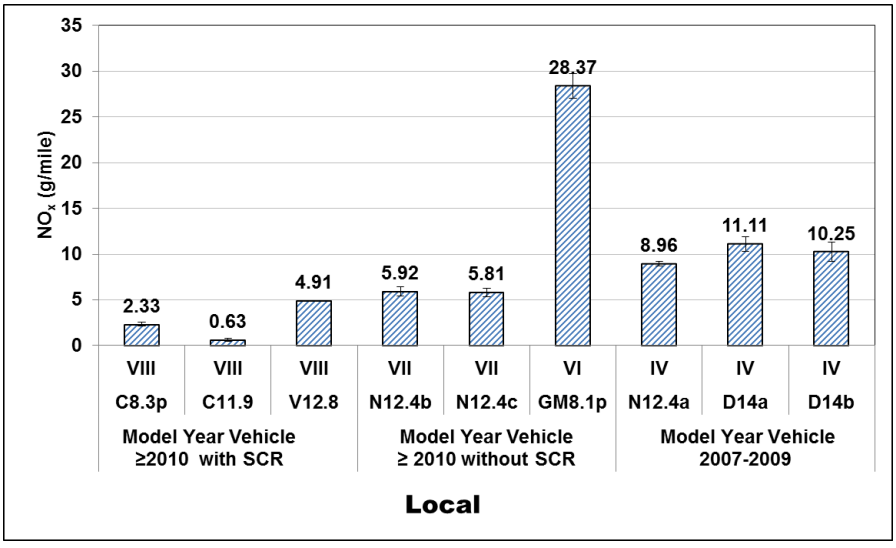

Figure 5-7: NOx Emission factors for Local Cycle (g/mile)

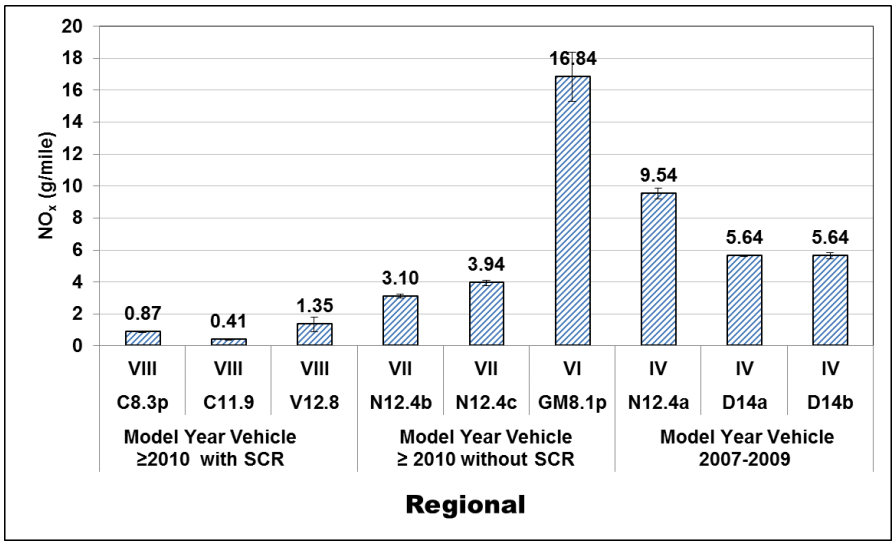

Figure 5-8: NOx Emission factors for Regional cycle (g/mile)

Category VII trucks had similar emissions for different driving cycles. These were the Navistar technology of cooled EGR and DPF. As mentioned in the background section, a discussion of these data is not warranted as this technology was pulled from the market and no longer offered.

5.4.2 Percentage of NOx emissions as NO_2

Apportioning the NOx emissions into NO and NO_2 for the port cycles was part of the analysis. These data are shown in Table 5-4. Excluding the LPG truck, the percentage of NO_2 ranged from 5% to 91%. Not surprising, the highest NO_2 level was observed for the vehicle with the lowest NOx level. Literature studies reveal that NO_2 reacts slower than NO over the SCR catalyst. Similar to the observation with the UDDS cycle, levels of NO_2 are high as compared with the ARB retrofit rule of 20% over baseline.

Table 5-4: Fraction of NO_2 to total NO_x for the Port Cycles

Vehicle			Near Dock			Local			Regional		
Category	Engine	MY	NO_2	NO_x	$\%NO_2$	NO_2	NO_x	$\%NO_2$	NO_2	NO_x	$\%NO_2$
VIII	C8.3p	2010	1.65	3.43	48%	1.18	2.33	51%	0.39	0.87	45%
VIII	C11.9	2011	0.79	0.87	91%	0.58	0.63	92%	0.36	0.41	86%
VIII	V12.8	2011	0.45	8.29	5%	0.28	4.91	6%	0.14	1.35	10%

IV	N12.4a	2009	3.18	8.69	37%	3.47	8.96	39%	4.17	9.54	44%
IV	D14a	2008	6.26	13.91	45%	6.59	11.11	59%	3.13	5.64	55%
IV	D14b	2008	5.12	13.75	37%	5.17	10.25	50%	3.04	5.64	54%

5.4.3 PM emissions

PM emission results for the different port cycles are presented in Figure 5-9, Figure 5-10, and Figure 5-11. Except for the LPG truck, PM emissions were ≤2 mg/mi for most vehicle/cycle combinations. There were a few vehicle/cycle combinations above 2 mg/mi for some of the 2010+ vehicles on the Regional and near dock cycles.

Figure 5-12 shows the PM emissions for the cold start and hot start UDDS cycles with the propane vehicle results removed. The cold start PM emissions for the Cummins 2010 SCR equipped 8.3 liter engine was 17 times higher than the hot start emissions (22.9 mg/mi vs 1.33 mg/mi respectively). After closer investigation it appears that a passive regeneration may have occurred as indicated by a high exhaust temperature, but no regeneration illumination lamp from the engine, see Real-Time analysis section. The cold-start PM was slightly higher for the other port vehicles tested, but the emission factors were still very low were the difference was not statistically significant based on the uncertainty of the measurement method and the low filter weight obtained.

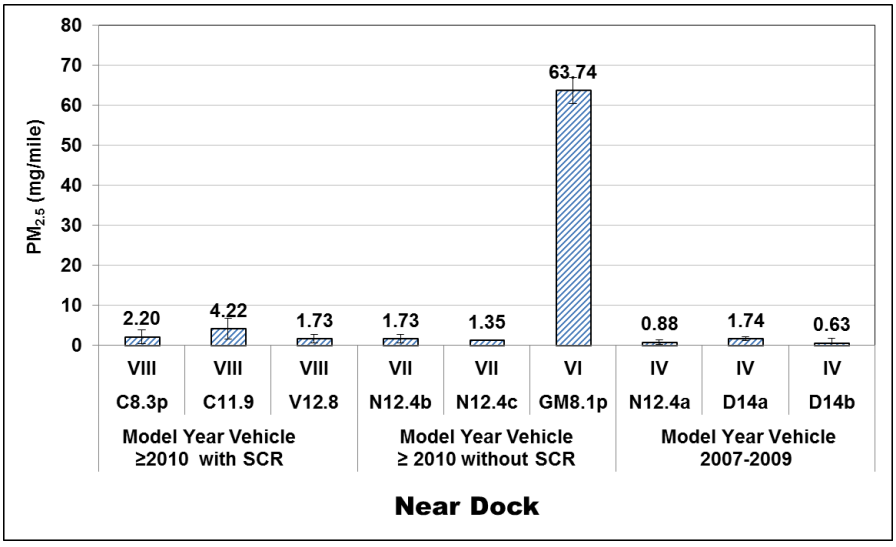

Figure 5-9: PM Emission factors for Near Dock cycle (g/mile)

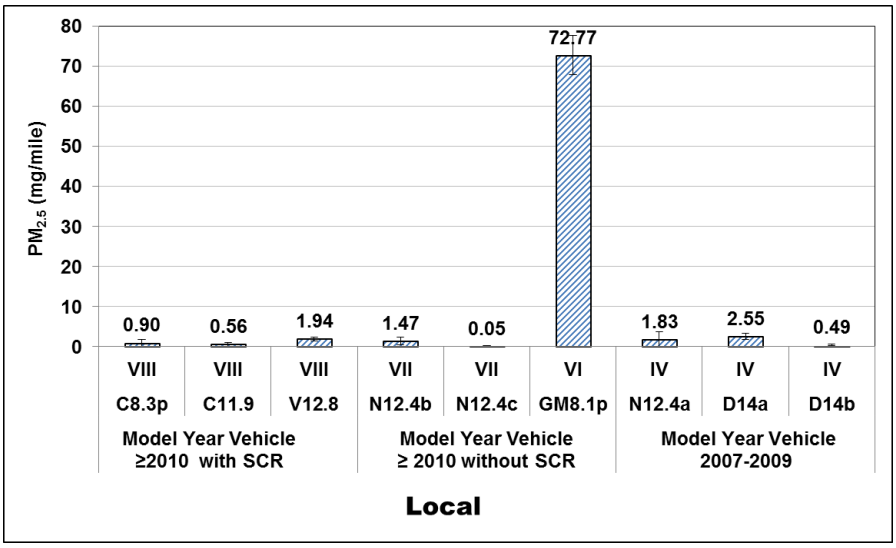

Figure 5-10: PM Emission factors for Local cycle (g/mile)

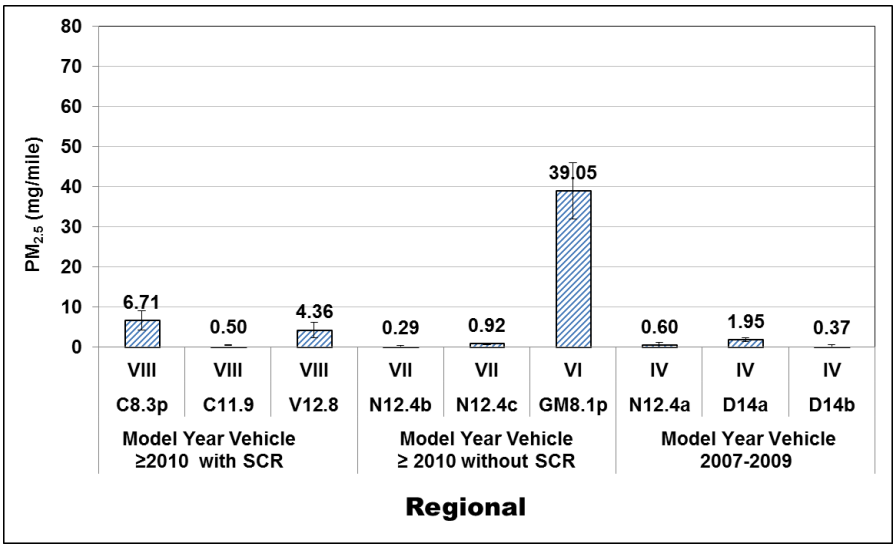

Figure 5-11: PM Emission factors for Regional cycle (g/mile)

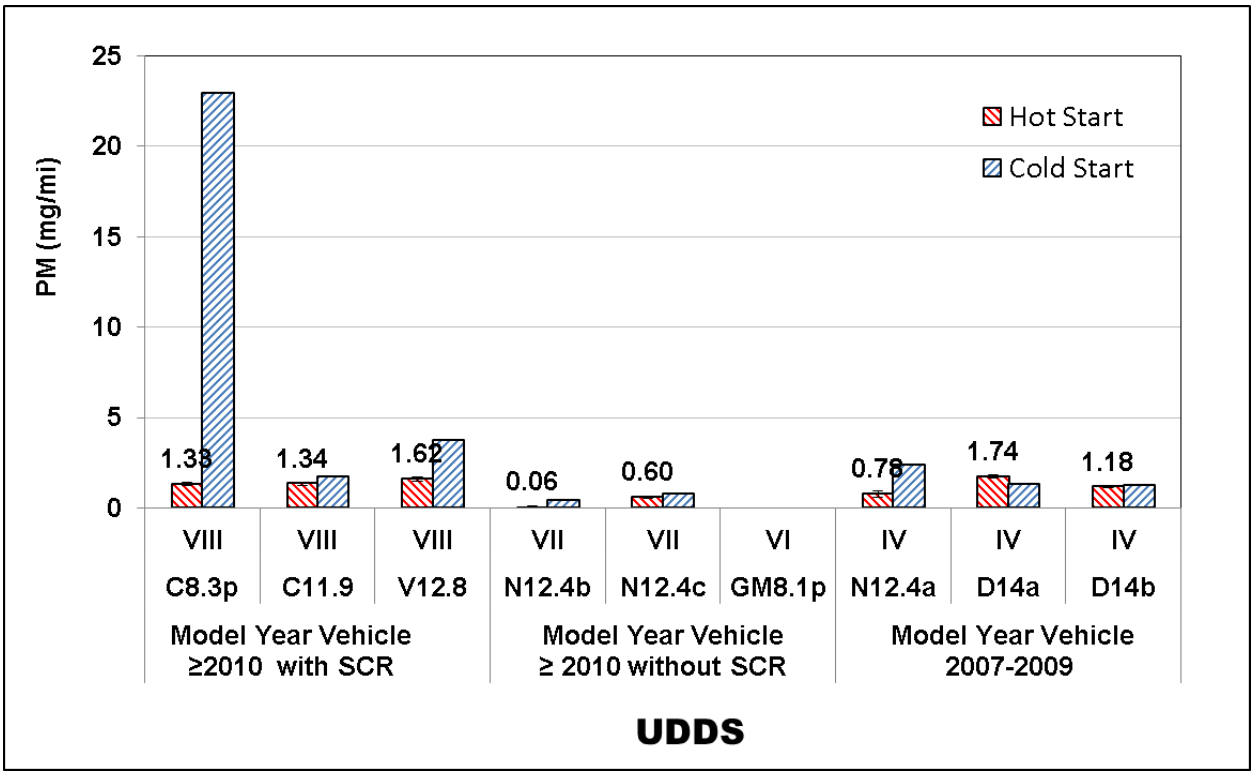

Figure 5-12 PM emissions for the cold and hot start UDDS cycles (port vehicles)

5.4.4 THC/NMHC/CH_4 and CO emissions—UDDS cycle

Table 5-5 and Table 5-6 show the emission factors for THC, CH_4, NMHC and CO for the hot and cold UDDS cycles. Except for the LPG truck, values are very low. This finding is not surprising given that the exhaust passes over a diesel oxidation catalyst (DOC) with noble metals, a catalyst that is well known to efficiently convert hydrocarbon and carbon monoxide to water and carbon dioxide.

Table 5-5: THC, CH4, NMHC, and CO emissions for the UDDS cycle

Vehicle			Emission Factor (g/mi)			
Category	Engine	MY	THC	CH4	NMHC	CO
VIII	C8.3p	2010	0.00	0.01	-0.01	-0.18
VIII	C11.9	2011	0.01	0.02	-0.01	-0.12

5.4.5 THC/NMHC/CH_4 and CO emissions—In-use port cycles

Table 5-7, Table 5-8 and Table 5-9 show the emission factors for THC, CH_4, NMHC and CO for all three port cycles. Except for the LPG truck, values are very low. As stated earlier this finding is not surprising given that the exhaust passes over a diesel oxidation catalyst (DOC) with noble metals, a catalyst that is well known to efficiently convert hydrocarbon and carbon monoxide to water and carbon dioxide. While truck emissions need to meet a carbon monoxide limit, the data show that NOx is more important as the measured values are <10% of the CO standard.

5.5 Non-regulated Gaseous Emissions

5.5.1 NH_3 emissions

Ammonia emissions were of interest for the trucks with the latest technology. Ammonia can be released from diesel trucks with SCRs if excess urea is added, so called ammonia slip. Ammonia is also created and released with trucks using natural gas as the three-way catalyst used for after treatment can produce ammonia by a complicated series of reactions on the catalyst surface. Results are shown from Figure 5-13 to Figure 5-17. NH_3 emissions ranged from approximately 10 to 100 mg/mi over all combinations of vehicle and hot cycles. Looking at the UDDS, the results show that vehicles had similar low ammonia releases with and without the SCR catalyst. This finding was true even with the lowest level of NOx measured when a SCR catalyst was used. The CS-UDDS cycle with SCR showed slightly higher NH_3 emissions than the other cycles suggesting a timing issue with the introduction of the urea.

Table 8-26 shows of the 54 diesel tests conducted, only 2 vehicles were 5 times the lower detection limit (LDL) (i.e. greater than 5ppm), and 26 tests were above 2 time the LDL (2 ppm), see Section 8.4.4 for discussion of the LDL's used in this report. Of the 2 tests above 5*LDL,

both were for a cold start SCR equipped diesel vehicle. For the 26 tests above 2* LDL these were both SCR and non-SCR equipped vehicles. It is not expected that a non-SCR equipped vehicle had more NH_3 emissions than an SCR equipped vehicle. Five of seven tests for the propane vehicle also had NH_3 greater than 5 ppm and 2 were over 50 ppm suggesting very high relative NH_3 emissions for the propane vehicles.

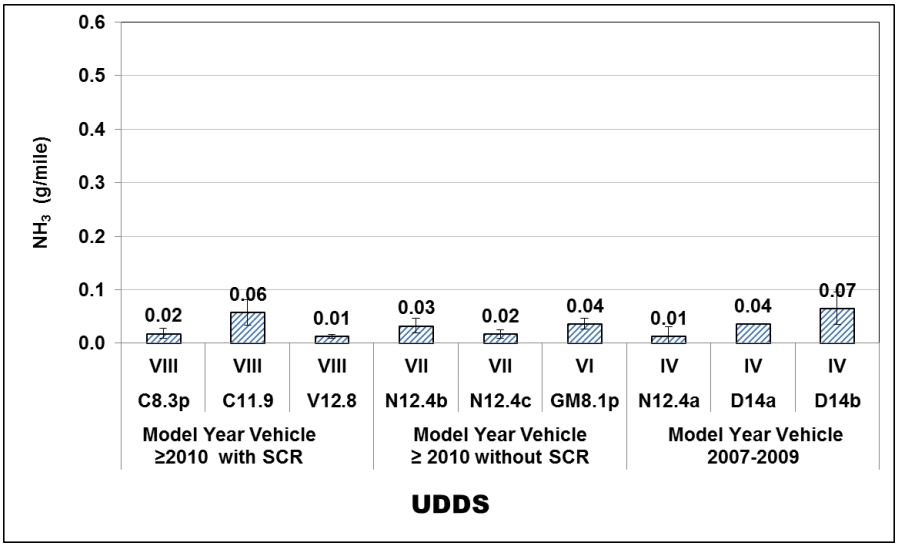

Figure 5-13: NH_3 Emission Factors for UDDS cycle (g/mile)[1]

[1] NH_3 scale is based on 10 ppm raw exhaust concentration

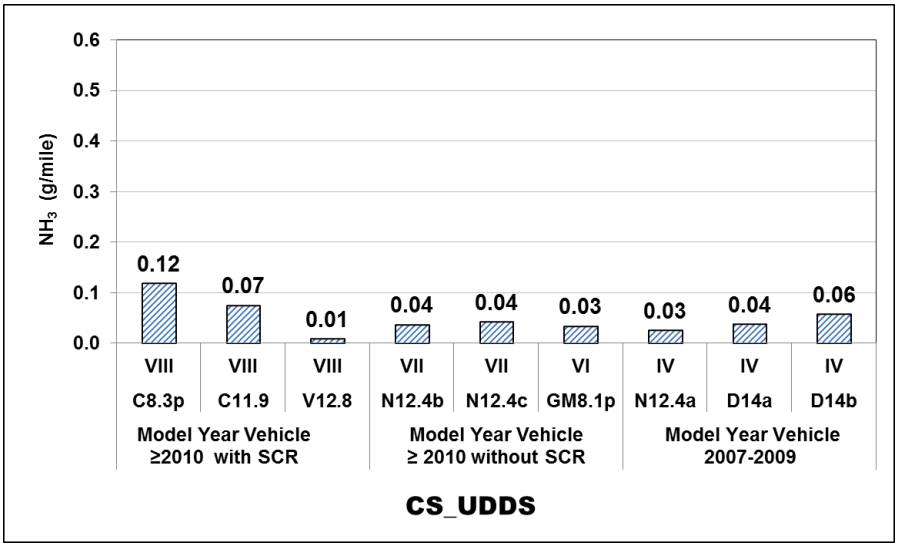

Figure 5-14: NH_3 Emission Factors for Cold Start UDDS cycle (g/mile)[1]

[1] NH_3 scale is based on 10 ppm raw exhaust concentration, thus 10 ppm NH3 in the raw exhaust will be approximately 0.6 g/mi (full scale) for perspective.

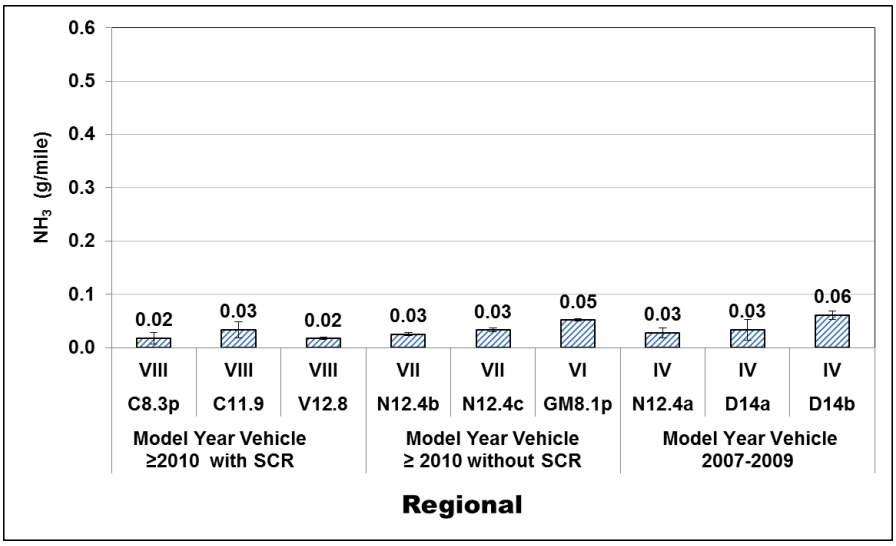

Figure 5-17: NH_3 Emission factors for Regional Cycle (g/mile)[1]

[1] NH_3 scale is based on 10 ppm raw exhaust concentration

5.5.2 Selected Toxic Emissions (1,3-butadiene and BTEX)

A slip stream of the exhaust was passed through tubes containing three beds of materials where hydrocarbon gases are adsorbed. Subsequent off-line analysis focused on the measurement of 1,3-butadiene and BTEX. Some early results for benzene were confounded with the co-elution of the butanol used in the CPC but those corrected results did not affect the conclusions. Basically with the DOC catalyst associated with the DPF the ACES project showed that all hydrocarbon emissions would be very low. Results are shown in Figure 5-18 to Figure 5-21. Except for the Navistar vehicles and a couple of apparent outliers, the rest of the values are <10mg/mile, at levels that were near the detection limit of the method. In some cases when exhaust emissions are compared with the ambient values, results are negative values showing the vehicle levels were below ambient levels. High uncertainty levels are one consequence of being near the low detection level.

The propane vehicle showed high BTEX emissions where the vehicles tested averaged 6.5±9.3 mg/mi, 9.7±12 mg/mi, and 22.4±19 mg/mi of 1,3-Butadiene, n-butane, and Benzene emissions respectively. The remaining BTEX species were below 2 mg/mi and were not statistically significant.

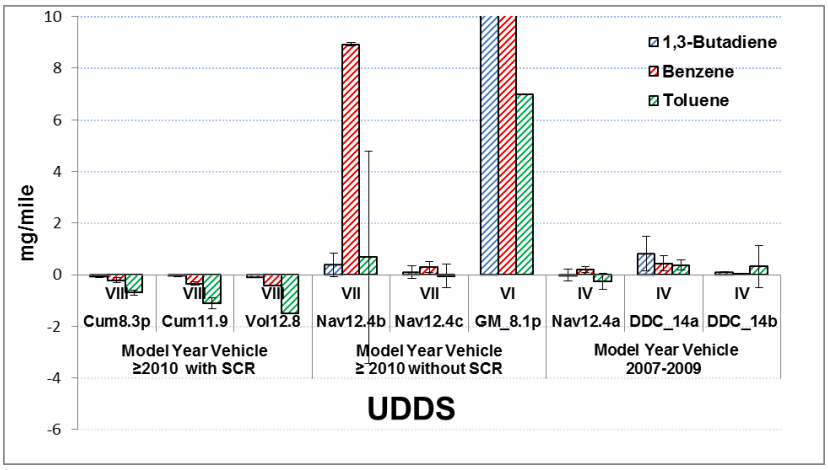

Figure 5-18 Emissions in mg/mile for Butadiene & BTEX for the UDDS Cycle

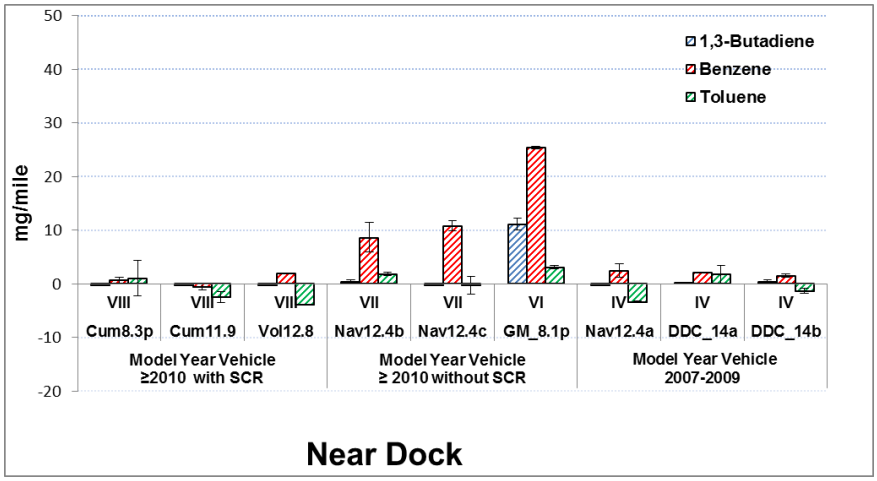

Figure 5-19 Emissions in mg/mile for Butadiene & BTEX for the Near Port Cycle

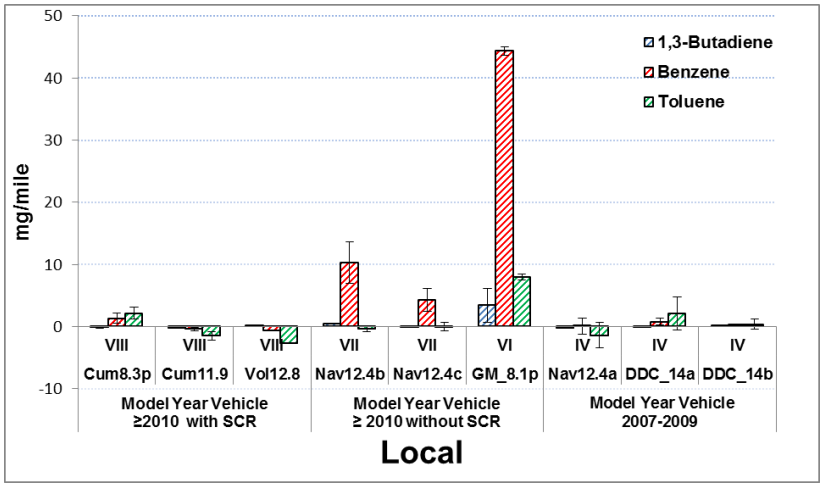

Figure 5-20 Emissions in mg/mile for Butadiene & BTEX for the Local Port Cycle

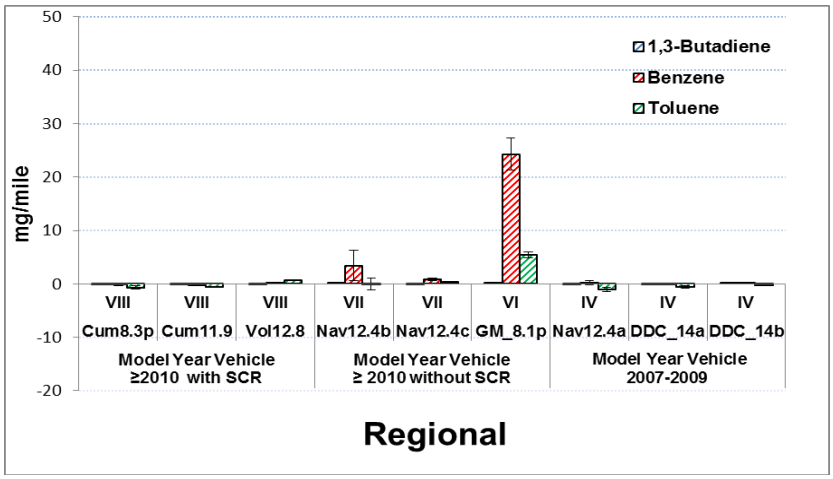

Figure 5-21 Emissions in mg/mile for Butadiene & BTEX for the Regional Port Cycle

5.5.3 Selected Toxic Emissions (carbonyls)

A slip stream of the exhaust was passed through tubes of silica gel with DNPH at controlled rates to adsorb the carbonyls and ketones in the exhaust stream. Subsequent off-line analysis focused on the measurement of aldehydes and ketones. However, as mentioned previously, the ACES project showed that all hydrocarbon emissions would be very low due to the DOC catalyst containing noble metals that is associated with the DPF.

Results are shown in Figure 5-22 to Figure 5-26. As expected, formaldehyde had by far the highest emissions. Except for the LPG vehicle with the three-way catalyst and one acetone outlier with the C11.9 vehicle for the hot UDDS cycle all values are low. We suspect the outlier sample picked up laboratory acetone during the handling. Otherwise the values are <50mg/mile, levels near the detection limit of the method. In some cases when exhaust emissions are compared with the ambient values, results are negative values showing the vehicle levels were below ambient levels. Confidence levels with this method were better than those for the volatile toxics.

The Carbonyls were high for the propane vehicle where formaldehyde and acetaldehyde emissions averaged 241±253 mg/mi and 42±48 mg/mi respectively (one standard deviation error bars). The remaining Carbonyls species were below 2 mg/mi and were not statistically significant.

5.6 Non-regulated PM Emission Data

This section covers some of the non-regulated PM data that was included in the contract. These data include: 1) the fractioning of the PM mass emissions into organic and elemental carbon (OC & EC) and 2) the particle size distribution with a focus on ultra-fines (<100nm).

5.6.1 Fractionation of the PM mass into OC and EC

As described earlier, samples of exhaust were filtered with quartz media and subsequently processed to measure the amount of OC and EC. Results are shown in Figure 5-27 to Figure 5-31. The results include background subtraction for both EC and CO PM emissions at 0.5 ug/filter and 10 ug/filter respectively (see discussion in Section 8.4.4). For all samples, the level of EC is <2mg/mile as DPF have very high filtration efficiencies for EC. The organic PM emissions were higher where the propane vehicle showed a large OC fraction for a cold start at 78 mg/mi and less than 7 mg/mi for the warm tests. The diesels were much lower at 6 mg/mi which is slightly higher than the EC, but not statistically significant. More OC was observed in the cold start UDDS for the diesels and propane vehicle than after the engine and catalysts were warm.

It is as expected that the precursors to OC are in the vapor phase and pass through the DPF. Findings in this project are similar to those of the Advanced Collaborative Emissions Study[10] which found that for DPF technology engine the PM was composed mainly of sulfate and organic carbon. In both studies, elemental carbon and metals were a small fraction of the PM mass.

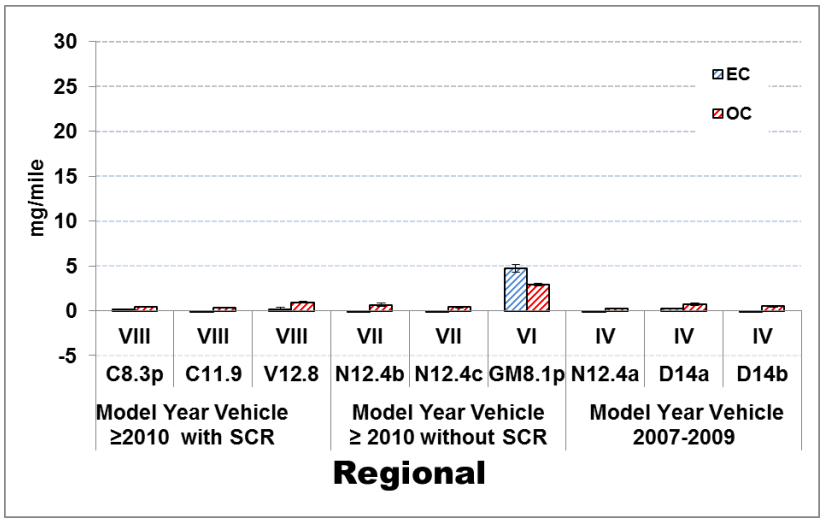

Figure 5-31 Emissions in grams/mile for the PM as OC & EC for the Regional Port Cycle

5.6.2 Measurement of the real-time and ultrafine PM emissions

Two instruments were used for the real time PM analysis as described earlier. These are the Dekati DMM and the f-SMPS. The DMM was used to characterize the real time PM mass concentration and the f-SMPS was used for the ultrafine PM emissions characterization.

Real-time PM mass DMM

As presented earlier the PM mass of the gravimetric method were very low and typically around 1.4 mg/mi or 0.4 gm/bhp-hr for most port vehicles tested. The average PM mass from the DMM measurement method averaged 0.5 mg/mi and 0.1 mg/bhp-hr for the same vehicles.

The lower real-time PM emission rate compared to the gravimetric method is not surprising as there is less confidence in the gravimetric method at filter weights below 40 µg. During the testing the actual filter weights ranged from 10-20 µg where UCR's CVS tunnel blank averages 5µg with a 5µg single standard deviation. As such many of the PM gravimetric measurements were at the detection limit of the method.

The DMM results suggest the actual PM mass at these low filter weights may be four times lower. The real-time instrument do have a lower detection limit, but that lower detection capability is not perfect and may have a poor mass correlation to the gravimetric mass method. As such, it is hard to quantify the true mass emission rate of DPF equipped vehicles and the actual PM mass may be lower than reported.

The real-time PM instrument is also useful for diagnosing PM anomalies and outliers. The Navistar vehicle showed a total PM mass of 0.68, 0.76 and 4.04 mg/mi on the local port cycle as reported earlier. Figure 5-32 shows the DMM PM mass concentration on a second by second basis for the 4.04 mg/mi test case. At 2500 seconds there was a large PM spike, as denoted with the blue line, which was not present in the other two tests. After closer investigation it appears that a passive regeneration occurred as can be seen by the high exhaust temperature, but no regeneration illumination lamp from the engine on this test.

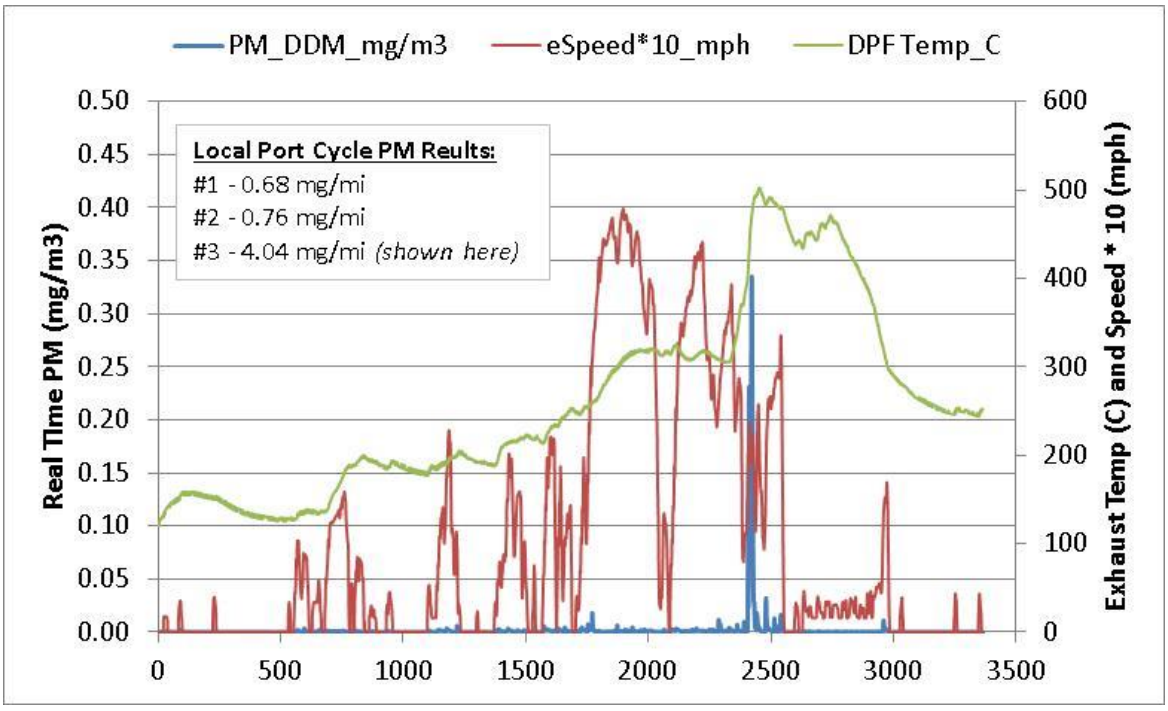

Figure 5-32: Navistar (12WZJ-B) real-time PM, vehicle speed, and DPF temp for local port cycle

In summary the low reading for the DMM suggests the actual PM mass is lower than reported by the filter mass method. Additionally, the real-time PM mass measurement method is useful for identifying test outliers and anomalies. Real-time PM is recommended with most source emissions research studies.

Ultra-fine PM emissions

In this sub section we investigate the size distribution nature of the particles. This analysis looks at particle diameters ranging from 7 nm to 200 nm, as described previously. High particle concentration at low particle diameters does not imply, necessarily, high PM mass. The calculation from particle size to mass is based on the particle diameter to the 3rd power and assumptions on density which is a strong function of particle size.

The ultra-fine PM emissions showed three unique cases, 1) the effect of cold start conditions, 2) the effect of the cycle, and 3) the difference between after treatment technologies. This section is broken down into those three categories.

Impact of cold start conditions

The cold start conditions are creating higher ultra-fine PM emissions compared to equivalent hot tests. Figure 5-33 - Figure 5-36 show the size distribution data for the UDDS hot and cold start test cycles. Figure 5-33 shows the average triplicate scans and single standard deviation error bars for the hot UDDS with the cold start UDDS from 0-200 seconds and from 200 seconds to the end of the cycle. The 0-200 seconds represents the average concentration for the first 200 seconds or the first 23 scans. Figure 5-33 is showing a very large concentration spike for the full size range from 7 to 200 nm compared to the hot UDDS. Figure 5-34 shows additional details with scan averaging from 0-100 seconds, 100-200 seconds, 0-end, and 200 – to the end.

The data in Figure 5-34 suggests the high concentration at the beginning of the UDDS cold start is occurring from the first 200 seconds since there is no change in scan from 0-100 and 100-200.

Figure 5-35 shows the data for a single particle diameter (60 nm) as a function of time to investigate the reason for the high concentration at the beginning of the scan. The results are suggesting the particles are produced at the beginning of the test and are well represented by the first 23 scans or the first 200 seconds (9 sec/scan setup time).

Figure 5-36 shows the same details as Figure 5-33, but for a different port vehicle. The results appear to be consistent where there is more PM concentration at the beginning of the cold start test. The higher concentration is also corroborated by higher PM filter masses as described previously during the $PM_{2.5}$ analysis and the real-time PM analysis sections.

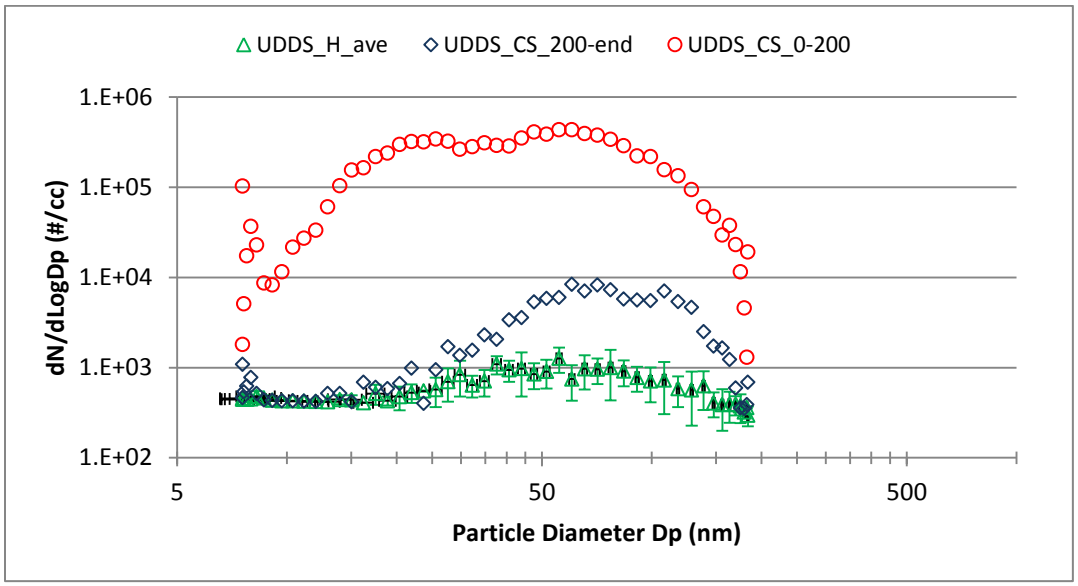

Figure 5-33Average size distributions for the V12.8 SCR equipped vehicle

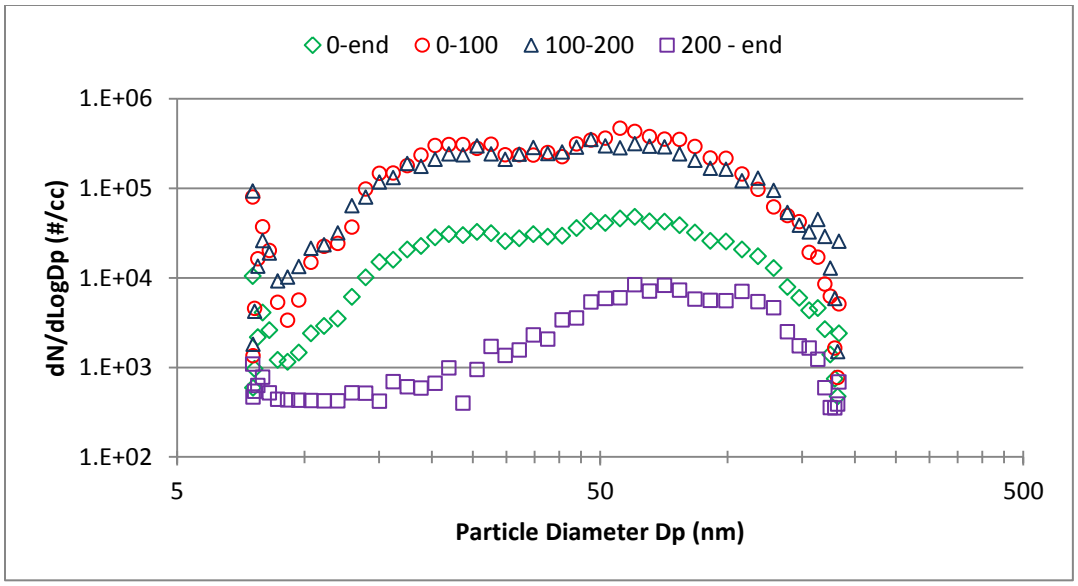

Figure 5-34 Average size distributions for the V12.8 SCR equipped vehicle selected times

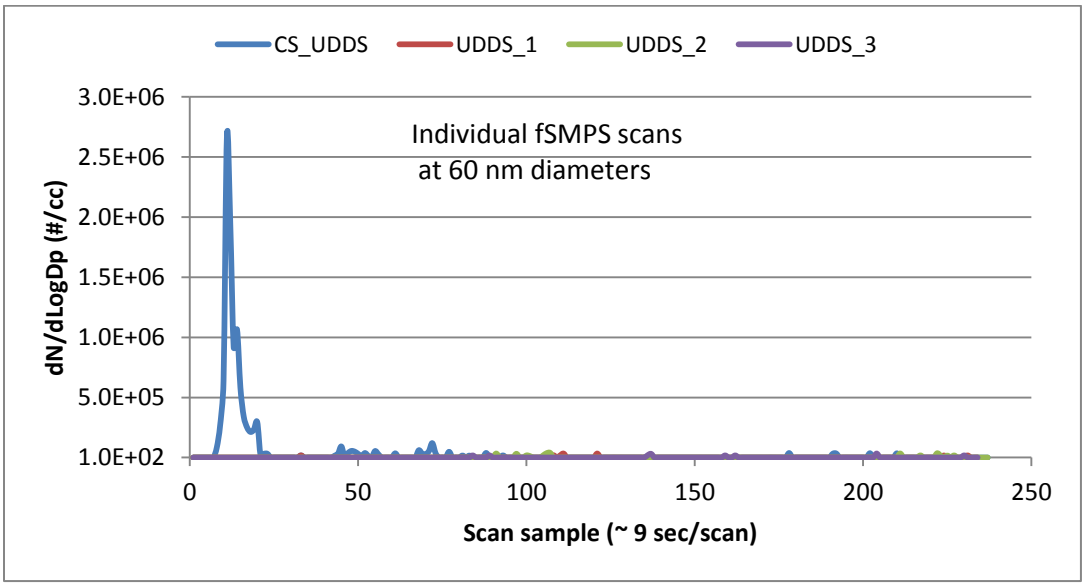

Figure 5-35 Real time scan at 60nm for the V12.8 SCR equipped vehicle

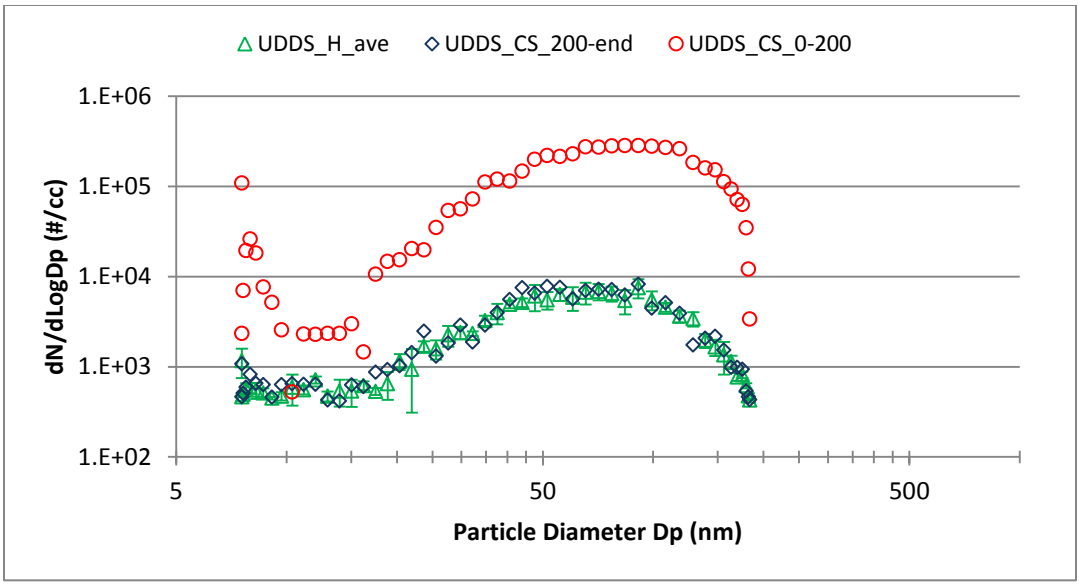

Figure 5-36 Average size distributions for the N12.3 non-SCR vehicle

Impact of cycle

The high speed regional port cycle appears to have a higher fine-particle mass impact compared to the other port cycles and the UDDS cycle. In some cases the high concentrations of the port cycle are similar to the cold start UDDS cycle, but with twice the work output of the UDDS cycle. Figure 5-37 and Figure 5-38 show the average size distributions compared between the UDDS, near dock, local, and regional. Figure 5-37 shows the comparison for an SCR equipped vehicle and Figure 5-38 shows the comparison for a non-SCR equipped vehicle. In both cases the PM concentration was much higher for the regional (Port3) cycle compared to the other cycles. For the Navistar vehicle in Figure 5-38 it appears most of the increase is for the lower size concentrations where for the Volvo vehicle in Figure 5-38 the increase was over the full size range.

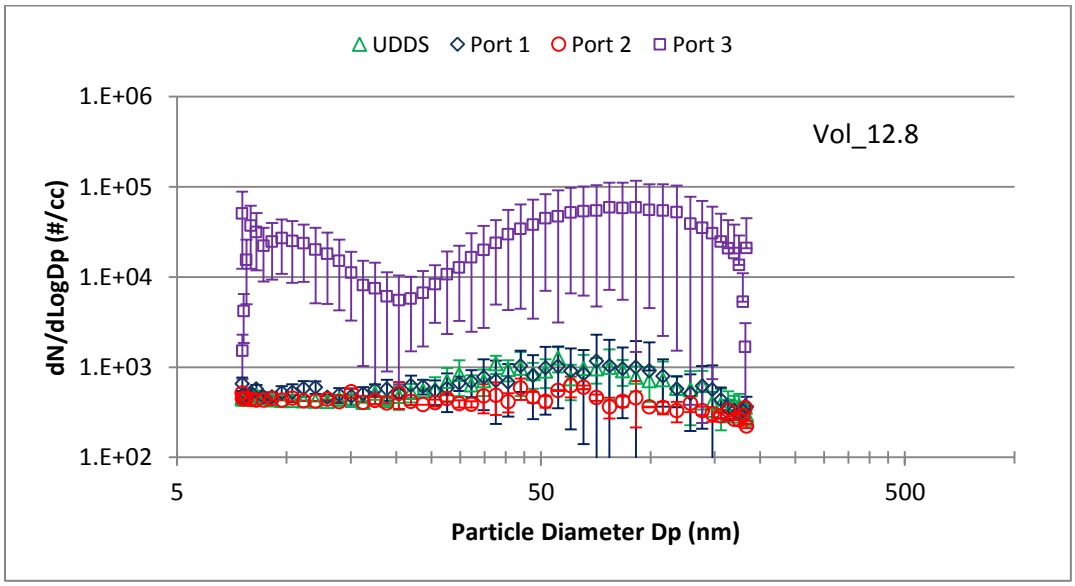

Figure 5-37 Average size distributions for the V12.8 SCR equipped vehicle by cycle

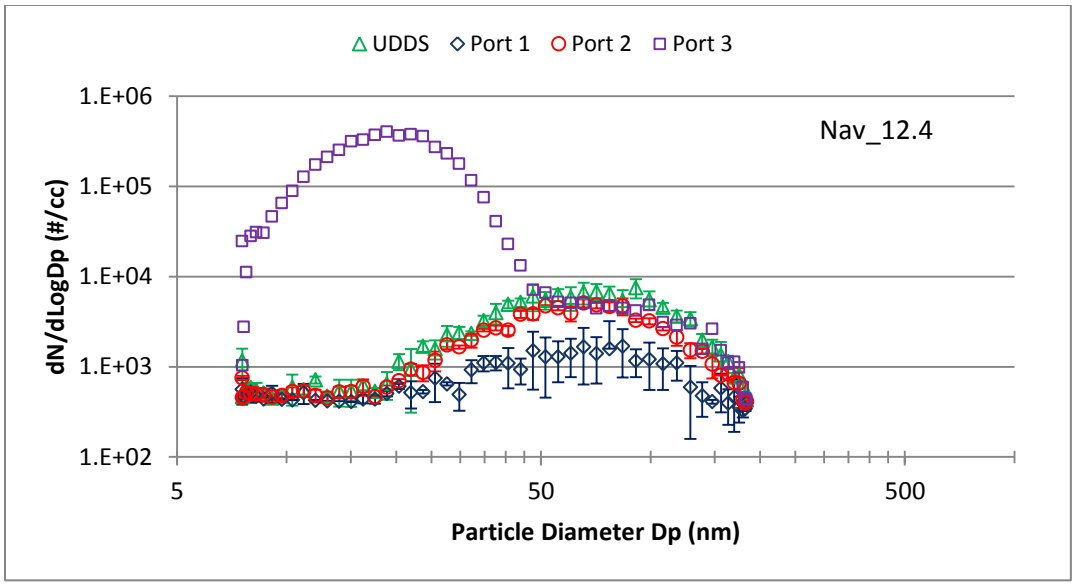

Figure 5-38 Average size distributions for the N12.3 non-SCR vehicle by cycle

Impact of after treatment technology

The basis of this research study was to consider different emission categories. The categories include with SCR, without SCR (two emission levels), high EGR, and alternative fuels. This section investigates the difference between emission control technologies. Figure 5-39 show the average size distributions for the UDDS test cycle compared between an SCR equipped truck and a non-SCR equipped truck. The two vehicles show similar size distributions where the non-SCR equipped vehicles (Nav_12.4) is slightly higher at the higher particle diameters near 50nm

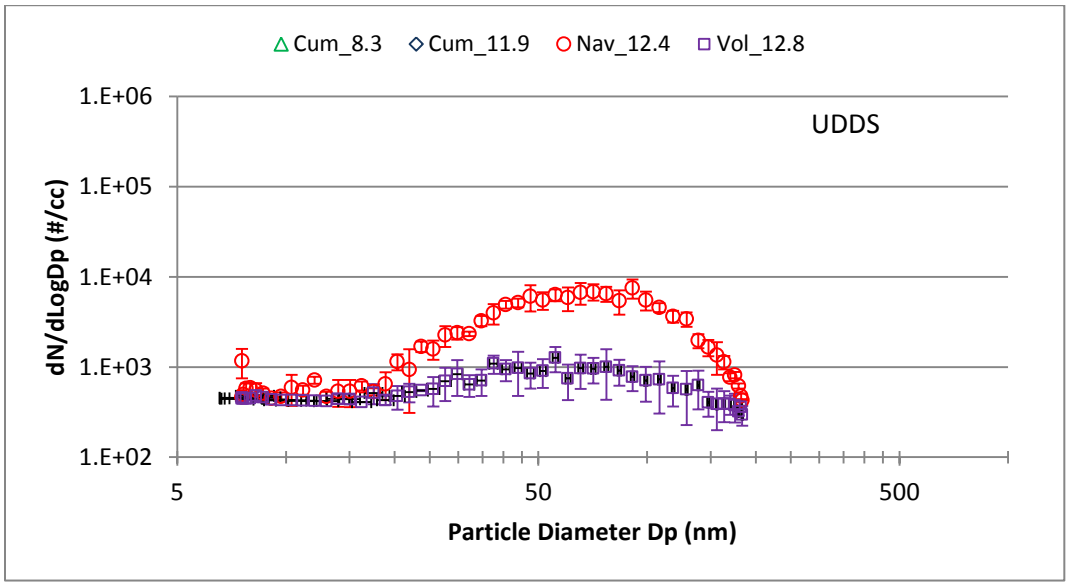

Figure 5-39 Average size distributions for various vehicles: UDDS cycle

5.7 Greenhouse Gas (N_2O, CH_4 & CO_2) Emissions and Fuel Economy

For greenhouse gases, UCR measured emissions factors of methane and carbon dioxide in real-time for all vehicles and N_2O with off-site analyses for selected vehicles. The off-site analyses were carried out by the California Air resources Board and West Virginia University. Results showed the measured values were close to ambient levels, as expected for diesel vehicles. Literature indicates N_2O is observed when vehicles rely on three way catalyst and UCR did not have any included in their fleet of test vehicles.

5.7.1 Emissions of nitrous oxide (N_2O)

N_2O emissions were measured by the IR methods described earlier and found to be near the detection limits. A literature review showed that Huai et alia[11] only found nitrous oxide when a three way catalyst was warming. Thus we only expected N_2O for the LPG truck with the three way catalyst. Unfortunately the LPG port vehicle equipped with a TWC did not have N_20 analysis available at the time of testing so no results for vehicles with TWC are reported in this section.

The N_2O measurements were very close to the ambient concentrations were negative numbers were reported. The reason for negative numbers is based on the correction of the ambient measured concentration exceeding the sample measurement, as described in a later section. It is expected that many of the measurements are near the detection limits of the N_2O measuring method. See Section 8.4.3 for analysis and summary of N_20 measurements and detection limits.

The general observations of the N_2O emissions from the vehicles tested can be summarized as:

- N_2O Analysis was done offsite when facilities were available. As such, not all vehicles or cycles were tested for N_2O. Only selected vehicles were tested for N_2O analysis.
- During the refuse and school bus testing there were no facilities for N_2O analysis thus they were not performed. Similar results are expected for all the vehicle categories.
- More than half (64%) of the measured toxic emissions were below the defined threshold (0.4 ppm), the average ambient background concentration plus one standard deviation.
- Only the SCR equipped vehicles showed signs of N_2O emissions not the non-SCR equipped vehicles.
- The cold start UDDS did not show higher integrated N_2O emissions compared with hot start UDDS tests (with or with/out SCR). It is not clear from the testing if higher N_20 emissions were created for a short duration at the cold start of the cold test cycles. Additional real time N_2O data would be necessary to evaluate the first 100 seconds of the cold start UDDS N_2O emissions.
- Of the values greater than the threshold, the average vehicle sample concentration was 1.06 ppm (only 2.6 times the threshold) and the single standard deviation was 0.44 ppm.

[11] T. Huai, Durbin, T.D., J.W. Miller, and J.M. Norbeck, *Estimates of the Emission Rates of Nitrous Oxide from Light-Duty Vehicles using Different Chassis Dynamometer Test Cycles*. Atmospheric Environment, vol. 38, 6621-6629 (2004)

- The N_2O emission rate in mg/mi for port vehicles with higher than threshold concentrations ranged from 1.5 mg/mi to 17 mg/mi where the highest concentrations were for the shorter test cycle.
- N_2O emissions appear to be below or near detection limit for diesel and propane vehicles appear operated on the UDDS and port related test cycles.

5.7.2 Emissions of methane (CH_4)

Vehicles emit methane, a greenhouse gas, with a global warming potential (GWP) over 20 years of 72. This factor means that methane will trap 72 times more heat than an equal mass of carbon dioxide over the next 20 years. There are factors for 100 and 500 years but the 20 year factor is used in this analysis. From results of this project, the CH_4 contribution to greenhouse gases with diesel trucks can be ignored given that the emissions rate for CO_2 was about >2,000 gram/mile and that of CH4 was ~0.02 grams/mile. Thus emissions of CO_2 predominate for the greenhouse calculation, even after adjusting the methane rate by a factor of 72.

The CH_4 contribution was considered with the LPG truck. In this case, the CO_2 emissions were about 1,500 grams/mile and that of methane was ~1.5 grams/mile. Thus for this case, multiplying by 72, the contribution to the greenhouse gases will be ~105/1,500 = 7% so significant and more important to consider.

5.7.3 CO_2 and Fuel Economy emissions

Emissions of CO_2 for the goods movement vehicles are provided in Table 5-10 for the different test cycles and ranges from 1,489 grams/mile with the LPG fuel to 3,904 grams/mile.

Table 5-10: CO_2 Emissions for the Goods Movement Vehicles.

Vehicle			CO_2 Emission Factor (g/mi)				
Category	Engine	MY	Near Dock	Local	Regional	UDDS	UDDS-CS

IV	D14b	2008	2696	2426	1821	2506	2455

Fuel economy for the goods movement vehicles in different driving cycles are provided in Figure 5-40 to Figure 5-44. Looking first at the hot-UDDS cycle, the fuel economy ranged from 3.31 to 4.25 miles per gallon with an average 3.48 miles/gallon and coefficient of variation of 1%. Thus the values were statistically the same, even though some paired values did show a significant difference. While we expected the vehicles with SCR to have advanced fuel injection, more NOx and better fuel economy, the results did not show that finding.

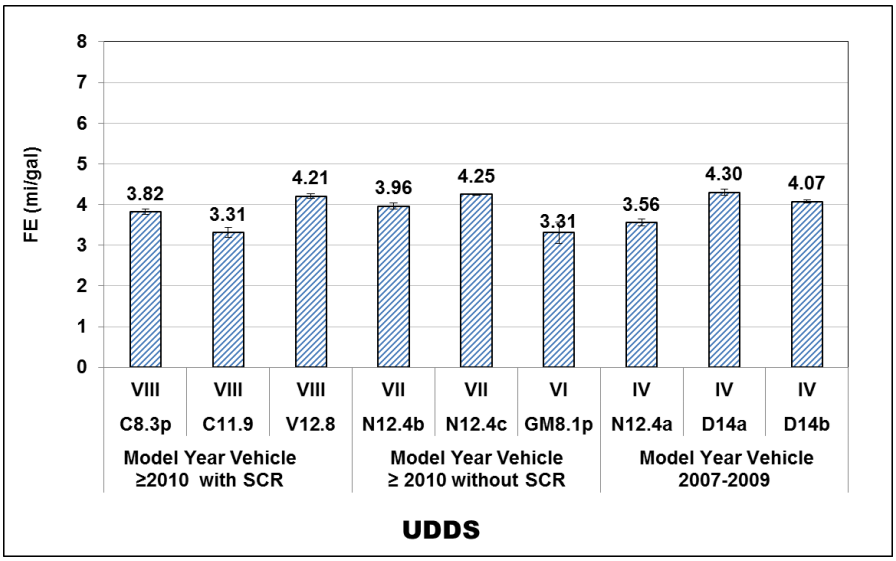

Figure 5-40: Fuel Economy in miles/gallon of Fuel for the UDDS Cycle.

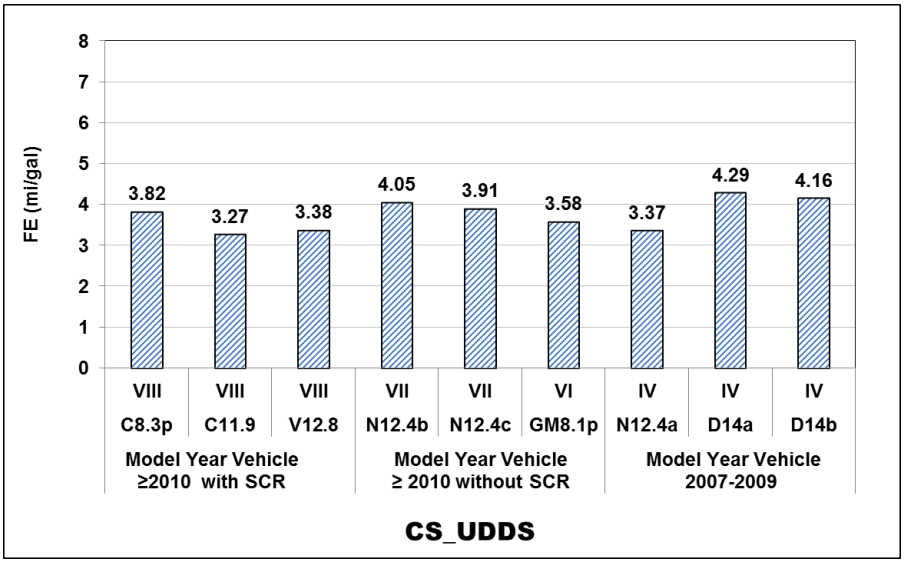

Figure 5-41: Fuel Economy in miles/gallon of Fuel for Cold start UDDS cycle.

[1] No error bars for the cold start tests because on only one test was performed

Reviewing the fuel economy for the three port cycles representing in-use activities shows that the fuel economy ranged from 2.62 to 6.02 miles per gallon. The lowest and highest fuel economy values were found for the engine with the lowest NOx emissions. Temperature appears to play a role in that finding as in the regional cycle the truck achieved the lowest NOx emissions with comparable fuel economy. Other trends showed that the lowest fuel economy was during the Near Dock driving schedule which is not surprising given the low power and creep cycles. The 2010+ Navistar vehicles without SCR had the highest fuel economy but as mentioned earlier, they failed to meet the NOx standard and were withdrawn from the market.

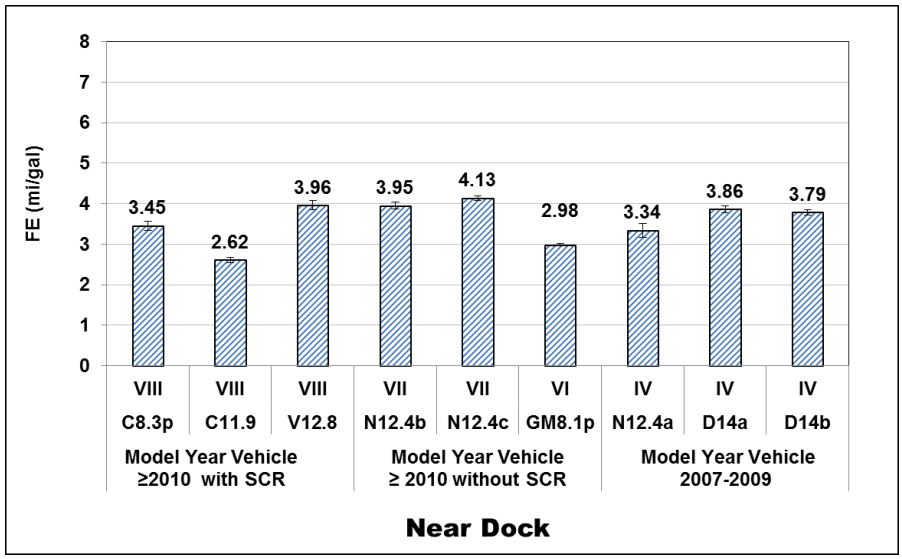

Figure 5-42: Fuel Economy in miles/gallon of Fuel for the Near Port Cycle

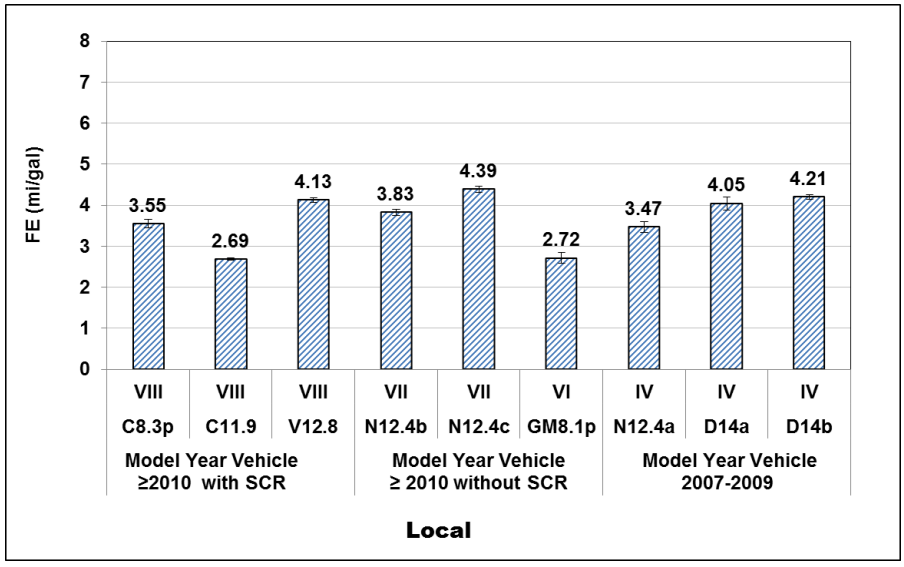

Figure 5-43: Fuel Economy in miles/gallon of Fuel for the Local Port Cycle

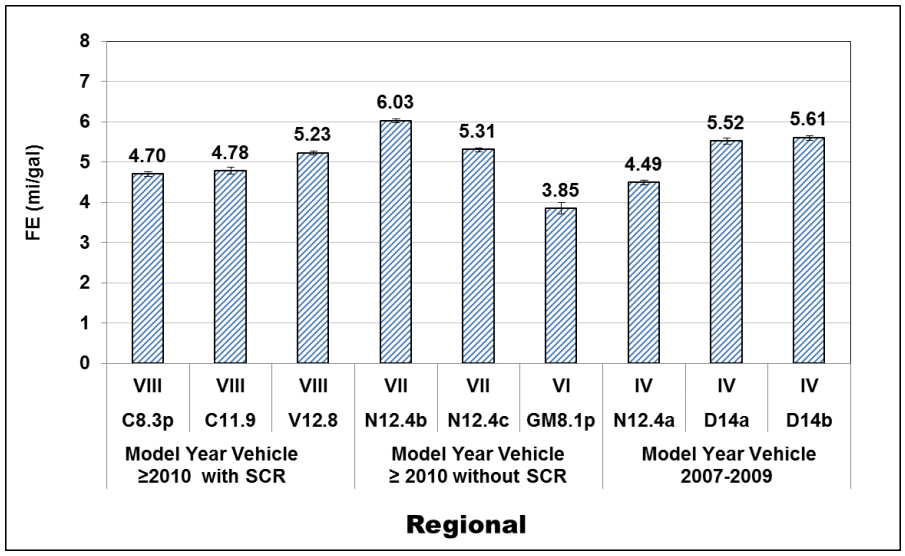

Figure 5-44: Fuel Economy in miles/gallon of Fuel for the Regional Port Cycle

6 Results and Discussion for Refuse Haulers

This section covers the emissions for refuse vehicles that were tested on the UDDS and the AQMD refuse truck cycles. Most emissions are based on grams per mile for inventory purposes and the UDDS cycle values are in grams/bhp-hr so as to compare with the certification values.

6.1 Test Trucks

Four trucks used as refuse haulers were tested on a number of chassis cycles. Selected information for the trucks is identified in Table 1-1. All of these vehicles were a challenge to find within the AQMD District as most trucks in the District use natural gas. Some were shipped in from Northern California where the air conforms to federal standards and diesel vehicles are still used.

6.2 Test Conditions

Vehicles were tested on the UDDS cycle and on the AQMD refuse hauler cycle as that cycle more closely represented in-use activities for a refuse hauler. The load for the refuse haulers was set at 56,000 lb. load as that value represents the typical load of a refuse hauler in the SCAQMD District. Commercially available CARB #2 diesel fuel was used rather than a certification fuel. Both load and fuel matched in-use conditions. The emission values represent the average of triplicate runs and the graphs show the confidence limits to one standard deviation.

6.3 NOx Emissions from the UDDS Cycle

As mentioned earlier, the brake specific emissions values from the UDDS chassis dyno test are often compared with the values measured in the heavy-duty FTP certification test on an engine dyno. This comparison provides some indication that the selected vehicle is representative of the desired FEL and technology. This section focuses on NOx emissions given the interest in the original RFP.

6.3.1 Brake-specific emissions for the UDDS Cycle

Figure 6-1 shows the UDDS values for NOx ranged from 0.13 to 2.0 g/bhp-hr versus certification standards of 0.2 and 1.2 g/bhp-h. The Value for one vehicle is on the high side; perhaps the manufacturer was using credits for that family of engines, but we do not know. Category VII with SCR had the lowest NOx emissions. The UDDS values ranged from 0.13 to 0.17 and were close to the certification values.

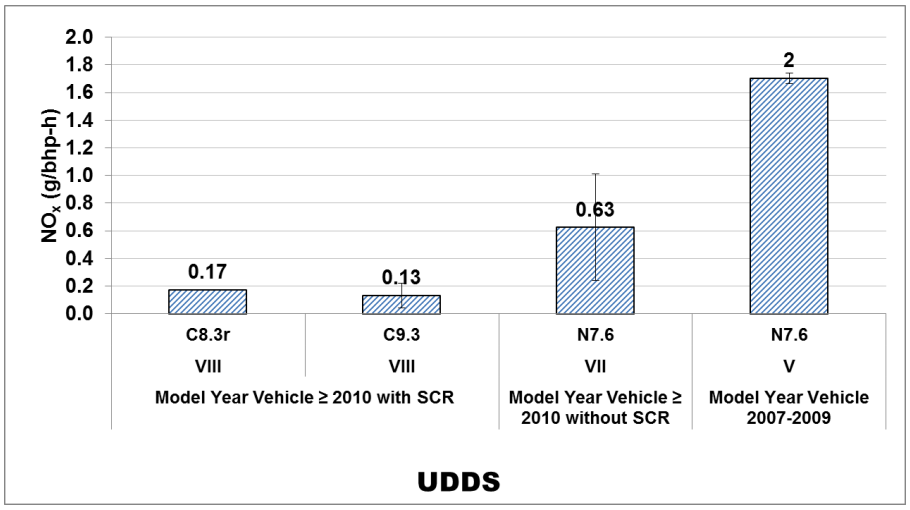

Figure 6-1 Brake Specific NOx Emissions for Hot & Cold UDDS Cycles

6.3.2 Emissions in g/mile for the UDDS cycle

Results were also analyzed and calculated on the basis of the emissions being expressed in grams per mile, the figure needed for calculating the inventory. These data are shown in Figure 6-2 and Figure 5-6.

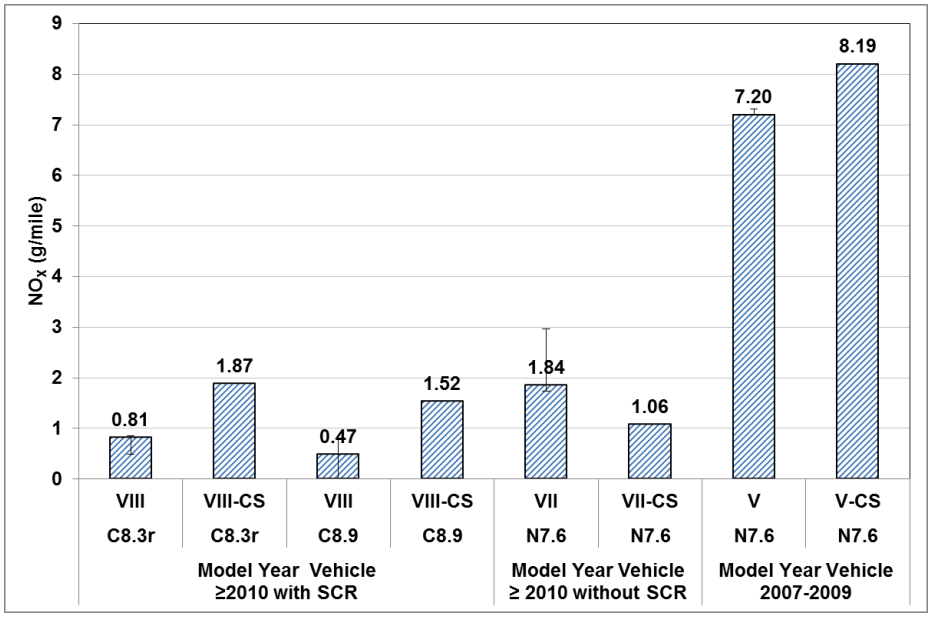

Figure 6-2: NO_x Emission Factors for Hot & Cold UDDS Cycles (g/mile)

[1] No error bars for the cold start tests because on only one test was performed

Many have asked whether there is a single factor to convert g/bhp-hr to g/mile. The answer to this question is presented in Table 6-1. The average factor is 3.73 with a coefficient of variation of 21%. This value is closer to the traditional value of 3.5. Also the coefficient of variation near 21% indicated the ratio is more dependent on technology than found with the goods movement vehicles.

Table 6-1 Relationship Between g/mile & g/bhp-hr for the Hot UDDS

Units				
g/mile	7.2	1.84	0.47	0.81
g/bkhp-hr	2	0.63	0.13	0.17
ratio	3.60	2.92	3.62	4.76

6.3.3 Percentage of NOx emissions as NO_2

NO_2 emissions are a health concern and values for the refuse trucks are presented in Table 6-2. These tables show the percentage of the total NO_x that is NO_2. On the UDDS cycle, values range from 18% to 53% and for the AQMD refuse cycle the values range from 23 to 69%. One finding is the AQMD refuse cycle increased the percentage of NO_2 significantly for the vehicles with an SCR technology. This is an important finding that should be further investigated. Not surprising the NO_2 percentage was high for the vehicles with the SCR technology. Similar to the observation with the goods movement vehicles, levels of NO_2 are high as compared with the ARB retrofit rule of 20% over baseline.

Table 6-2: Fraction of NOx (g/mile) as NO_2 for the Refuse Trucks

Vehicle			AQMD RTC			UDDS			CS_UDDS RTC		
Category	Engine	MY	NO_2	NO_x	$\%NO_2$	NO_2	NO_x	$\%NO_2$	NO_2	NO_x	$\%NO_2$

6.4 Regulated Emissions from the AQMD Cycle in g/mile

6.4.1 NO_x emissions for the UDDS (grams/mile)

The NO_x emission results in grams/mile for the refuse trucks are presented in for the Refuse Truck cycle, the UDDS, and the CS-UDDS, respectively. The refuse trucks show a clear trend of NO_x emissions reductions with advancing technology. For the refuse truck cycle, the 2010+ vehicles with SCR show significant reductions relative to both the 2010+ refuse truck without SCR and the 2007-2009 vehicle. For the UDDS cycle, the 2010+ vehicles with SCR also show reductions relative to both the 2010+ refuse truck without SCR and the 2007-2009 vehicle, although the differences between the 2010+ refuse trucks with and without SCR was smaller than for the refuse truck cycle. For the CS-UDDS, the 2010+ vehicles showed significant reductions relative to the 2007-2009 vehicles, but the 2010+ vehicles with SCR actually showed higher emissions than those for the 2010+ vehicles without SCR. In comparing emissions between the refuse trucks and the goods movement vehicles, the trends depended on the specific vehicle and cycle, with the refuse trucks showing lower emissions for come cycle vehicle combinations and higher emissions for others.

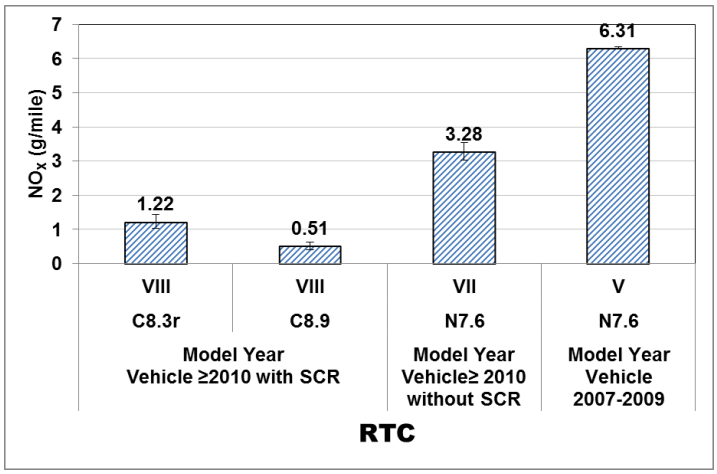

Figure 6-3: NOx Emission Factors in g/mile for AQMD Refuse Truck Cycle

6.4.2 PM emissions

The PM emission results for the refuse trucks are presented Figure 6-4 and Figure 6-5 for the, the UDDS, and the AQMD Refuse Truck cycle. The PM emissions were relatively low and were around 2 mg/mi or less for most of the hot start vehicle/cycle combinations, with only the 2010+ vehicle with SCR being slightly above 2 mg/mi. The emissions for the refuse trucks were slightly higher for the CS-CBD for each of the vehicles, and the 2010+ C8.3 vehicle showed a larger increase to 18.4 mg/mi.

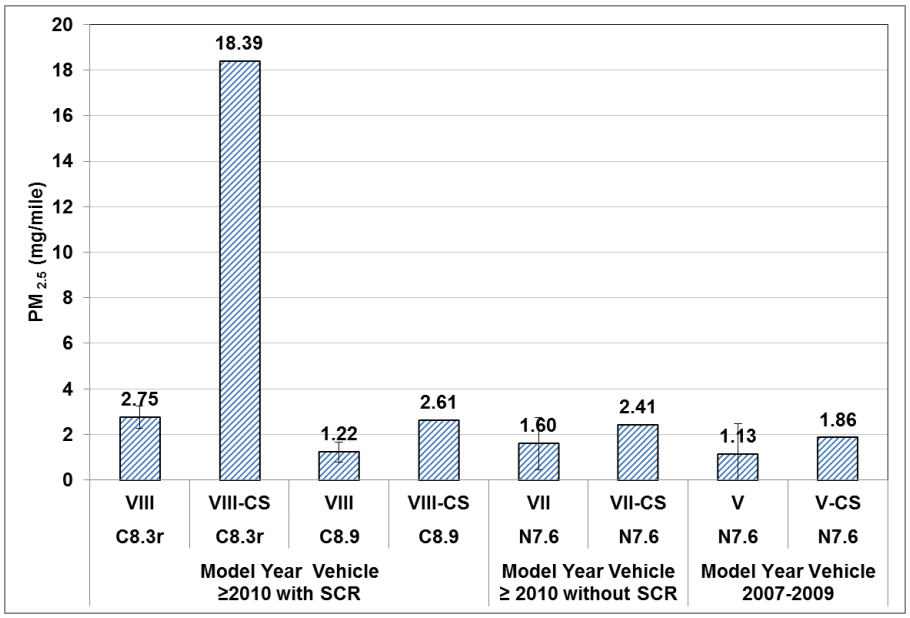

Figure 6-4 Emission factors for PM UDDS and cold start UDDS cycles (mg/mile)

[1] No error bars for the cold start tests because on only one test was performed

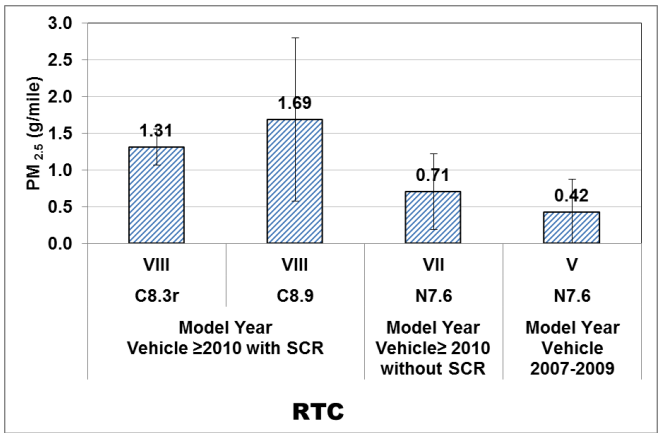

Figure 6-5: Emission factors for PM AQMD Refuse Truck Cycle (g/mile)

6.4.3 THC/NMHC/CH_4 and CO emissions

Table 6-3 through Table 6-5 show the emission factors for THC, CH4, NMHC and CO in g/mile for the hot/cold UDDS Cycle and the AQMD Refuse Truck Cycle. The emission factors for THC, CH_4, and NMHC were low for nearly all vehicle/cycle combinations. THC emissions were at or below 0.45 g/mi for nearly all vehicle/cycle combinations. NMHC emissions were at or below 0.30 g/mi for nearly all vehicle/cycle combinations. CH_4 emissions were at or below 0.20 g/mi for nearly all vehicle/cycle combinations. The 2010+ N7.6 refuse truck also had a slightly higher emissions ranging from 1.11 to 1.13 g/mi for THC, from 0.70 to 0.74 g/mi for NMHC, and from 0.45 to 0.48 g/mi for CH_4. Cold start emissions were also low for most vehicle/cycle combinations, except the 2010+ N7.6 refuse truck showed somewhat higher cold start THC, NMHC, and CH_4 emissions.

Table 6-3: THC, CH4, NMHC, and CO Emissions for UDDS Cycle for Refuse Trucks (g/mile)

V	N7.6	2008	0.01	0.02	-0.01	-0.10

6.5 Non-regulated Gaseous Emissions

6.5.1 NH_3 emissions

The NH_3 emission results for the refuse trucks are presented in

Figure 6-7 and Figure 6-6 for the Refuse Truck. NH_3 emissions for all of the refuse trucks were in the range of 10 to 50 mg/mi for most of the cycle combinations, with the exception of the 2010+ C8.3 vehicle for the CS-UDDS being slightly higher at 120 mg/mi. This is roughly the same range seen for the good movement vehicles.

Table 8-26 shows of the 54 diesel tests conducted, only 2 vehicles were 5 times the LDL (i.e. greater than 5ppm), and 26 tests were above 2 time the LDL (2 ppm), see Section 8.4.4. Of the 2 tests above 5*LDL, both were for a cold start SCR equipped diesel vehicle. For the 26 tests above 2* LDL these were both SCR and non-SCR equipped vehicles. It is not expected that a non-SCR equipped vehicle had more NH_3 emissions than an SCR equipped vehicle. Five of seven tests for the propane vehicle also had NH_3 greater than 5 ppm and 2 were over 50 ppm suggesting very high relative NH_3 emissions for the propane vehicles.

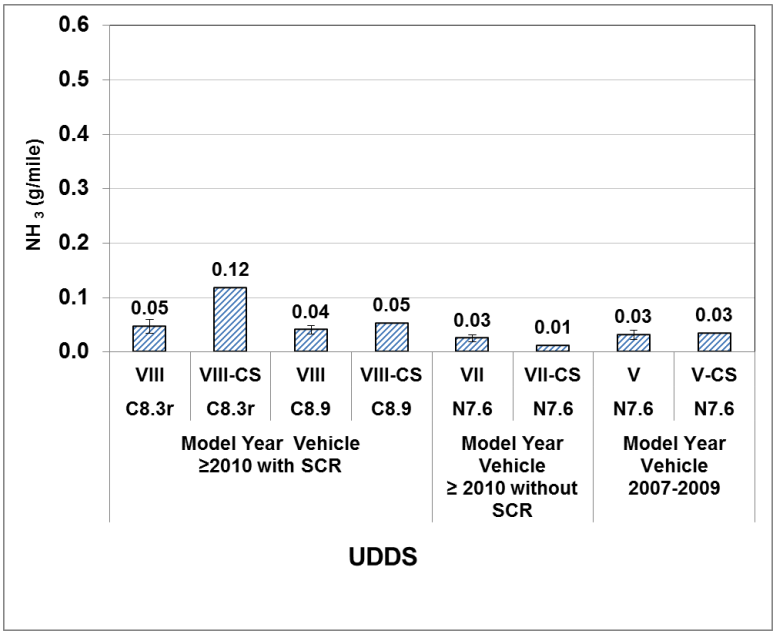

Figure 6-6: Emission of NH_3 in the cold/hot UDDS Cycle (g/mile)[1]

[1] NH_3 scale is based on 10 ppm raw exhaust concentration

[2] No error bars for the cold start tests because on only one test was performed

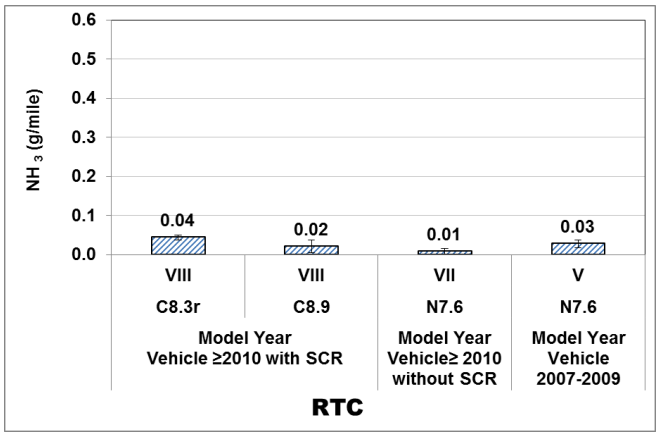

Figure 6-7: Emission of NH_3 in the AQMD Refuse Truck Cycle (g/mile)[1]

6.5.2 Selected Toxic Emissions (1,3butadience & BTEX)

The 1,3 butadiene, benzene, and toluene results for the refuse haulers are shown in Figure 6-8 and Figure 6-9. All values are low as expected based on the ACES study and that the exhaust passes over a DOC catalyst containing noble metals. Only the 2010+ N7.6 showed measureable levels of these species for both cycles. The 2007-2009 N7.6 vehicle also showed measureable levels for 1,3 butadiene and toluene for the UDDS. These findings match the NMHC results.

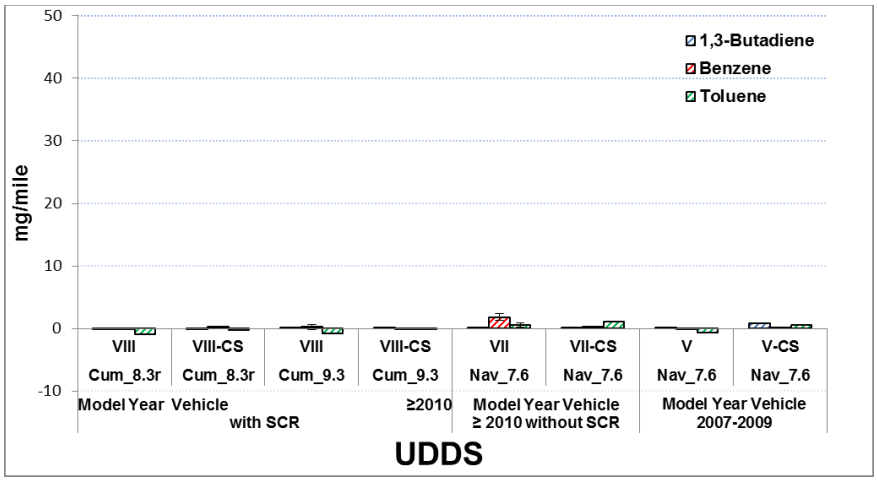

Figure 6-8 Emissions of Selected Toxics in mg/mile for UDDS Cycle

[1] No error bars for the cold start tests because on only one test was performed

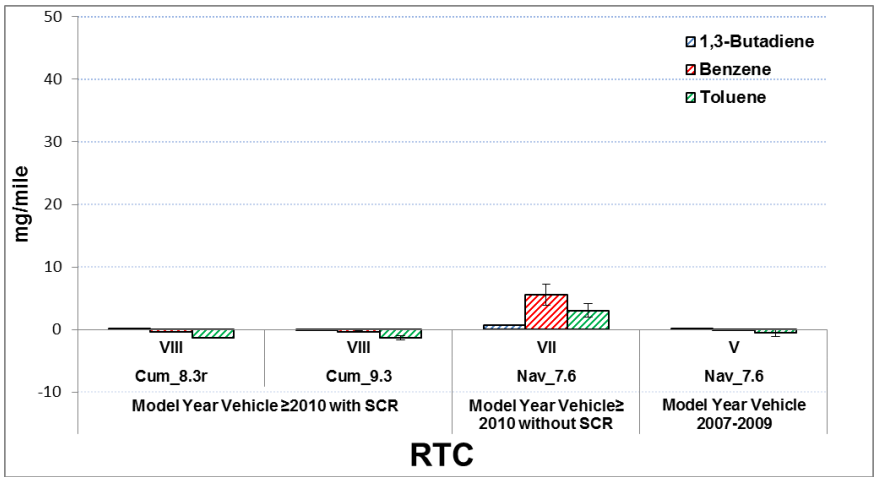

Figure 6-9 Emissions of Selected Toxics in mg/mile for AQMD Refuse Cycle

6.5.3 Selected Toxic Emissions (carbonyls & ketones)

The formaldehyde, acetaldehyde, and acetone carbonyl results for the refuse haulers are shown in Figure 6-10 and Figure 6-11. Emissions are very low, as expected. Formaldehyde emissions were the highest of the carbonyl species, which were measureable for most vehicles on both cycles. The highest formaldehyde emissions were seen for the 2007-2009 N7.6 for both cycles. Acetaldehyde emissions were measureable for several vehicles for both cycles. Acetone emissions were not measureable for any of the vehicle/cycle combinations.

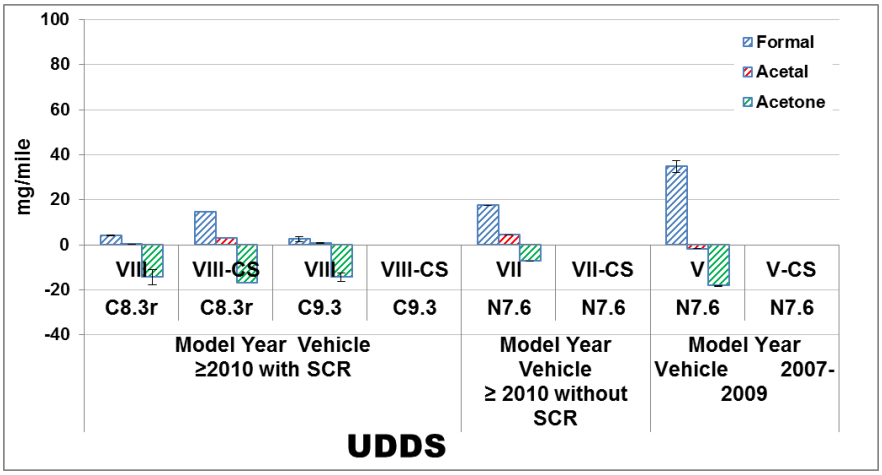

Figure 6-10 Emissions of Carbonyls & Ketones in mg/mile for UDDS Cycle

[1] No error bars for the cold start tests because on only one test was performed

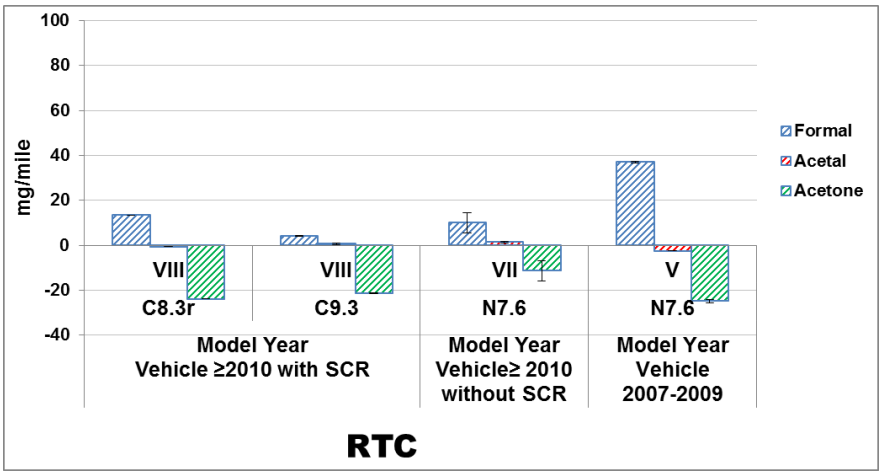

Figure 6-11 Emissions of Carbonyls & Ketones in mg/mile for AQMD Refuse Cycle

6.6 Non-regulated PM Emissions

6.6.1 Fractionation of the PM mass into OC and EC

Fractioning the PM into elemental and organic carbon was carried out by analysis of the quartz filter media collected at the test site. Results for the refuse haulers are shown in Figure 6-12 and Figure 6-13. For the Refuse Truck Cycle, the elemental and organic carbon emissions were essentially at the background levels. See Section 8.4.4 for a discussion on EC and OC detection limits. For the UDDS only the cold start emissions for the C8.3 showed organic carbon emissions measurably above the background levels, consistent with the higher $PM_{2.5}$ emissions for that vehicle/cycle combination. Elemental carbon emissions were not measurably above the background levels for the UDDS, as expected due to the high filter efficiency of the DPF.

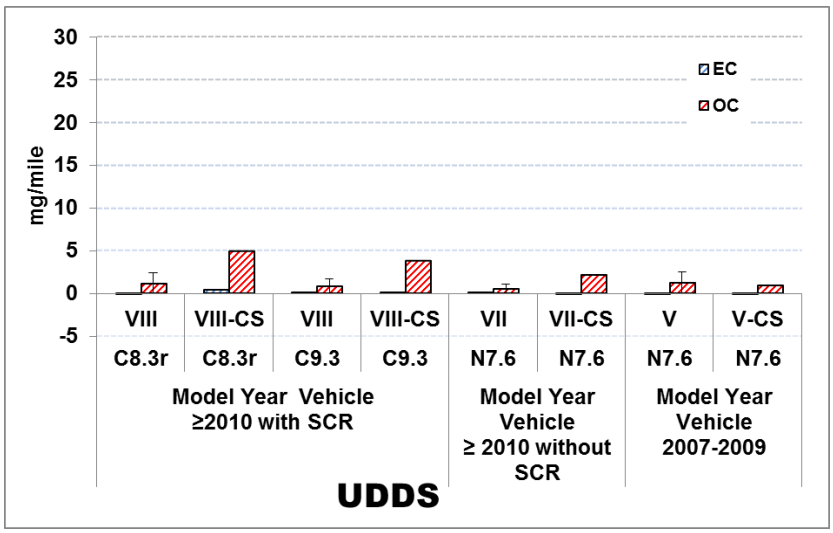

Figure 6-12 Emissions in grams/mile for the PM as OC & EC for the UDDS Cycle

[1] Error bars for the cold start tests were available for this vehicle because multiple tests were performed

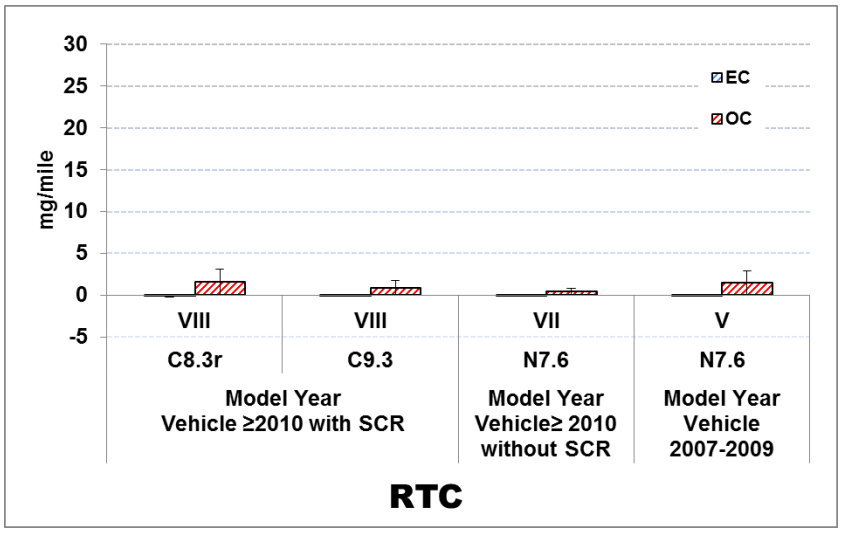

Figure 6-13 Emissions in grams/mile for the PM as OC & EC for the Refuse Cycle

6.6.2 Measurement of the real-time and ultrafine PM emissions

As described previously, The DMM was used to characterize the real time PM mass concentration and the f-SMPS was used for the ultrafine PM emissions characterization.

Real-time PM mass DMM

As presented earlier the PM mass of the gravimetric method were very low and typically around 2.1 mg/mi or 0.5 gm/bhp-hr for all the refuse vehicles tested. The average PM mass from the DMM measurement method averaged 0.3 mg/mi and 0.1 mg/bhp-hr for the same vehicles. The low PM mass emission factors were near the detection limits of the measurement method as discussed previously in Section 5.6.2.

Figure 6-14 shows the DMM PM mass concentration on a second by second basis for the Cummins 8.3 liter SCR equipped refuse hauler on the cold start UDDS cycle. At 600 seconds, the beginning of the large hill, there was a large PM spike, as denoted with the blue line, which was not present in the hot UDDS tests. The total PM from the gravimetric method was 18.4 mg/mi for the CS UDDS and between 3.2 to 2.2 mg/mi for the hot UDDS's. The cold start UDDS PM was 6 times higher than the hot UDDS cycles. ThisAfter closer investigation it appears that a passive regeneration occurred as can be seen by the high exhaust temperature, but no regeneration illumination lamp from the engine on this test.

Figure 5-32 shows the DMM PM mass concentration on a second by second basis for the 4.04 mg/mi test case. At 2500 seconds there was a large PM spike, as denoted with the blue line, which was not present in the other two tests. After closer investigation it appears that a passive regeneration occurred as can be seen by the high exhaust temperature, but no regeneration illumination lamp from the engine on this test.

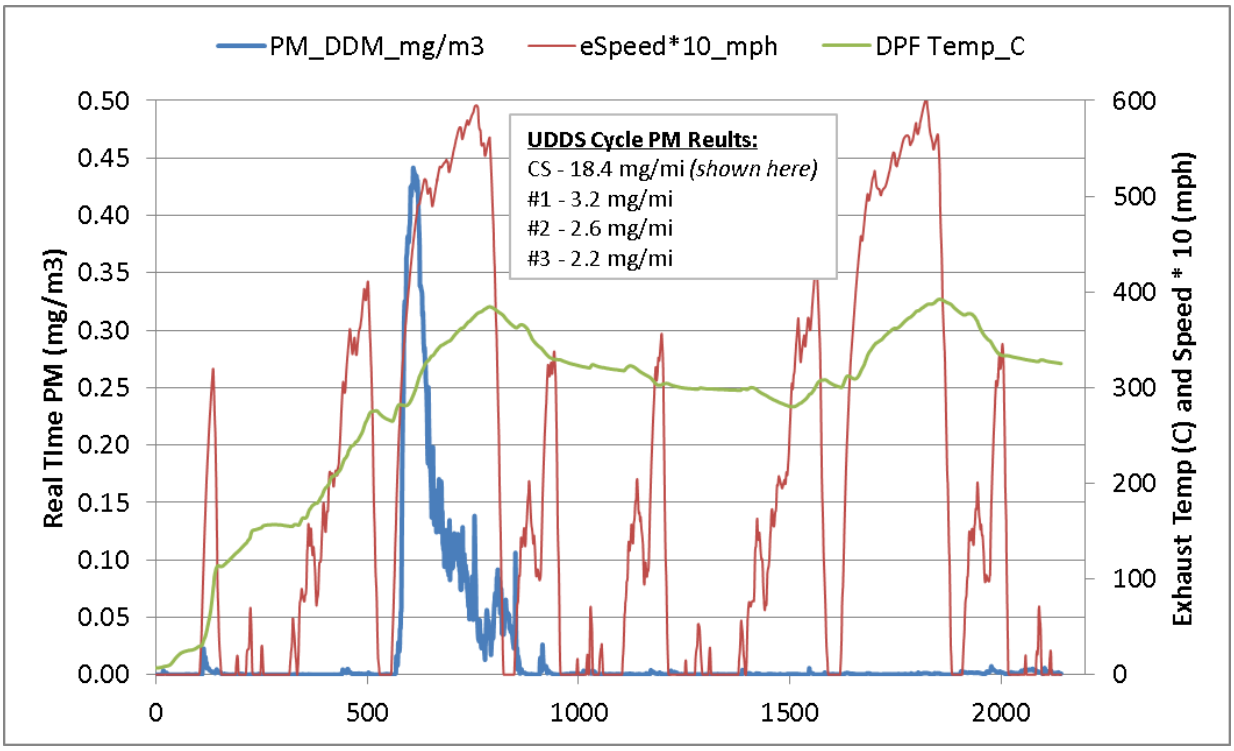

Figure 6-14 Refuse vehicle real-time PM emissions for the cold start UDDS cycle

Ultra-fine PM emissions

The cold start UDDS fine particles was also high for the refuse vehicle as compared to the port vehicles. Figure 6-15 through Figure 6-17 show the size distribution results for a selected SCR equipped refuse hauler. The results show a higher fine particle concentration for the first 200 seconds that cover most of the size range sampled. Figure 6-16 shows the real time scan at 60 nm which supports the idea that there is a burst of fine particles at the cold start then after about 200 seconds (23 scans) the high concentration is gone. The size distribution continues to drop as time progresses for the refuse vehicle as seen by the still high concentration at 200 seconds to the end, see Figure 6-15.

Figure 6-17 shows the comparison between the UDDS (hot and cold) compared to the AQMD refuse cycle. The UDDS and refuse cycle show similar fine particles were the small peak at 7-30 nm may be measurement error for the SMPS. Additional data is needed to confirm this response.

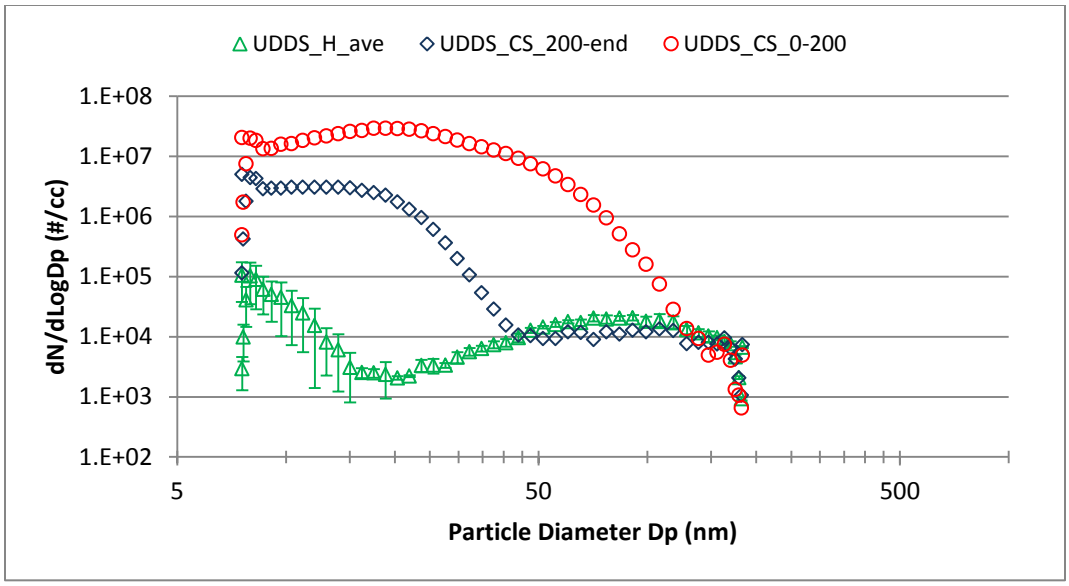

Figure 6-15 Average size distributions for the an SCR equipped refuse vehicle: UDDS

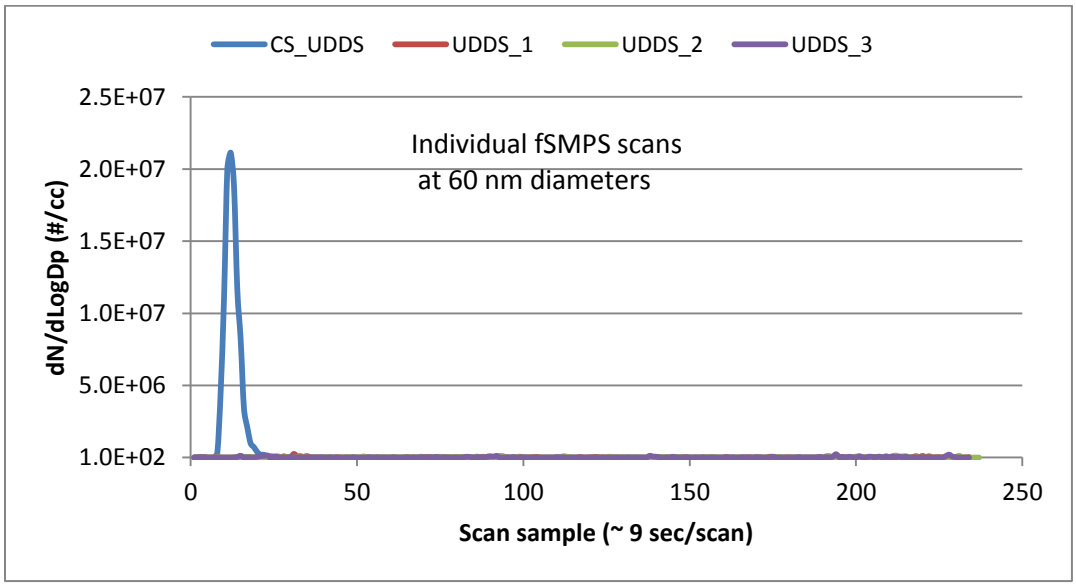

Figure 6-16 Selected scan particle size (60 nm) for the an SCR equipped refuse vehicle

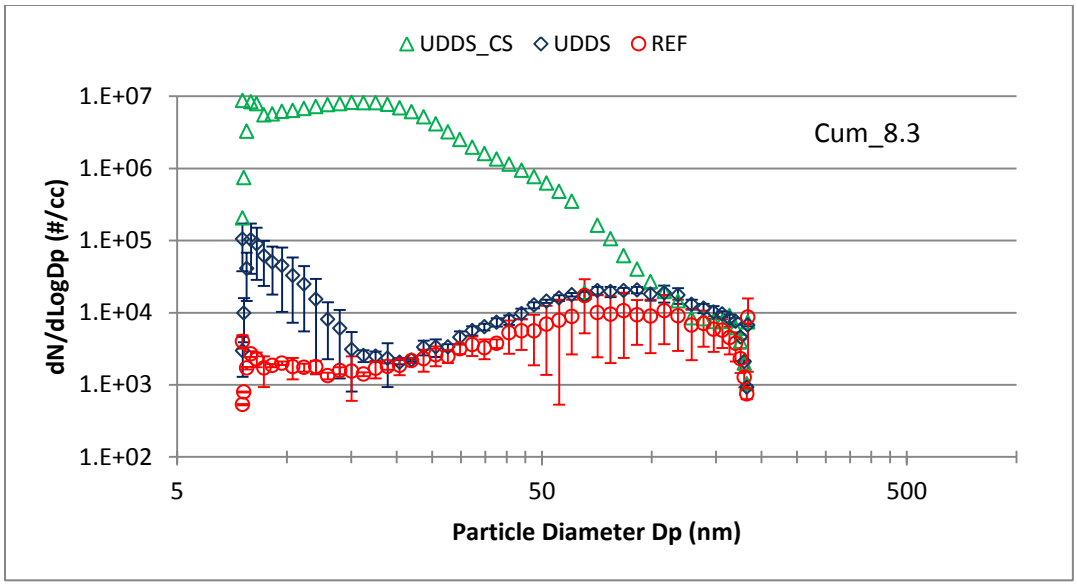

Figure 6-17 Average size distributions for an SCR equipped refuse vehicle: by cycle

In summary the refusle hauler PM mass was higher for the cold start than for the warm vehicles. This agrees with the higher measured size concentration and a similar behavior for the port vehicles.

6.7 Greenhouse Gas (N_2O, CH_4 & CO_2) Emissions and Fuel Economy

For greenhouse gases, UCR measured emissions factors of methane and carbon dioxide in real-time for all vehicles and N_2O with off-site analyses for selected vehicles. The off-site analyses were carried out by the California Air resources Board and West Virginia University. Results showed the measured values were close to ambient levels, as expected for diesel vehicles. Literature indicates N_2O is observed when vehicles rely on three way catalyst and UCR did not have any included in their fleet of test vehicles.

6.7.1 Emissions of nitrous oxide (N_2O)

N_2O emissions were measured on selected refuse haulers by the IR methods described earlier. The N_20 concentrations were found to be near the detection limits for those vehicles sampled for N_20. A literature review showed that Huai et alia[12] only found nitrous oxide when a three way catalyst was warming. Thus we only expected N_2O for the LPG school bus and LPG port truck as the after treatment was a three way catalyst. There were no refuse hauler LPG vehicles tested.

Of the vehicles tested for N_20, the N_2O measurements were very close to the ambient concentrations were negative numbers were reported for the refuse haulers sampled for N_2O. The reason for negative numbers is based on the correction of the ambient measured concentration exceeding the sample measurement, as described in a later section. It is

[12] T. Huai, Durbin, T.D., J.W. Miller, and J.M. Norbeck, *Estimates of the Emission Rates of Nitrous Oxide from Light-Duty Vehicles using Different Chassis Dynamometer Test Cycles*. Atmospheric Environment, vol. 38, 6621-6629 (2004)

expected that many of the measurements are near the detection limits of the N_2O measuring method. See Section 8.4.3 for analysis and summary of N_20 measurements and detection limits.

The general observations of the N_2O emissions from the vehicles tested can be summarized as:

- N_2O Analysis was done offsite when facilities were available. As such, not all vehicles or cycles were tested for N_2O. Only selected vehicles were tested for N_2O analysis.
- During the refuse and school bus testing there were no facilities for N_2O analysis thus they were not performed. Similar results are expected for all the vehicle categories.
- More than half (64%) of the measured toxic emissions were below the defined threshold (0.4 ppm), the average ambient background concentration plus one standard deviation.

6.7.2 Emissions of methane (CH_4)

Vehicles emit methane, a greenhouse gas, with a global warming potential (GWP) over 20 years of 72. This factor means that methane will trap 72 times more heat than an equal mass of carbon dioxide over the next 20 years. There are factors for 100 and 500 years but the 20 year factor is used in this analysis. From results of this project, the CH_4 contribution to greenhouse gases with diesel trucks can be ignored given that the emissions rate for CO_2 was about >2,000 gram/mile and that of CH4 was ~0.02 grams/mile. Thus emissions of CO_2 predominate for the greenhouse calculation, even after adjusting the methane rate by a factor of 72.

6.7.3 CO_2 and Fuel Economy emissions

CO_2 emissions for the refuse trucks are shown in Table 6-6 for the different test cycles. CO_2 emissions varied from 1,717 to 3,035 for the refuse trucks. The CO_2 emissions follow the same trends as for the fuel economy, since CO_2 is the predominant product of the combustion of the fuel.

Table 6-6: CO_2 Emissions for the Refuse Haulers in g/mile.

Vehicle			CO_2 (g/mi)		
Category	Engine	MY	RTC	UDDS	UDDS-CS
VIII	C8.3r	2012	2313	2818	3035
VIII	C9.3	2011	2016	2825	2590
VII	N7.6	2011	1717	1941	1811
V	N7.6	2008	2014	2356	2412

Fuel economy for the refuse haulers in different driving cycles are provided in Figure 6-18 to Figure 6-19. The refuse trucks showed slightly higher fuel economy values for the RTC compared to the UDDS. The 2010+ N7.6 refuse truck showed the highest fuel economy for the refuse trucks, while the lowest fuel economy for the refuse trucks was found for the 2010+ refuse trucks with SCR over the UDDS. There were no consistent trends between the UDDS and CS_UDDS cycles for the refuse haulers.

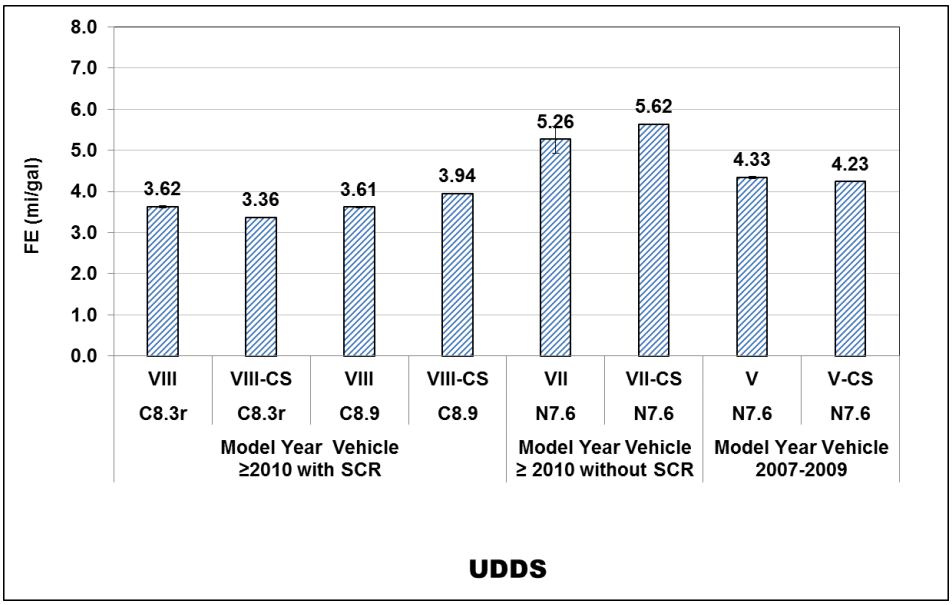

Figure 6-18: Fuel economy in miles/gallon of fuel for the UDDS cycle on the Refuse haulers.

[1] No error bars for the cold start tests because on only one test was performed

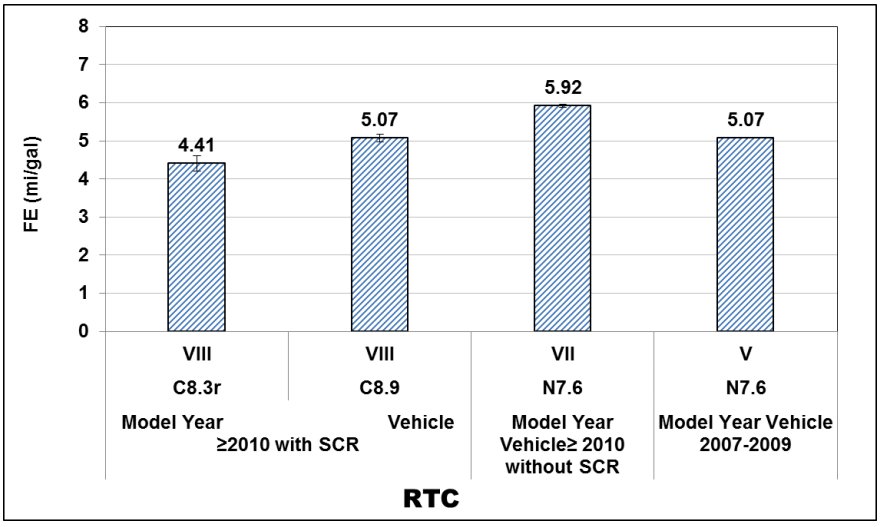

Figure 6-19: Fuel economy in miles/gallon of fuel for the AQMD Refuse Truck Cycle.

7 Results and Discussion for School Buses

This section covers the emissions for school buses for the Central Business District (CBD) cycle. The emissions are primarily reported on a grams per mile basis and where needed on a work basis to relate back to emission standards. The results represent the average from triplicate runs with one standard deviation error bars.

7.1 Test Buses

Two vehicles used as school buses were tested on a number of chassis cycles. Selected information for the school buses is identified in Table 1-1. One of the buses was fueled by LPG and the other was fueled by diesel and the aftertreatment included a DPF.

7.2 Test Conditions

Vehicles were tested on the CBC cycle, both cold and hot as these better represented what in-use values would look like. The loads for the goods movement vehicles were set at 20,000 lb., a value representative of a school bus with a capacity of 64 passengers at 100 lb. The weight accounted for the sum of the vehicle weight with school kids. Street fuels were used so both load and fuel matched in-use conditions. The emission values represent the average of triplicate runs and the graphs show the confidence limits to one standard deviation.

7.3 Regulated emissions

7.3.1 NO_x emissions

The NO_x emission results for the school buses are presented in Figure 7-1 for the CBD and the CS-CBD, respectively. The school buses showed significant differences between the two vehicles tested, with the 2007-2009 GM8.1 showing much lower emissions compared to the 2007-2009 C6.7 vehicle. These reductions were greater for the UDDS than the CS-UDDS, although the difference between the vehicles was still significant for the CS-UDDS. The emissions of the 2007-2009 C6.7 vehicles were comparable to those of the 2007-2009 vehicles in the other categories. The 2007-2009 GM8.1 had emissions that were lower than those of other vehicles in other vehicle categories, including the 2010+ vehicles with SCR.

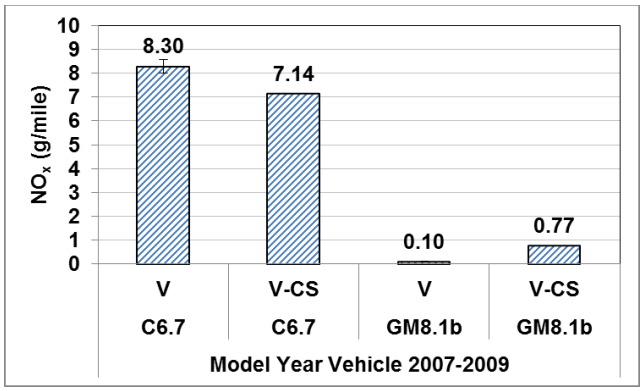

Figure 7-1: Emission factors for NOx CBD and cold start CBD cycles (g/mile)

[1] No error bars for the cold start tests because on only one test was performed

7.3.2 Percentage of NOx emissions as NO_2

NO_2 emissions are a health concern and values for the school buses are presented in Table 7-1. These tables show the percentage of the total NO_x that is NO_2 in g/mile. Interestingly the LPG vehicle did not have NOx or NO_2 while the diesel vehicle with the DPF did have up to 40% as NO_2. Similar to the observation with the goods movement vehicles, levels of NO_2 are high as compared with the ARB retrofit rule of 20% over baseline

Table 7-1: NO_2, NO_x and fraction of NO_2 to total NO_x for the bus cycles (g/mi)

Vehicle			CBD			CS_CBD		
Category	Engine	MY	NO_2	NO_x	$\%NO_2$	NO_2	NO_x	$\%NO_2$
V	C6.7	2007	2.86	7.14	40%	3.91	8.30	47%
V	GM8.1b	2008	-0.01	-0.01	n/a	-0.03	0.77	n/a

7.3.3 PM emissions

The PM emission results for the school buses are presented in Figure 7-2 for the CBD and the CS-CBD, respectively. The school buses showed differences in baseline PM emissions, which were approximately 2 mg/mi for the LPG fueled 2007-2009 GM8.1 vehicle and 6 mg/mi for the 2007-2009 C6.7 diesel vehicles. While measureable, these values are very low. The PM emissions for the CS-CBD for the 2007-2009 C6.7 were similar to those for that vehicle for the regular CBD, while the CS-CBD emissions for the 2007-2009 GM8.1 vehicle were at the limits of the measurement capability.

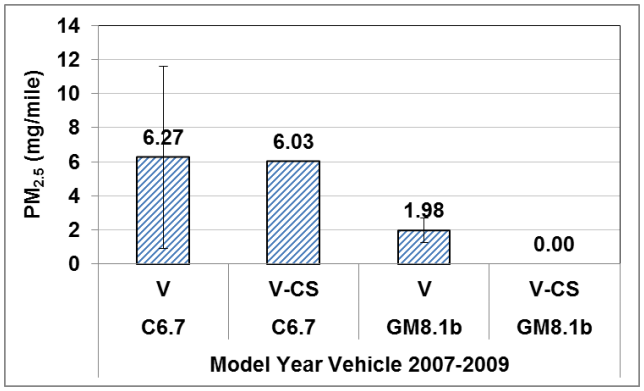

Figure 7-2: PM Emission factors for hot/cold CBD cycles (mg/mile)

[1] No error bars for the cold start tests because on only one test was performed

7.3.4 THC/NMHC/CH_4 and CO emissions

Table 7-2 and Table 7-3 show the emission factors for THC, CH_4, NMHC and CO for the CBD for buses. The emission factors for the THC, CH_4, and NMHC were low for all vehicle/cycle combinations. THC emissions were at or below 0.45 g/mi for most vehicle/cycle combinations. NMHC emissions were at or below 0.30 g/mi for nearly all vehicle/cycle combinations. CH_4 emissions were at or below 0.20 g/mi for nearly all vehicle/cycle combinations. Cold start

emissions were low for most vehicle/cycle combinations, with the 2007-2009 GM8.1 bus showing somewhat higher cold start THC, NMHC, and CH_4 emissions.

CO emissions were below 1 g/mi for most vehicle/cycle combinations, except the 2007-2009 LPG-fueled GM8.1 school buses. Cold start emissions were below 2 g/mi for all but the 2007-2009 GM8.1 school bus, which showed considerably higher CO emissions compared to the other vehicles of 16.0 g/mi.

Table 7-2: THC, CH_4, NMHC, and CO emissions for the Bus cycles

Vehicle			Emission Factor (g/mi)			
Category	Engine	MY	THC	CH4	NMHC	CO
V	C6.7	2007	0.04	0.02	0.03	0.20
V	GM8.1b	2008	0.30	0.20	0.13	9.82

Table 7-3 THC, CH_4, NMHC, and CO emissions for the Cold Start test cycles

		Vehicle		Emission Factor (g/mi)			
Cycle	Category	Engine	MY	THC	CH4	NMHC	CO
CS-CBD	V	C6.7	2007	-0.19	0.02	-0.21	-0.04
CS_CBD	V	GM8.1b	2008	0.77	0.25	0.56	16.03

7.4 Non-regulated Gaseous Emissions

7.4.1 NH_3 Emissions in g/mile

The NH_3 emission results for the school buses are presented in Figure 7-3 for the CBD and the CS-CBD. The NH_3 for the LPG-fueled 2007-2009 GM8.1 school bus was the highest among the vehicles being tested, in the range of 0.45 to 0.5 g/mi. The NH_3 emissions for the 2007-2009 C6.7 diesel-fueled vehicle were on the order of 10 to 20 mg/mi, which is near the lower end of the range of the vehicles tested for the this study.

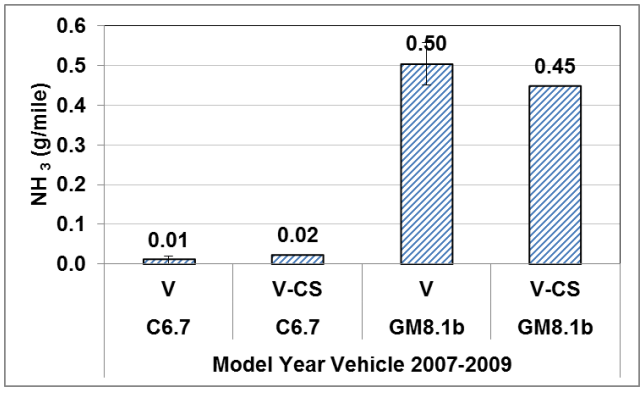

Figure 7-3: Emission factors for NH_3 CBD cycle (g/mile)[1]

[1] NH_3 scale is based on 10 ppm raw exhaust concentration

[2] No error bars for the cold start tests because on only one test was performed

7.4.2 Selected toxic emissions (1,3-butadiene & BTEX)

The 1,3 butadiene, benzene, and toluene results for the school buses are shown in Figure 7-4. Measureable levels for benzene were found for both vehicles for the cold start CBD, and measureable levels of toluene were found for the c6.7 for the CBDx2 and for the GM8.1 for the cold start CBD.

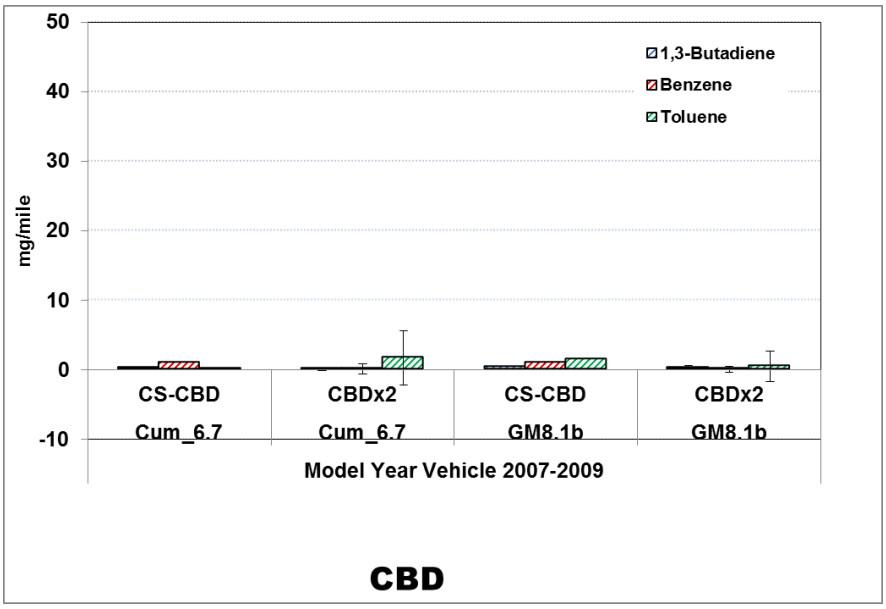

Figure 7-4 Emissions of Selected Toxic in mg/mile

[1] No error bars for the cold start tests because on only one test was performed

7.4.3 Selected toxic emissions (aldehydes & ketones)

The formaldehyde, acetaldehyde, and acetone carbonyl results for the school buses are shown in Figure 7-5. The GM 8.1 showed the highest levels of acetone and formaldehyde for cold start CBD, with the emissions of acetone being higher than those of formaldehyde. This is not surprising that there was partial oxidation of the LPG fuel on startup. The carbonyl emissions were very low for the other vehicle/cycle combinations.

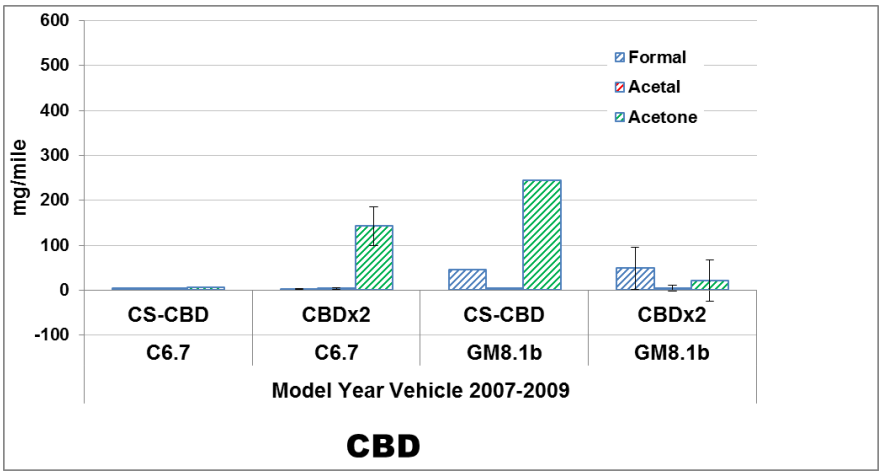

Figure 7-5 Emissions of Carbonyls & Ketones in mg/mile

[1] No error bars for the cold start tests because on only one test was performed

7.5 Non-regulated PM emissions

7.5.1 Fractionation of PM mass into OC and EC

The elemental and organic PM results for the school buses are shown in Figure 7-6. The GM8.1 showed elemental and organic carbon emissions that were essentially at the background levels. Not surprising the DPF captured all of the PM and elemental carbon. The C6.7 and GM8.1 school bus shows that OC was the primary PM for the cold start and the warm tests. Deeper analysis on the detection limits of the method used suggest the result may not be statistically significant since the OC measurement was very low and at detection limits of the method. See Section 8.4.4 for a discussion on EC and OC detection limits.

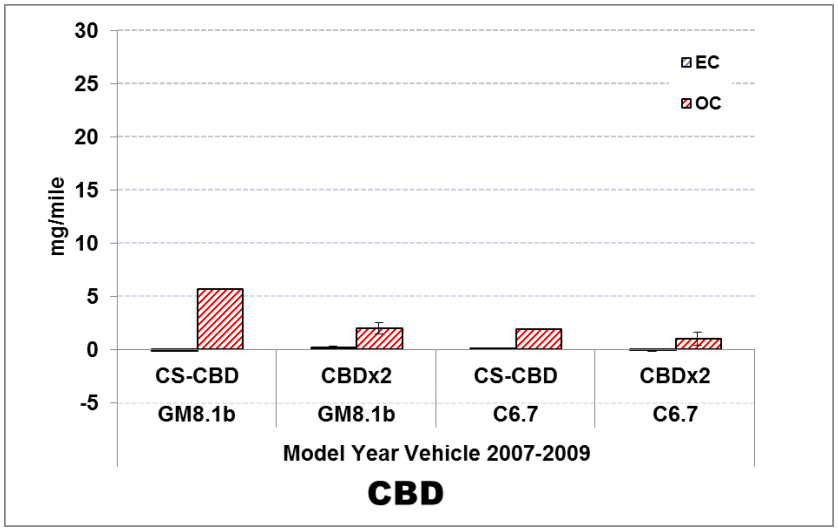

Figure 7-6 Fractionation of PM mass into OC and EC (mg/mile)

[1] No error bars for the cold start tests because on only one test was performed

7.5.2 Measurement of real-time and ultrafine PM

As described previously, The DMM was used to characterize the real time PM mass concentration and the f-SMPS was used for the ultrafine PM emissions characterization.

Real-time PM mass DMM

As presented earlier the PM mass of the gravimetric method were very low and typically around 3.8 mg/mi or 3.1 gm/bhp-hr for all the school bus vehicles tested. The average PM mass from the DMM measurement method averaged 0.5 mg/mi and 0.1 mg/bhp-hr for the same vehicles.

Ultra-fine PM emissions

There was no significant difference between cold start emissions and vehicle technology for the school bus tests. Figure 7-7 shows the size distribution for the propane and disel school bus tests for hot CBD tests cycles. The propane total PM mass was lower than the diesel PM mass on a g/mi basis which is supported by the lower size concentration at the 50 to 200 nm size range (ie most of the PM mass due to the diameter to the 3rd power). Additionally there is not a large cold start fine particle concentration for either the diesel or LNG school bus.

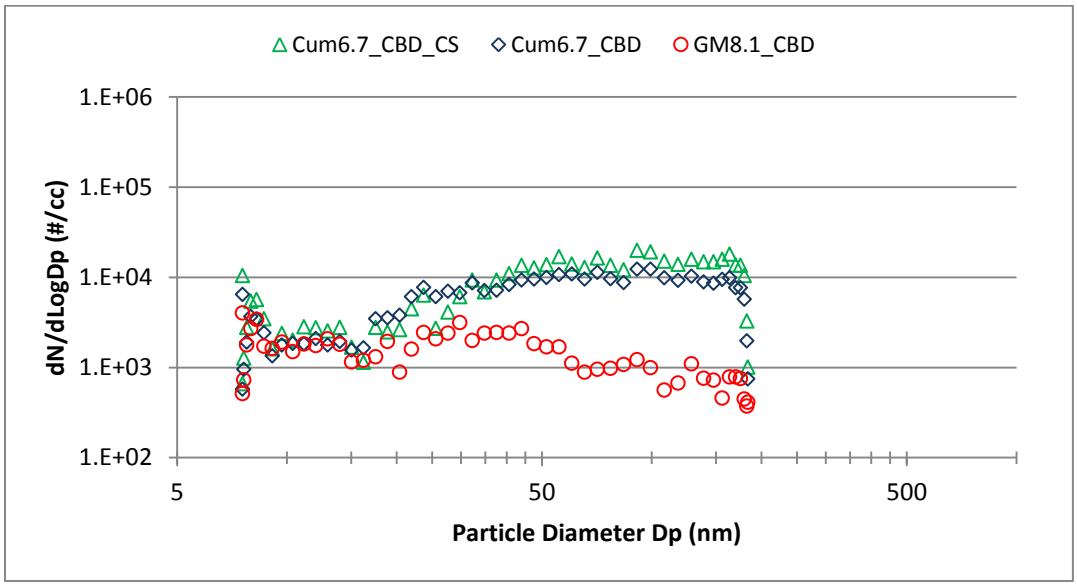

Figure 7-7 Average size distributions for the two school bus vehicles: CBD

7.6 Greenhouse Gas (N_2O, CH_4 & CO_2) Emissions and Fuel Economy

For greenhouse gases, UCR measured emissions factors of methane and carbon dioxide in real-time for all vehicles and N_2O with off-site analyses for selected vehicles. The off-site analyses were carried out by the California Air resources Board and West Virginia University. Results showed the measured values were close to ambient levels, as expected for diesel vehicles. Literature indicates N_2O is observed when vehicles rely on three way catalyst and UCR did not have any included in their fleet of test vehicles.

7.6.1 Emissions of nitrous oxide (N_2O)

N_2O emissions were measured by the IR methods described earlier and found to be near the detection limits. A literature review showed that Huai et alia[13] only found nitrous oxide when a three way catalyst was warming. Thus we only expected N_2O for the LPG truck as the after treatment was a three way catalyst.

The N_2O measurements were very close to the ambient concentrations were negative numbers were reported. The reason for negative numbers is based on the correction of the ambient measured concentration exceeding the sample measurement, as described in a later section. It is expected that many of the measurements are near the detection limits of the N_2O measuring method. See Section 8.4.3 for analysis and summary of N_20 measurements and detection limits.

The general observations of the N_2O emissions from the vehicles tested can be summarized as:

- N_2O Analysis was done offsite when facilities were available. As such, not all vehicles or cycles were tested for N_2O. Only selected vehicles were tested for N_2O analysis.
- During the refuse and school bus testing there were no facilities for N_2O analysis thus they were not performed. Similar results are expected for all the vehicle categories.
- More than half (64%) of the measured toxic emissions were below the defined threshold (0.4 ppm), the average ambient background concentration plus one standard deviation.

7.6.2 Emissions of methane (CH_4)

Vehicles emit methane, a greenhouse gas, with a global warming potential (GWP) over 20 years of 72. This factor means that methane will trap 72 times more heat than an equal mass of carbon dioxide over the next 20 years. There are factors for 100 and 500 years but the 20 year factor is used in this analysis. From results of this project, the CH_4 contribution to greenhouse gases with diesel trucks can be ignored given that the emissions rate for CO_2 was about >2,000 gram/mile and that of CH4 was ~0.02 grams/mile. Thus emissions of CO_2 predominate for the greenhouse calculation, even after adjusting the methane rate by a factor of 72.

7.6.3 CO_2 and Fuel Economy emissions

CO_2 emissions for the school busses are shown in Table 7-4 for the CBD cycle. CO_2 emissions varied from 1,354 to 1,516 for the school busses. The CO_2 emissions follow the same trends as for the fuel economy, since CO_2 is the predominant product of the combustion of the fuel. Fuel economy for the school busses is provided in Table 7-5 for the CBD cycle.

Table 7-4: CO_2 Emissions for School Buses.

8 Deeper Analysis of the NOx, NH_3, Toxic Emissions, and N_2O

This section was written to provide more detail on topics that the authors thought would provide better insight to the results section because of the interest in the SCAQMD District in learning more about the differences between the certification values for NOx and the values measured for near in-use conditions. As stated in the introduction, having emissions levels at certification values is assumed in the AQMP so knowing why in-use emission are higher is an important question.

8.1 NOx Emissions Control Technology & Results

8.1.1 Cooled exhaust gas recirculation (EGR)

Cooled exhaust gas recirculation (EGR) was an early solution to meet lower NOx standards. This project produced a surprising finding when the emissions from the UDDS emissions were compared with those of the three in-use port cycles. Results showed the NOx emissions for the near port cycle were 250% greater than those of the regional cycle. Furthermore the near port emissions were about 35% higher than the UDDS suggesting that the emissions from the in-use driving near the port will be greater than assumed in the AQMP. On the other hand, emissions from travel to regional distribution centers is about 55% lower so the final impact on inventory will depend on the activity-weighted mix of the driving cycles.

8.1.2 Three way catalysts (TWC)

Some vehicles have switched from diesel fuel to gaseous fuels, such as LPG or natural gas. In those cases, the NOx starts with precise metering of the air-fuel ratio so combustion is at stoichiometric conditions and then passing the exhaust over a three way catalyst. In cases where the combustion is lean, then NOx is high. The cases of the LPG truck showed higher NOx; however, the school bus had a lower NOx level.

8.1.3 Selective Catalytic reduction (SCR)

Figure 8-1 illustrates the after treatment system found on a typical exhaust after 2010 in order to meet the strict NOx standards. With Selective Catalytic Reduction (SCR) NOx is converted into nitrogen by reaction with ammonia over a special catalyst. When operating temperatures are >250°C, an aqueous solution of urea is injected into the exhaust upstream of the SCR catalyst. The heat converts the urea into ammonia and water which is the reactant to convert NOx to nitrogen. At temperatures <250°C, urea is not injected so the full engine out NOx emissions are emitted.

In actual operation catalyst temperatures are not simply either less/greater than 250°C. Instead the exhaust temperature is highly dynamic and follows the dynamic nature of the actual driving schedule. Figure 8-2 shows the temperature trace of the temperatures in three places in the exhaust as a function of time in seconds for the port cycle. Note for a significant portion of the beginning that the temperature is <250°C so urea is not added and there is no NOx control. Even after 250°C is reached, there are times that the temperature goes below the desired temperature.

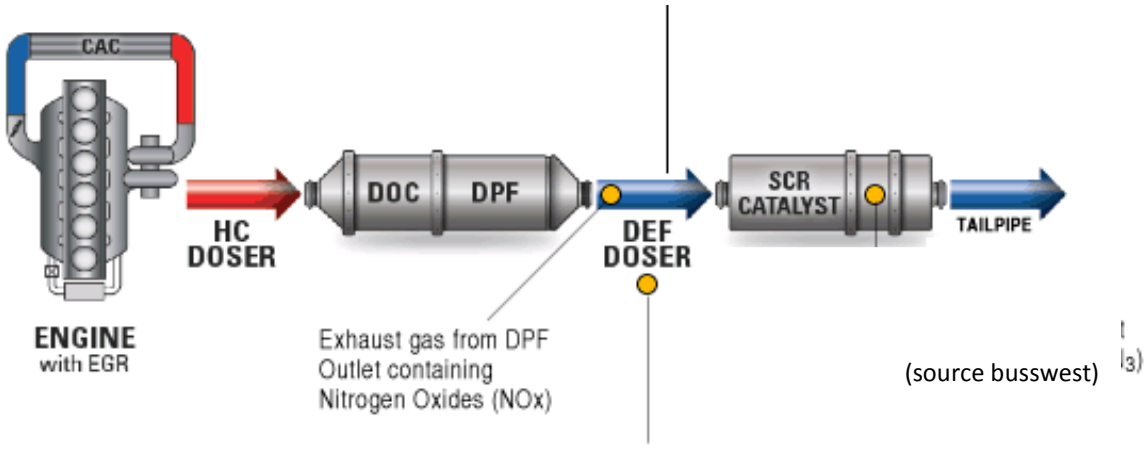

Figure 8-1: Figure of diesel DOC, DPF, and SCR after treatment system arrangement

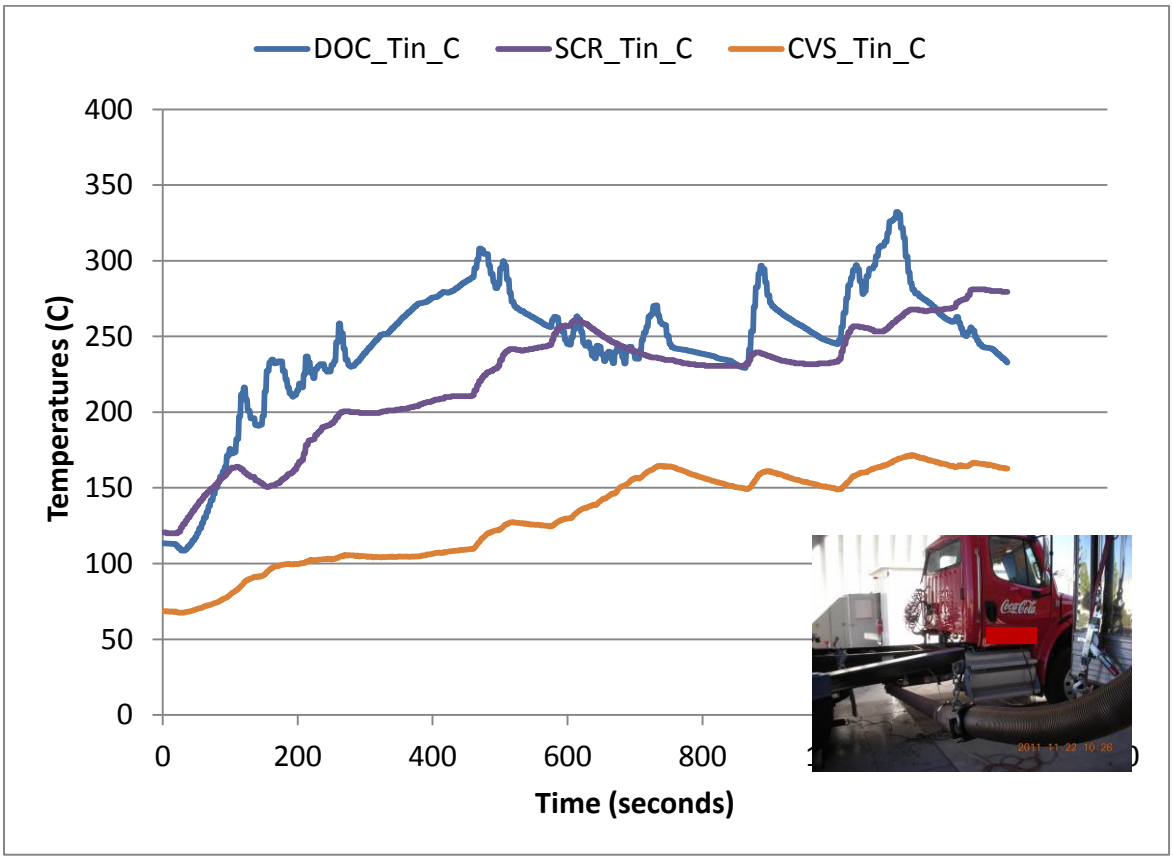

Figure 8-2: Typical engine catalyst temperatures as measured during this project

8.2 NO_x from Goods Movement Vehicles

Figure 8-3 shows how the cumulative NO_x rate varies over the regional port cycle for a SCR equipped goods movement vehicle as a function of time. Superimposed on the figure is the driving schedule with targeted vehicle speed. The results show that 2/3rd of the NOx accumulate in 1/3rd of the cycle time as the exhaust temperature at the SCR inlet is below approximately 250°C.

For the first 1750 seconds of the cycle the average NO_x emission rate is 1.34 g/bhp-h. After that time the vehicle is cruising at ~50mph and the SCR inlet temperature is above 325°C when relatively little NO_x is emitted. The average NO_x emission rate during the cruise portion of the cycle is 0.028 g/bhp-h, a value that shows the catalyst efficiency is 98%. Additional NO_x is emitted near the end of the cycle, as the temperature of the SCR inlet cools on the deceleration from the cruise. The average NO_x emission rate for the last portion of the cycle is 0.128 g/bhp-h.

The same run results are plotted as function of accumulated power in Figure 8-4, again showing that NO_x is predominately emitted during the initial period of the cycle where there is very little accumulated power and the SCR inlet temperature remains below 325°C.

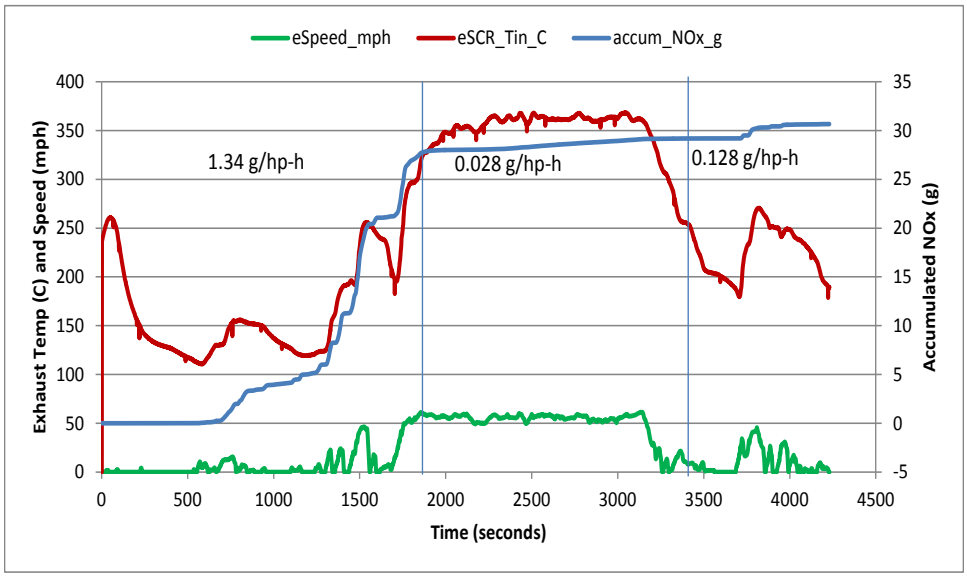

Figure 8-3: Brake specific NO_x Emissions for Regional Port Cycle versus Time

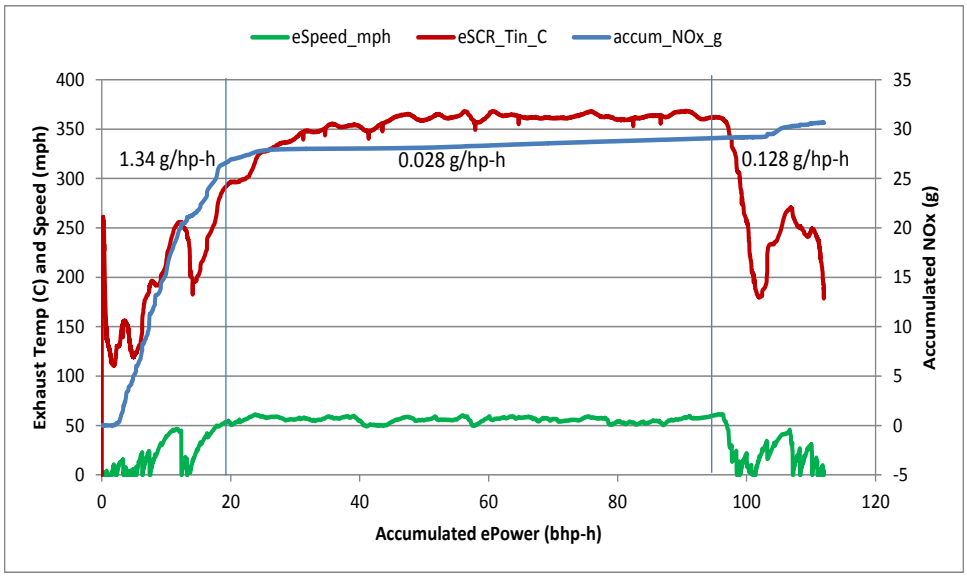

Figure 8-4: Brake specific NO_x emissions for the Regional port cycle as a function of work

The cold start catalyst temperatures were lower than the hot start catalyst temperatures and thus, showed much higher NO_x emissions. Figure 8-6 shows the Cummins ISX 11.9 liter engine's NO_x accumulated mass emissions for a cold and hot start UDDS. The cold start catalyst temperatures started at 10C and 230C for the hot start tests. The $bsNO_x$ for the first ½ mile, 1 mile, and from 1 to 11miles are computed and shown in the figure. The cold and hot start $bsNO_x$ emissions for the first ½ mile were 2.29 g/bhp-hr and 0.006 g/bhp-hr respectively. Similarly, the cold and hot start $bsNO_x$ emissions for the first 1 mile of the test were 1.48 g/bhp-hr and 0.005 g/bhp-hr respectively. The amount of emissions accumulated in 1 mile of the cold start UDDS are equivalent to 32 miles of the hot start UDDS for the Cummins ISX 11.9 engine.

Figure 8-5 show profiles of NO_x emissions in comparison with after treatment system (ATS) temperature for goods movement vehicles. For the goods movement vehicles, the highest NO_x emissions and corresponding lowest percentage of operation with the ATS >250°C were found for the Near Dock cycle. The lowest NO_x emissions and the highest percentage of operation with the ATS >250°C were found for the Regional cycle. Interestingly, for the 2010+ V12.8 vehicle, a relatively large portion of the NO_x emissions were produced when the ATS temperature was >250°C for the near dock and local cycles compared to the percentage of operation when the ATS temperature was >250°C.

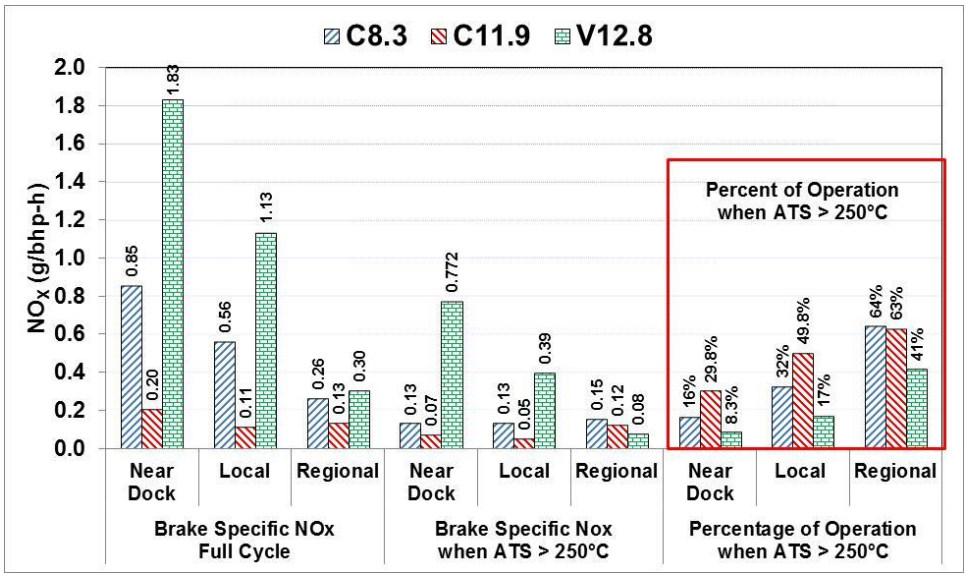

Figure 8-5: NO_x emissions in g/bhp-hr for the whole port cycle

[1] NO_x emissions only when the ATS temperature was >250^{0}C.

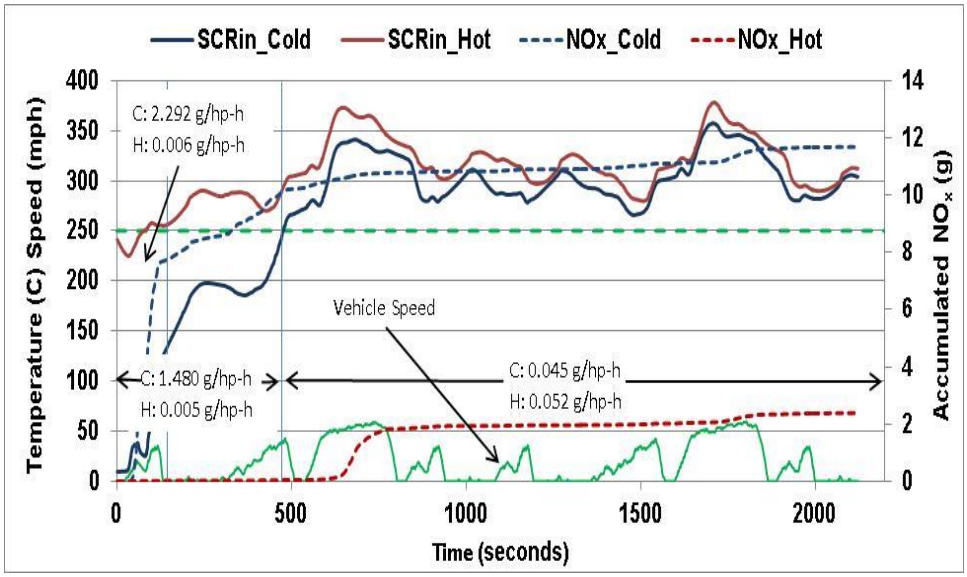

Figure 8-6: Accumulated NOx emissions for the C11.9 during hot and cold start UDDS

8.3 NO_x from Refuse Haulers

Figure 8-7 shows profiles of NO_x emissions in comparison with after treatment system (ATS) temperature for the refuse trucks. For the two refuse trucks, there was a higher percentage of operation with the ATS >250°C, with most combination have over 70% of operation with the ATS >250°C. Of the two vehicles, the 2010+ C9.3 refuse trucks showed strongest trends in NO_x emissions as a function of temperature. In particular, a relatively small percentage of NO_x emissions were formed when the ATS temperature was >250°C for the near dock and RTC cycles, even though 70+% of the operation was at these higher temperatures. For the 2010+

C8.3 refuse truck and the 2010+ C9.3 refuse truck for the UDDS, the percentage of NO_x produced when ATS was >250°C was more similar to the percentage of operation at the higher temperature operation.

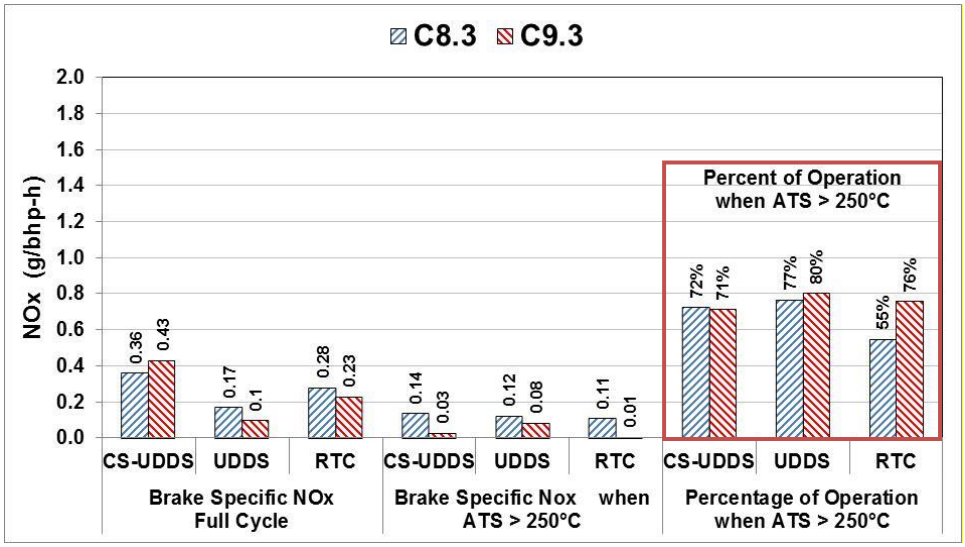

Figure 8-7: NOx emissions in g/bhp-hr for the whole AQMD Refuse Truck Cycle

[1] NO_x emissions only when the ATS temperature was >250^{0}C.

Figure 8-8 how the temperature profiles for the Refuse Truck cycle for one of the refuse trucks. The plot includes several of the different temperatures that were measurements were available for, including the exhaust temperature, pre- and post DOC temperatures, and the post-DPF temperature. The temperatures all show the same trends, where the temperature peaks after the first main double peak of the transit portion of the cycle and then slowly declines throughout the remainder of the transit portion and during the curbside portion. Temperatures during the compaction portion of the cycle show a slight increase, but overall are similar to those near the end of the curbside segment.

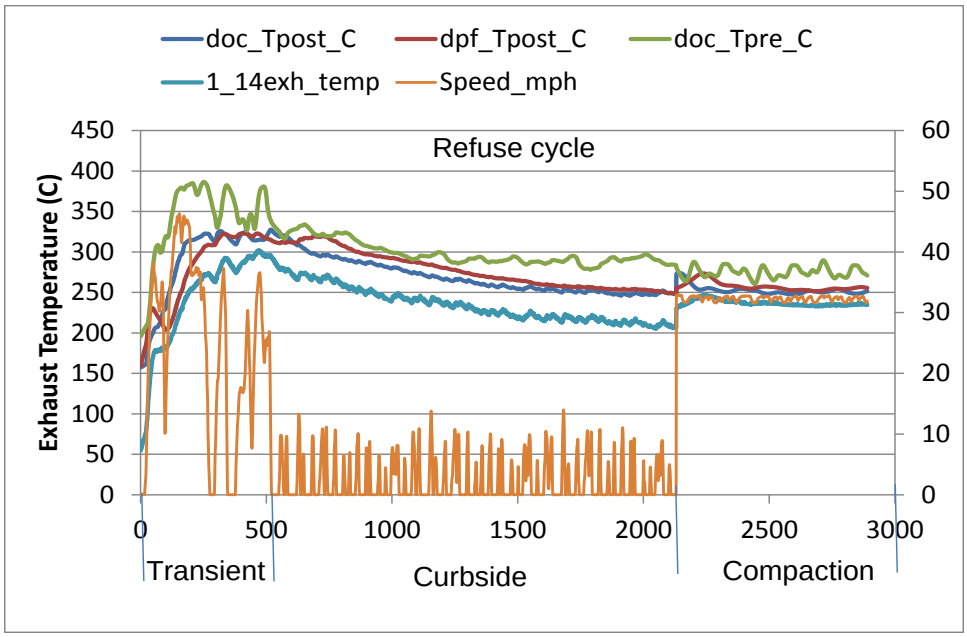

Figure 8-8: Example of SCR equipped refuse hauler exhaust temperatures

Figure 8-9 shows how cumulative NO_x varies over a refuse truck cycle for one of the SCR equipped refuse trucks as a function of cycle time. NO_x emissions over the refuse truck cycle showed some trends similar to the goods movement vehicle, but also showed a stronger dependency on the driving operation. Approximately 1/3rd of the cumulative NO_x emissions were from the first 200 seconds of operation when the post-DPF temperature was below 250˚C, with an average emission rate of 0.72 g/bhp-h. For the main part of the cycle, after the initial peak and including the curbside pickup portion of the cycle, relatively little NO_x is produced, with an average emission rate of 0.11 g/bhp-h. The greatest percentage of NO_x was formed during the latter stages of the cycle, when the compaction portion of the cycle was conducted. The average post-DPF temperature was around 250˚C during the compaction portion of the cycle and the average emission rate was 0.99 g/bhp-h. These same results for the refuse truck are plotted as function of accumulated power in Figure 8-10. The results show that the majority of the work is performed during the middle portion of the cycle, where the post-DPF temperatures are steadily above 250˚C. The initial segment of the cycle represents a relatively small portion of the overall cycle work. The compaction portion of the cycle represents only about 25% of the total work, but over 50% of the total accumulated NO_x.

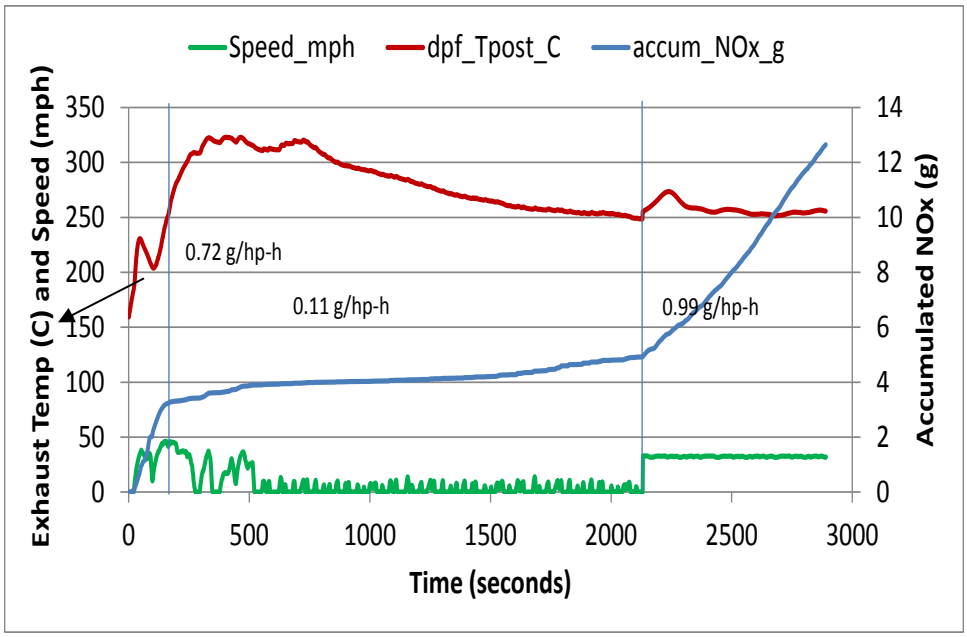

Figure 8-9: Brake specific NO_x emissions for the Refuse Truck Cycle as a function of time

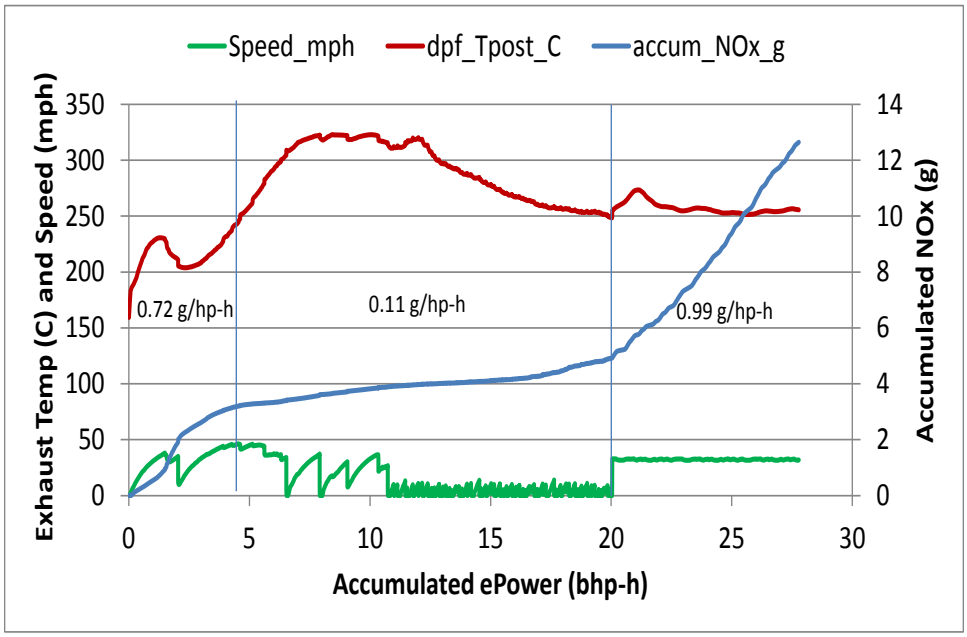

Figure 8-10: Brake specific NO_x emissions for the Refuse Truck Cycle as a function of work

The cold start catalyst temperatures were lower than the hot start catalyst temperatures and thus, showed much higher NO_x emissions. Figure 8-11 shows the Cummins ISX 11.9 liter engine's NO_x accumulated mass emissions for a cold and hot start UDDS. The cold start catalyst temperatures started at 10°C and 230°C for the hot start tests. The $bsNO_x$ for the first ½ mile, 1 mile, and from 1 to 11miles are computed and shown in the figure. The cold and hot start $bsNO_x$ emissions for the first ½ mile were 2.29 g/bhp-hr and 0.006 g/bhp-hr respectively. Similarly, the cold and hot start $bsNO_x$ emissions for the first 1 mile of the test were 1.48 g/bhp-

hr and 0.005 g/bhp-hr respectively. The amount of emissions accumulated in 1 mile of the cold start UDDS are equivalent to 32 miles of the hot start UDDS for the Cummins ISX 11.9 engine.

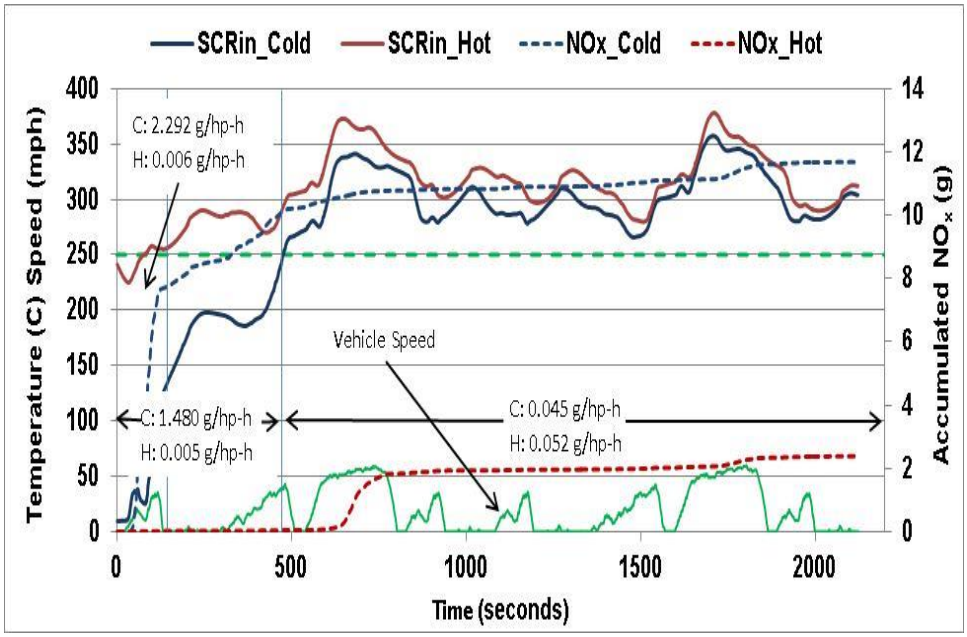

Figure 8-11: Accumulated NOx emissions for the C11.9 during hot and cold start UDDS

8.4 Discussion of detection limits

Results in this study showed that emissions of gaseous toxics were typically at or below detection level. In fact, some data showed that the exhaust values were less than ambient. A suitable reference for the discussion of hydrocarbons in diesel engines with DFPs is the Advanced Collaborative Emissions Study (ACES) which showed that hydrocarbons were reduced by up to 98% over a diesel engine without a DPF. The reason for the reduction is the DOC is an active catalyst for converting hydrocarbons to water and carbon dioxide.

8.4.1 Discussion of 1,3-butadiene & BTEX

As discussed previously many of the measurements for the non-regulated emissions were very low and sometimes negative. This section describes the BETEX concentration in relationship to measurement detection limits to help understand the limitations in making non-regulated emission measurements.

Table 8-1 through Table 8-8 shows the toxic average concentrations for the ambient and vehicle samples. The ambient concentration for the toxics ranged from 0.5 ppbv to 5 ppbv at one standard deviation. The ambient measured concentration single standard deviation is about equal to the measured value. If we establish a lower threshold for the toxic results to be equal to the average concentration pulse one standard deviation then we can visual display the data above and below this threshold. The sample concentrations in Table 8-1 through Table 8-8 are presented with this threshold in mind. If the cycle average measured concentration is less than the established threshold no value is displayed and if it is larger than the threshold than a value

will be displayed. Cells with no color are less than two times the threshold, green is less five times, orange less than ten times, and red is more than ten times.

As one can see many of the data points are not visible and are thus, below the established threshold. Additionally of the values shown in the tables most of these are still less than twice the established threshold and represent measurement at or near ambient detection limits.

The general observations about the toxic emissions from the vehicles tested can be summarized as:

- More than half (75%) of the measured toxic emissions were below a defined threshold of the average ambient background concentration pulse one standard deviation.
- More than half (55%) of the remaining values were less than two times the threshold. About 31% were between two and five times, 9% between five and ten times and only 5% were above ten times the threshold.
- Benzene appears to be the most dominate species measured for all the vehicles tested.
- More toxics emissions appear to be present for the port vehicles compared to the bus and refuse vehicles.
- The propane powered GM port vehicle showed the highest Benzene emissions. The regional cycle showed the highest Benzene emissions at more than 30 times the threshold. The Benzene emissions were highest for the port cycles compared to the UDDS cycle.
- One of the cold start port vehicles showed high ethyl benzene, m,p-xylene, and 0-xylene emissions. These measurements were only single samples (no duplicates were taken). Additional samples may be needed to confirm.
- The Advanced EGR vehicles appear to show more benzene emissions compared to the SCR equipped diesel vehicles. Additional testing would be needed to confirm this observation.

8.4.2 Discussion of Carbonyls & Ketones

As discussed previously many of the measurements for the non-regulated emissions were very low and sometimes negative. This section describes the carbonyl concentration in relationship to measurement detection limits to help understand the limitations in making un-regulated emission measurements.

Table 8-9 through Table 8-17 show the average and single standard deviation for the carbonyl emissions concentrations as measured for the back ground and vehicle samples. Table 8-9 shows the toxic average concentrations for the ambient samples. The ambient concentration for the toxics ranged from 0.15 µg/l for acetone to, 0.1 µg/l for acetal, and 0.02µg/l for Formaldehyde to below detection for most of the remaining carbonyls. The ambient concentrations have a single standard deviation approximately equal to their average measurement suggesting the analysis method and measurements are near the detection limits of the method.

To investigate the emissions from carbonyls from the vehicle samples, a lower threshold for the toxic results to be equal to the average concentration plus one standard deviation was used. The sample concentrations in Table 8-10 through Table 8-16 are presented with this threshold in mind. If the cycle average measured concentration is less than the established threshold, then no value is displayed and if it is larger than the threshold than a value will be displayed. Cells with no color represent measurements less than two times the threshold, color green represents less than five times, orange less than ten times, and red more than ten times the threshold value. Table 8-17 shows the percentage of samples for all vehicles for each species that were above the defined threshold.

As it can be seen in the tables, most of the data points are below the threshold. Amongst the reported results a majority of them were less than five times and the rest less than two times the threshold value. Therefore they represent measurement at or near measurement method detection limits. The following can be summarized about the results:

- Formaldehyde was the most significantly observed carbonyl from all the vehicles in all the categories and all the test cycles. It amounted to more than half (78%) of defined threshold of the average ambient background concentration pulse one standard deviation. Acetaldehyde was next, amounting to 27% of the above threshold limit of the respective acetaldehyde concentration. The detailed table below provides a clear understanding of the distribution of the above threshold values for all the thirteen carbonyls.
- More toxics emissions appear to be present for the port vehicles compared to the bus and refuse vehicles.
- The propane powered GM port vehicle showed the highest formaldehyde emissions for all the port cycles and the UDDS cycle. The regional cycle showed >50 times threshold values of formaldehyde, and the port cycles showed higher formaldehyde than the UDDS cycle for this vehicle.
- Advanced EGR vehicles had more above threshold emissions in comparison with the SCR technology vehicles. Although, the above threshold emissions from the EGR were less than five times the average threshold concentrations.

8.4.3 Discussion of N_2O limits

This section describes the nitrogen dioxide (N_2O) concentrations in relationship to measured detection limits to help understand the limitations in making un-regulated emission measurements. The first part of the analysis describes the comparison between the MEL's laboratory NDIR CO_2 measurement. The reason for CO_2 comparison is to provide the reader confidence the samples were aligned properly and the bags were sampled properly and agree well with the MEL. After the CO_2 comparison the N_2O analysis is presented. Then a final description of the fuel specific, brake specific, and mile specific N_2O emissions are presented to show typical contributions of the measured values.

CO_2 NDIR and FTIR analysis and comparison

Figure 8-12 and Figure 8-13 below show the vehicle CO_2 and ambient CO_2 measurement comparisons between the FTIR and MEL laboratory NDIR instruments. The FTIR system is a bag measurement that was transported from UCR to an outside laboratory for N_2O Analysis. Additionally these systems report several other species which include CO_2. Since CO2 is a large signal by the FTIR they should roughly agree with the MEL laboratory NDIR measurement. Figure 8-12 shows that the source comparison varied from 0.2 % to 1% for the selected tests. The average ratio of FTIR/NDIR CO_2 averaged 0.84 with a 95% confidence standard deviation of 0.24. The 95% confidence suggests the measurement ranges from just over 1 to 1 to about 50% of the signal. For the ambient FTIR CO_2 data in Figure 8-13, the measurement uncertainty is around 0.05 %. Four points were driving the large 95% confidence value of 0.24. These occurred at low concentrations where the 0.05% FTIR uncertainty could explain the bias. As such, it appears all the provided N_2O data is reasonably and represents good bag samples and should be accurate for vehicle comparisons.

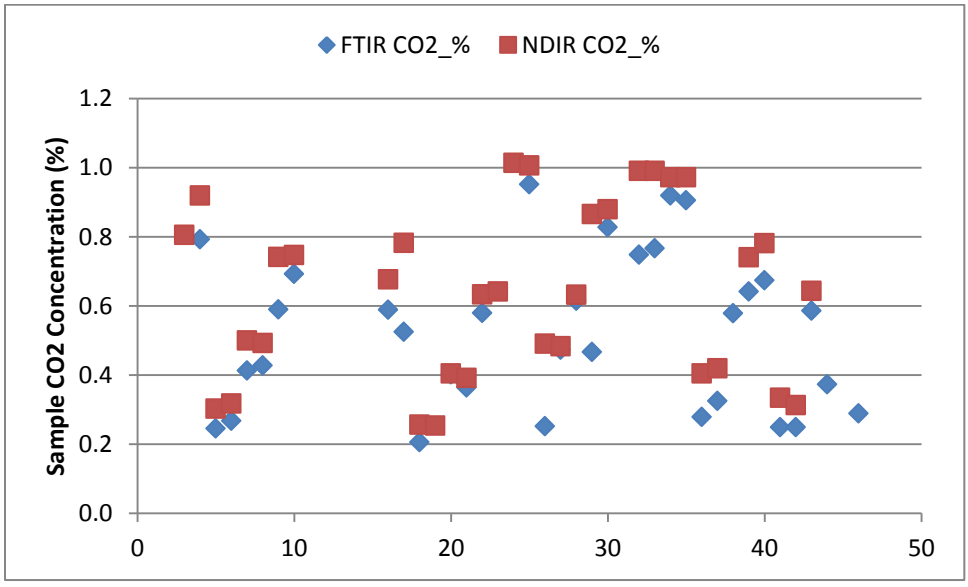

Figure 8-12 FTIR compared to laboratory CO_2 measurement for selected vehicle sources

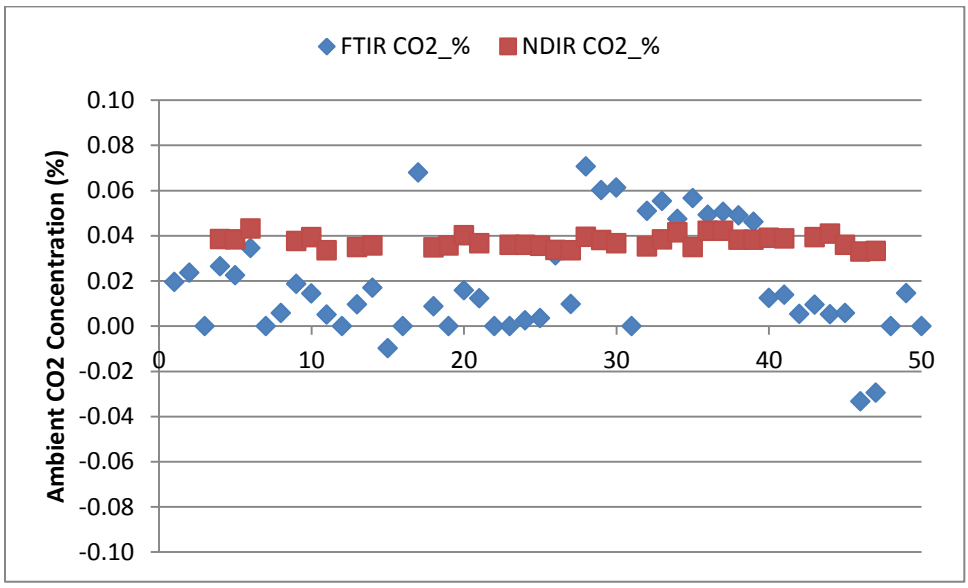

Figure 8-13 FTIR compared to laboratory CO_2 measurement for selected ambient bags

N_20 analysis and detections limits

Table 8-18 and Table 8-24 show the average N_2O concentrations for ambient as well as for sampled vehicles. The average measured background concentration for N_2O was 0.138 ppm with a single standard deviation of 0.264 ppm. The ambient N_2O concentrations have a single standard deviation approximately equal to twice their average measurement suggesting the analysis method and measurements are near the detection limits of the method or there is a large variability in the ambient N_2O concentrations.

Others show that the ambient concentrations for N_2O are around 0.314 – 0.320 ppm [14,15,16] with a steady increase of about 0.01ppm/decade. Their data suggest the true ambient average is probably closer to 0.325 ppm instead of the average of 0.138 ppm. Also this suggests the measurement method is not sensitive enough to quantify the presence of N_20 neither in the ambient nor the ability to measure source N_2O emissions near the ambient levels.

To examine the N_2O being emitted from vehicle samples, a lower threshold in the results was established and set equal to the average concentration plus one standard deviation (0.402 ppm). This threshold is only slightly higher than the average N_2O ambient concentration predicted by several studies[13,14,15].

The sample concentrations in Table 8-20 through Table 8-24 are presented with this threshold in mind. If the measured average cycle concentration is less than the established threshold no value is displayed and if it is larger than the threshold than a value will be displayed. Not all vehicles were sampled for N_2O analysis due to limited laboratory accessibility. The greyed cells represent test runs that were not analyzed for N_2O analysis.

N_2O emission factors (g/mi)

The previous tables showed the N_2O concentrations relative to the ambient measured concentration and standard deviation of those values. Additionally the tables showed the calculated N_2O emission rates on a grams per mile basis. The N_2O emissions rates were calculated by correcting for ambient concentrations as shown by equation 2 below:

Equation 2

$$EF = * \frac{V_{mix} * \rho_{N20} * \left(C_i - C_{bk} * \left(1 - \frac{1}{DF} \right) \right)}{Miles}$$

Where:

EF	is the emission factor in g/mi
V_{mix}	volume through the CVS in m^3
ρ_{N20}	density of N_20 from ideal gas law at 1 atm and 20C and molar mass N_2O
C_i	sample concentration
C_{bk}	background concentration
DF	dilution ratio from CVS sampling system
Miles	distance traveled in miles

The N_2O measurements were very close to the ambient concentrations were negative numbers were reported. The reason for negative numbers is based on the correction of the ambient measured concentration exceeding the sample measurement. It is expected that many of the measurements are near the detection limits of the measuring method.

The general observations of the N_2O emissions from the vehicles tested can be summarized as:

- N_2O Analysis was done offsite when facilities were available. As such, not all vehicles or cycles were tested for N_2O. Only selected vehicles were tested for N_2O analysis.
- During the refuse and school bus testing there were no facilities for N_2O analysis thus they were not performed.
- More than half (64%) of the measured toxic emissions were below the defined threshold (0.4 ppm), the average ambient background concentration plus one standard deviation.
- Only the SCR equipped vehicles showed signs of N_2O emissions not the non-SCR equipped vehicles.
- The cold start UDDS did not show higher integrated N_2O emissions compared with hot start UDDS tests (with or with/out SCR). It is not clear from the testing if higher N20 emissions were created for a short duration at the cold start of the cold test cycles. Additional real time N_2O data would be necessary to evaluate the first 100 seconds of the cold start UDDS N_2O emissions.
- Of the values greater than the threshold, the average vehicle sample concentration was 1.06 ppm (only 2.6 times the threshold) and the single standard deviation was 0.44 ppm.
- The N_2O emission rate in mg/mi for port vehicles with higher than threshold concentrations ranged from 1.5 mg/mi to 17 mg/mi where the highest concentrations was

- N_2O emissions appear to be below or near detection limit for diesel and propane vehicles appear operated on the UDDS and port related test cycles.

8.4.4 Discussion of NH_3 limits

The measurement of NH_3 for a properly operating SCR equipped diesel vehicle can be close to that of a non-SCR equipped diesel vehicle. Thus, it was necessary to describe the measurement system to prevent misinterpreting the meaning of emissions at or below the detection limits of

the TDL measurement method. This analysis follows what was performed for the other non-regulated emissions.

This section describes the limits of detection for UCR's NH_3 measurement via a tunable diode laser (TDL) instrument. Past experience shows that NH_3 measurements are difficult and can be influenced with ambient NH_3 concentrations, water, and other sampling issues. The TDL has been configured to show low water interference (less than 1 ppm) and is calibrated on a per-test basis using a span of 40ppm and a zero of 5 ppm dry NH_3 concentrations. Zero ppm zero is not used since the correlation to the reference cell at zero is below 40% and is thus a non-representative value. A zero of 5 ppm was utilized as the zero point where a correlation coefficient of more than 80% was achieved. The upper span point was 100 ppm were the correlation coefficient was greater than 99%.

During the course of this measurement program several ambient tunnel background checks were performed to determine an appropriate measurement detection limit defined as the lower detection limit (LDL) for NH_3 system. Table 8-25 shows the average and standard deviation of 25 ambient samples collected with the TDL instrument over the two year testing program. The sum of the average bias and the standard deviation is used as the LDL. The LDL for the measurement program and typical usage is approximatly1 ppm. This agrees with our expectation that the TLD measurement is good to about 1 or 2 ppm.

Table 8-25 Measured ambient concentration during NH_3 back ground checks

Descritiption	Value	Units
N	25	#
ave	0.23	ppm
stdev	0.81	ppm
ave+stdev	**1.04**	ppm

[1] LDL defined as ave+1stdev or 1 ppm for the NH3 measurement

Table 8-26 shows of the 54 diesel tests conducted, only 2 were 5 times the LDL (i.e. greater than 5ppm), and 26 tests were above 2 time the LDL (2 ppm). Of the 2 tests above 5*LDL, both were for a cold start SCR equipped diesel vehicle. For the 26 tests above 2* LDL these were both SCR and non-SCR equipped vehicles. It is not expected that a non-SCR equipped vehicle had more NH_3 emissions than an SCR equipped vehicle.

Table 8-26 Diesel vehicles NH_3 concentration in relationship to NH_3 ambient background

All Tests	> 1* LDL	> 2*LDL	> 5*LDL	> 10 * LDL
54	43	26	2	0

Five of seven tests for the propane vehicle also had NH_3 greater than 5 ppm and 2 were over 50 ppm suggesting very high relative NH_3 emissions for the propane vehicles.

8.4.5 Discussion of EC/OC limits

This section describes the element and organic carbon (EC and OC) mass accumulation measurement and detection limits in relationship to measured detection limits to help understand the limitations in making un-regulated emission measurements.

This section describes the elemental and organic carbon PM emission results in relationship to measured detection limits to help understand the limitations in making un-regulated PM emission measurements. Table 8-28 through

show the average elemental and organic carbon filter loadings for all the vehicles tested. Table 8-27 shows the ambient tunnel blank results from the AQMD test program. The average measured background concentration for elemental and organic carbon was 0.5 µg/filter and 10 µg/filter respectively with a standard deviation near the measured levels, see Table 8-27. These tunnel blanks agree with previous research performed with the MEL.

The filter weight gain for EC and OC are not completely dependent on the sample volume through the filter, but are more subjective to handling and traveling to from the laboratory. Higher volumes through the filter do not necessarily produce larger tunnel blanks as has been demonstrated during other research projects. This suggests the EC/OC measurements (similar also for total PM) are a function of the mass on each filter tested. Thus, the detection limits were considered on a µg/filter basis and not a µg/liter. Since the standard deviation was near the average value, the estimated detection limits were set at 1 µg/filter and 20 µg/filter for EC and OC respectively.

To examine the elemental and organic carbon being emitted from vehicle samples, a lower threshold in the results was established and set equal to the average concentration plus one standard deviation. Table 8-27 shows the lower threshold for EC and OC at 1 µg/filer and 10 µg/filter respectively.

The filter weights in Table 8-28 through Table 8-34 are presented with in relationship to the threshold. If the measured average cycle filter weight is less than the established threshold no value is displayed and if it is larger than the threshold than a value is displayed. Cells with no color are less than two times the threshold, green is less five times, orange less than ten times, and red is more than ten times.

The general observations of the carbon and elemental emissions from the vehicles tested can be summarized as:

- More than half (69% for both) of the measured EC and OC emissions were below a defined threshold of the average ambient background concentration plus one standard deviation.
- Of the EC values over the threshold, 17% of those were less than two times the threshold. About 50% were between two and five times, 14% between five and ten times and only 17% were above ten times the threshold for EC.
- Of the OC values over the threshold, 65% of those were less than two times the threshold. About 30% were between two and five times, 0% between five and ten times and only 5% were above ten times the threshold for EC.

9 Summary

The SC AQMD path to cleaner air depends on achieving the strictest NOx standards for heavy-duty vehicles. Recently, the District saw data that indicated the in-use emissions exceeded the certification values. The University of California, Riverside (UCR) was contracted to test 16 heavy-duty vehicles, mainly diesel fueled engines, used for goods movement, refuse hauling and transit applications. The testing protocol involved measuring the emissions identified in the RFP while the vehicles operated following driving cycles that better represented the in-use conditions as well as certification conditions. The testing measured: 1) regulated emissions; 2) unregulated emissions such as ammonia and formaldehyde; 3) greenhouse gas levels of CO_2 and N_2O and 4) ultrafine PM emissions. A number of vehicles and engines were tested based on the population, emission standards and technology.

The emission results for PM and NO_x are summarized below:

- PM emissions from the diesel test vehicles were below 0.01 grams per brake horsepower-hour (g/bhp-h) measured over port drayage, CBD, and UDDS drive cycles. Cold start PM emissions were relatively high for two diesel vehicles; one was a port SCR equipped vehicle and the other was a refuse SCR equipped vehicle. The port vehicle was 17 times higher (22.9 mg/mi vs 1.33 mg/mi) and the refuse vehicle was 8 times higher (18.4 mg/mi vs 2.75 mg/mi). In both cases the high cold start emission factors were below the certification standard. PM emissions were well below the certification for all diesel tests, thus suggesting DPF-based solutions are robust and reliable in meeting targeted standards. In addition, PM emissions from a liquefied petroleum gas (LPG) test vehicle was approximately 0.14 g/bhp-hr measured over the UDDS cycle, which is above the certification standard.
- NO_x results covered a wide range of emission factors, where the emissions depended on the certification standard, vehicle application, driving cycle, and manufacturer. For example, NO_x emissions were lowest for goods movement vehicles powered by diesel engines equipped with SCR technology; however, increases from 0.112 g/mi (0.028 g/bhp-h) during high speed cruise operation to 5.36 g/mi (1.34 g/bhp-h) for low speed transient operation were measured. Unique to the high NO_x emissions was a condition in which the temperature of the SCR was less than 250°C. Advanced EGR 2010 certified engines showed higher NO_x emissions compared to SCR equipped engines, and pre-2010 certified engines were higher than the 2010 certified engines.
- The NO_x impact of SCR equipped diesel engines depends on the vehicles' duty cycles and manufacturers' implementation for low temperature SCR performance. For the near dock port cycle, the SCR was below 250°C approximately 80% of the time, 65% of the time for the local port cycle, and approximately 45% of the time for the regional port cycle. The percentage of time below 250°C varied significantly between manufacturers, from 8% to 30% for the near dock cycle, and from 41% to 64% for the regional cycle. The difference in time below 250°C suggests some manufacturers have better strategies for maintaining high exhaust temperatures than others.
- The SCR equipped engines were within their certification standards and were typically below 0.2 g/bhp-h. Only during low SCR temperature were the emissions found to be higher than the certification standard. In-use compliance testing does not enforce the

emissions standards when the SCR is below 250 °C, thus the SCR equipped vehicles were typically compliant based on the results presented in this report.

- Cold start NO_x emissions can be as high as 2.3 g/bhp-hr compared to an equivalent warm test of 0.006 g/bhp-h. Although cold start emissions do not contribute to the inventory, it is important to consider the extreme nature of cold start emissions if vehicles are allowed to cool frequently. The NO_x emissions accumulated in 1 mile after a cold start were equivalent to emissions accumulated during 32 miles of running hot.
- The 2010 certified diesel engines with advanced cooled EGR and no SCR were tested. These vehicles operated utilizing a lug curve with peak torque starting as low as 1000 revolutions per minute (RPM), where the driver was instructed to operate the vehicle down to 900 RPM before shifting. The truck behavior was unusual, and both UCR and WVU trained drivers commented on the strange operation. Additionally, the certified emissions had a family emission limit (FEL) of 0.5 g/bhp-hr for 2010 MY, but the measured NO_x emissions were around 1 g/bhp-hr (0.25 g/mi) for the UDDS cycle, which represents a certification-like cycle. Even the port cycles showed brake specific emissions higher than 1 g/bhp-hr and as high as 2 g/bhp-hr for the near dock cycle.
- Pre-2010 certified diesel engines exhibited regulated emissions that were very close to the standard and were found to be repeatable for randomly selected models tested. This suggests that pre-2010 emissions inventories may be more reliable than SCR-equipped diesel engines due to SCR performance variability.
- Most NO_x emissions from SCR equipped diesel refuse vehicles were produced during the compaction portion of the in-use test cycle. The high NO_x emissions corresponded with a low SCR exhaust temperature, where the emissions increased from 0.27 g/bhp-hr NO_x for the transient and curbside cycles to 3.8 g/bhp-hr NO_x for the compaction cycle.
- The percentage of NO_x as NO_2 ranged from 10% to near 90%, with the highest levels of NO_2 emissions from non-SCR-equipped diesel vehicles. NO_2 was highest for the pre-2010 certified engines (averaging 1.15 ± 0.48 g/mi for the UDDS cycle). In general NO_2 ratios were similar for all tests at around 45%±8%, except for the SCR equipped diesel vehicles, which showed high variability with a NO_2 ratio of 47%±36%.

The emission results for ammonia, hydrocarbons, toxics, and fine particles are summarized below:

- Ammonia (NH_3) emissions from the vehicles tested ranged from about 0.01 to 0.1 g/mi. The diesel vehicles' NH_3 emissions averaged 0.04±0.03 g/mi (0.01±0.01 g/hp-h), where the port vehicle emissions were similar (0.03±0.02 g/mi), but the propane school bus had relatively higher NH_3 emissions (0.48±0.04 g/mi) over the CBD test cycle. All the diesel vehicles showed cycle averaged raw NH_3 emission concentrations less than 10ppm. Of the 54 diesel tests conducted, only 2 vehicles had NH_3 emissions over 5 parts per million (ppm). Half of the tests were below 2 ppm. Five of seven propane vehicle tests had NH_3 emissions greater than 5 ppm and two were over 50 ppm, suggesting that relatively higher NH_3 emissions exist for the propane vehicles compared to the diesel vehicles.
- The emission factors for total hydrocarbon (THC), methane (CH_4), non-methane hydrocarbon (NMHC) and toxics were very low for all diesel vehicles tested. This agrees

with other research from the Advanced Collaborative Emissions Study (ACES) project that showed a 98% reduction from diesel engines with catalytic exhaust systems. THC, NMHC, and CH_4 emissions were at or below 0.09 g/mi, 0.06 g/mi, and 0.04 g/mi, respectively, for all vehicles (except the LPG vehicle) for both the UDDS and port regional cycles. Slightly higher THC, CH_4, and NMHC emissions were found for the lower power near dock port cycle (0.36 g/mi, 0.10 g/mi, and 0.29 g/mi, respectively). Toxic emissions were low and near the detection limits of the method where 75% of the measured carcinogenetic species (benzene, toluene, ethylbenzene, and xylenes - BTEX) were below the average ambient background concentration pulse one standard deviation (< 10 mg/mi and typically < 2 mg/mi background corrected). Carbonyl emissions were also low relative to the measurement method, where more than 75% of the measured species were below the same threshold except for formaldehyde. Formaldehyde showed a relatively higher emission concentration, with 75% of the measurements above the threshold. Even though the formaldehyde samples were relatively high, their absolute contribution were below 72 mg/mi, with an average of 18±19 mg/mi. Acetaldehyde was the next largest carbonyl with maximum emissions of 18 mg/mi and an average of 1.5±4 mg/mi. The rest of the carbonyls were below 2 mg/mi. Cold start UDDS emissions were similar to the hot start UDDS emissions for THC, CH_4, NMHC, and toxics (note the UDDS was performed as a 2xUDDS cycle, which may have minimized the cold start effect for the HCs and toxics).

- The LPG goods movement vehicle showed higher THC, NMHC, CH_4, and toxic emissions than the diesel vehicles tested. THC, NMHC and CH_4 were 22.4 g/mi, 1.43 g/mi, and 21.4 g/mi respectively for the UDDS hot cycle. BTEX and formaldehyde samples were more than 10 times the average ambient background concentration plus one standard deviation. The propane vehicle averaged 6.5±9.3 mg/mi, 9.7±12 mg/mi, and 22.4±19 mg/mi for 1,3-butadiene, n-butane, and benzene respectively for the BTEX sample. The Carbonyls were high for formaldehyde and acetaldehyde (241±253 mg/mi and 42±48 mg/mi respectively) with the remaining aldehydes below 2 mg/mi. These results should be confirmed with additional testing on LPG port vehicles.

- Real-time PM measurements suggest the reported reference PM emission rate may be lower due to low filter weights for DPF equipped vehicles. The PM mass of the gravimetric method averaged 0.78±1.57 mg/bhp-hr for selected diesel vehicles. The average PM mass from the real-time measurement method averaged 0.05±0.09 mg/bhp-hr for the same vehicles. The average filter weight for these selected vehicles ranged from 10-20 µg, where UCR's CVS tunnel blank averages were 5µg with a 5µg single standard deviation. Thus, there is speculation that some of the uncertainty may be artifacts on the filter. As such, real-time PM measurements are useful for identifying low level PM mass in addition to real-time analysis.

- Elemental carbon (EC) and organic carbon (OC) PM was very low for all the vehicles tested and was typically below 0.2 mg/mi and 2.2 mg/mi respectively. More than half (69%) of the measured EC and OC emissions were below the average ambient background concentration plus one standard deviation. The propane vehicles had the highest organic PM contribution (>10 mg/mi for the near dock port cycle).

- Fine-particle emissions were typically higher during the first 200 seconds of the cold start UDDS cycle compared to the hot stabilized UDDS cycle ($5x10^5$ #/cc vs $1x10^3$ #/cc,

respectively). The fine particle emissions appear to be higher for the regional port cycle compared to the near dock, local, and UDDS cycles ($8x10^4$ #/cc vs $1x10^3$ #/cc, respectively). The higher concentration of the regional port cycle may be a result of higher ATS temperatures and possible passive regenerations.

The results for greenhouse gas emissions and fuel economy are summarized below:

- The greenhouse gases (GHG) and fuel economy are characterized by CO_2 emissions for the diesel vehicle, but with the LPG truck, methane emissions represented approximately 8% of the GHG. The diesel fuel economy averaged 3.5 mi/gal (Port 1, 2 and UDDS) to 5.06 mi/gal (Port 3) for the port vehicles, 7.0 mi/gal for the school buses, and 4.2 mi/gal (UDDS) to 2.0 mi/gal (RTC) for the refuse haulers. The regional cycle (Port 3) showed 20% higher fuel economy than the more transient Port 1, 2, and UDDS cycles. The fuel economy from the refuse trash cycle (with integrated compaction phase) was about 50% lower than the transient UDDS cycle. The propane port vehicle showed 19% lower fuel economy than the diesel vehicles (3.3 mi/gal).
- The project measured N_2O greenhouse gases on selected tests. For those vehicles measured more than half (64%) of the N_2O emissions were below 0.4 ppm, which is the average ambient background concentration plus one standard deviation. The emission factors averaged 3.6±1.9 mg/mi with a maximum of 18 mg/mi (Cum_11.9 near dock port cycle).

The results for cross laboratory check are summarized below:

- The work comparison averaged around 3% negative bias (-3%), where UCR's laboratory was slightly lower than WVU's, with a spread of -9% to +4% on average. Both WVU and UCR show very low test-to-test variability, with a coefficient of variation (COV) less than 2% for all tests.
- The $bsCO_2$ was close and averaged around 5% positive bias, where UCR's laboratory was slightly higher than WVU's with a spread of 0% to 10% overall. Both WVU and UCR show very low test-to-test variability, with a COV less than 3% for all tests.
- The $bsNO_x$ correlation was also good, but the comparison varied for the SCR equipped vehicles due to the low emission levels and the variable conditions of the SCR. For the non-SCR equipped vehicles, the deviation averaged about 3% positive bias, where UCR's laboratory was slightly higher than WVU's, with an average of -2% to 8%. The NO_x correlation was poor for the cold start SCR equipped vehicles and for two refuse haulers due to variability in the aftertreatment systems.

In summary, the data from this study suggests that 2010 compliant SCR-equipped HDD vehicles are exhibiting high in-use NO_x emissions that can be as high as 2 g/hp-h under low load conditions represented by short trips or frequent stops. The cause of the high NO_x emissions appears to be low load exhaust temperatures and, thus, low SCR aftertreatment temperatures. For SCR-equipped diesel engines, some accounting of vehicle duty cycle and SCR exhaust temperature is needed to properly characterize NO_x inventories. Additionally, there were differences in SCR performance that varied between manufacturers, suggesting future performance will continue to vary. The ratio of NO_2 in the NO_x has been demonstrated to be about 45% for all diesel vehicles tested, where there is more variability with the SCR equipped diesels. Both NO_x emission factors and NO_2 ratios suggest NO_x emissions are more variable for SCR equipped diesels compared to non-SCR equipped diesel vehicles. This also suggests activity

studies are needed to assess the impact of SCR performance on NO_x inventories. Other results showed the diesel PM, CO, THC, and selected toxics were all very low, well below certification limits, and near the limits of the measurement method for all the tests performed. The low PM, CO, THC, and selected toxics for all the diesel vehicles tested suggest these emissions are well controlled. Looking ahead, the overall results suggest NO_x emissions are still a concern for selected activities, and SCR performance needs to be investigated during wide in-use, on-road operation to characterize its impact on local inventories.

Attachment A. Test Cycles

Central Business District (CBD)

The Central Business District (CBD) Cycle is a chassis dynamometer testing procedure for heavy-duty vehicles (*SAE J1376*). The CBD cycle represents a "sawtooth" driving pattern, which includes 14 repetitions of a basic cycle composed of idle, acceleration, cruise, and deceleration modes. The following are characteristic parameters of the cycle:

- Duration: 560 s
- Average speed: 20.23 km/h
- Maximum speed: 32.18 km/h (20 mph)
- Driving distance: 3.22 km
- Average acceleration: 0.89 m/s^2
- Maximum acceleration: 1.79 m/s^2

Vehicle speed over the duration of the CBD cycle is shown in Figure A-1.

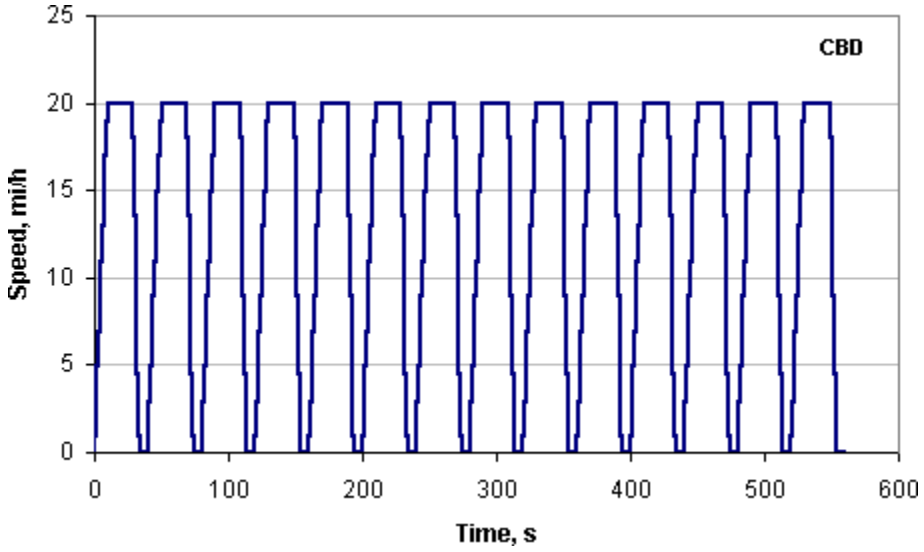

Figure A-1. CBD Driving Cycle

The standard CBD test cycle will be used for bus testing where three cycles will be combined for a triple CBD for a total sample time of 30 minutes. Performing the CBD cycle three times in one test allows for additional sample volumes to be collected for all batched type analysis (filters, DNPH, BETEX and N_2O). Preconditioning is defined as performing a previous triple CBD and a 20 minute soak to improve repeatability between hot repeats. Emissions analyses for gaseous emissions will also be collected over the triple CBD cycles. This cycle is shown in Figure A-2. The triple CBD cycle will be repeated in triplicate for repeatability metrics as described earlier.

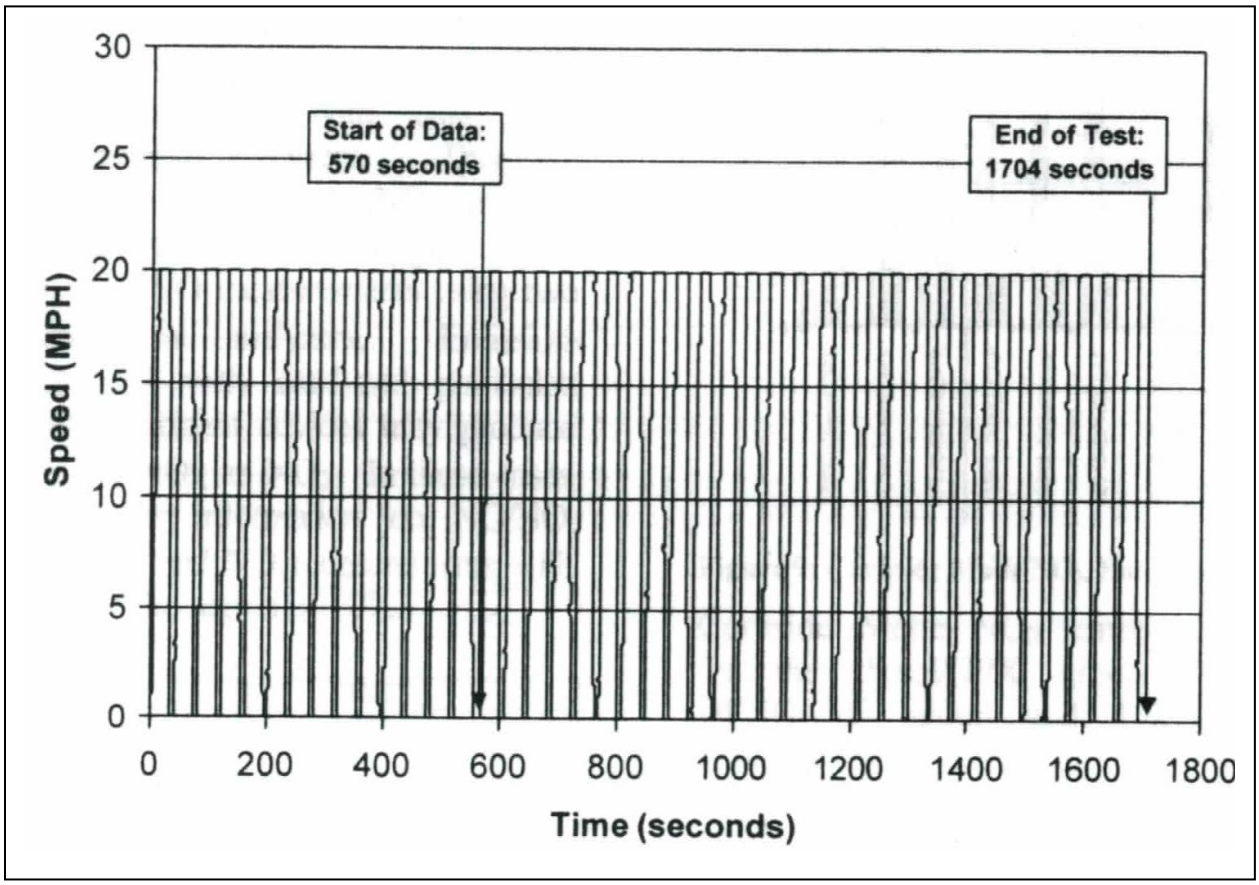

Figure A-2. Triple CBD Cycle

AQMD refuse truck cycle

The waste haulers cycle will be tested using the AQMD refuse truck cycle (AQMD-RTC). This cycle was developed by West Virginia University to simulate waste hauler operation and is a modification of the William H. Martin Refuse Truck Cycle. The original William H. Martin (WHM) refuse truck cycle was created from data logged from sanitation trucks operating in Pennsylvania. The modified cycle consists of a transport segment (phase 1), a curbside pickup segment (phase 2), and a compaction segment (phase 3), see Figure A-2. The modified cycle will be used for this study since this represents the operation of refuse haulers in the SC AQMD district.

The transient phase starts runs for 538 seconds, the curbside phase runs fro 1591 seconds where it starts at 539 and ends at 2130 seconds. The final phase is a compaction cycle that runs from 2201 to 2961 and is 760 seconds long.

The compaction load is simulated by applying a predetermined torque to the drive axel while maintaining a fixed speed of 30 mph. Previous studies by WVU have used an engine load varying between 20 hp to 80 hp for the compaction load, as shown in the right hand side of Figure A-2. To perform the compaction cycle the vehicle is accelerated up to 30 mph where no emissions are collected. Once steady state load conditions are achieved the emissions collection starts and then the varying load is applied. The emissions collection stops before the vehicle is decelerated back to zero speed.

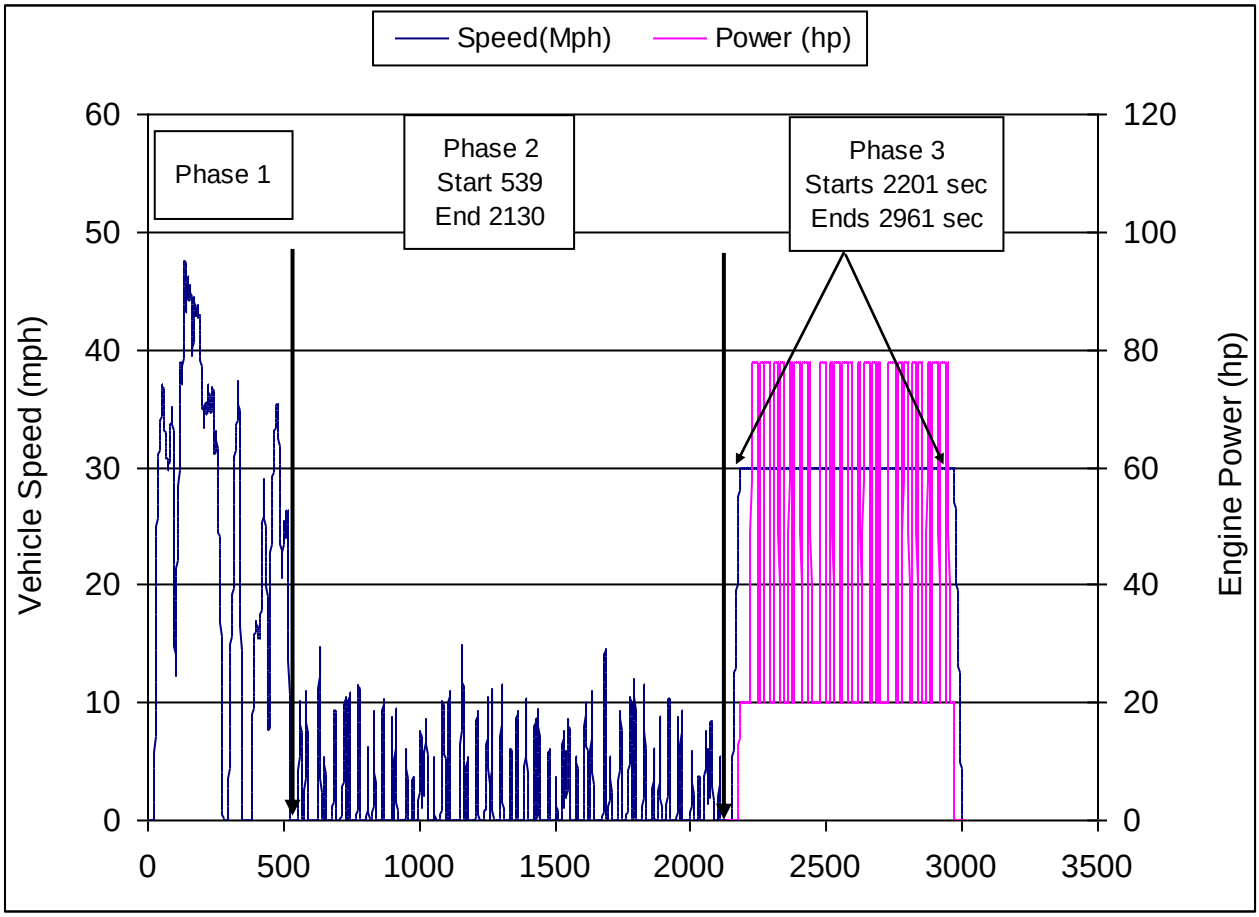

Figure A-3. AQMD Refuse Truck Cycle (AQMD-RTC)

Drayage Truck Port (DTP) cycle

The port cycle was developed by TIAX, the Port of Long Beach and the Port of Los Angeles. Over 1,000 Class 8 drayage trucks at these ports were data logged for trips over a four-week period in 2010. Five modes were identified on the basis of several driving behaviors average speed, maximum speed, energy per mile, distance, and number of stops. These behaviors are associated with different driving conditions such as queuing or on-dock movement, near-dock, local or regional movement, and highway movements. The data were compiled and analyzed to generate a best fit trip. The best-fit trip data was then additionally filtered (eliminating accelerations over 6 mph/s) to allow operation on a chassis dynamometer. The final driving schedule is called the drayage port tuck (DPT) cycle and is represented by 3 modes where each mode has three phases to best represent near dock, local, and regional driving as shown in Table A-5 and Figure A-3. Figure A-4 shows the preconditioning cycles that will be performed for the first test of the day. This will be accomplished after warming up the vehicle and chassis dyno.

Table A-1. Drayage Truck Port cycle by mode and phases

Description	Distance mi	Ave Speed mph	Max Speed mph	Phase 1	Phase 2	Phase 3
Near-dock	5.61	6.6	40.6	Creep	Low Speed Transient	Short High Speed Transient
Local	8.71	9.3	46.4	Creep	Low Speed Transient	Long High Speed Transient
Regional	27.3	23.2	59.3	Creep	Low Speed Transient	High Speed Cruise

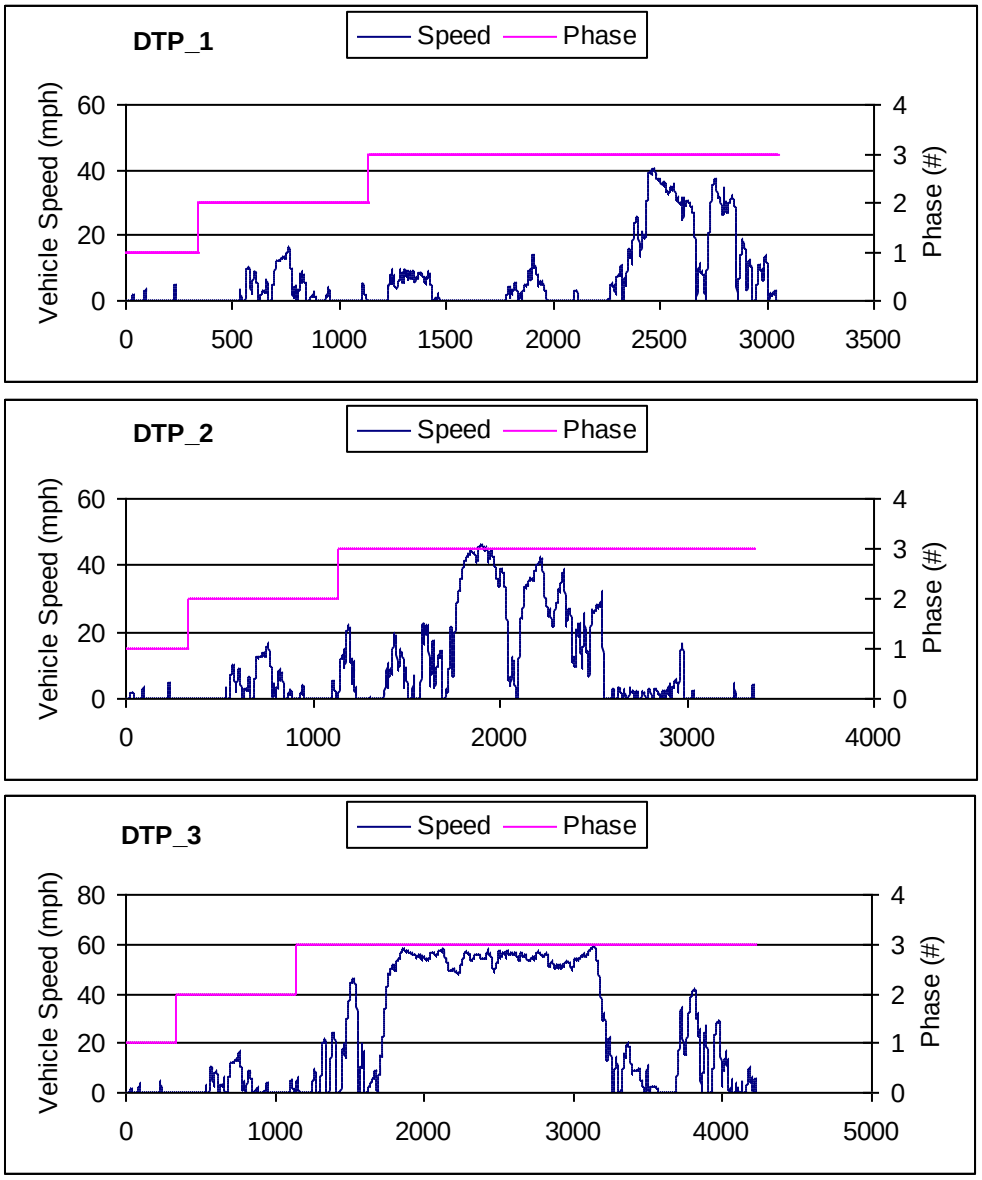

Figure A-4 Drayage truck port cycle near dock (DTP_1), local (DTP_2), and regional (DTP_3)

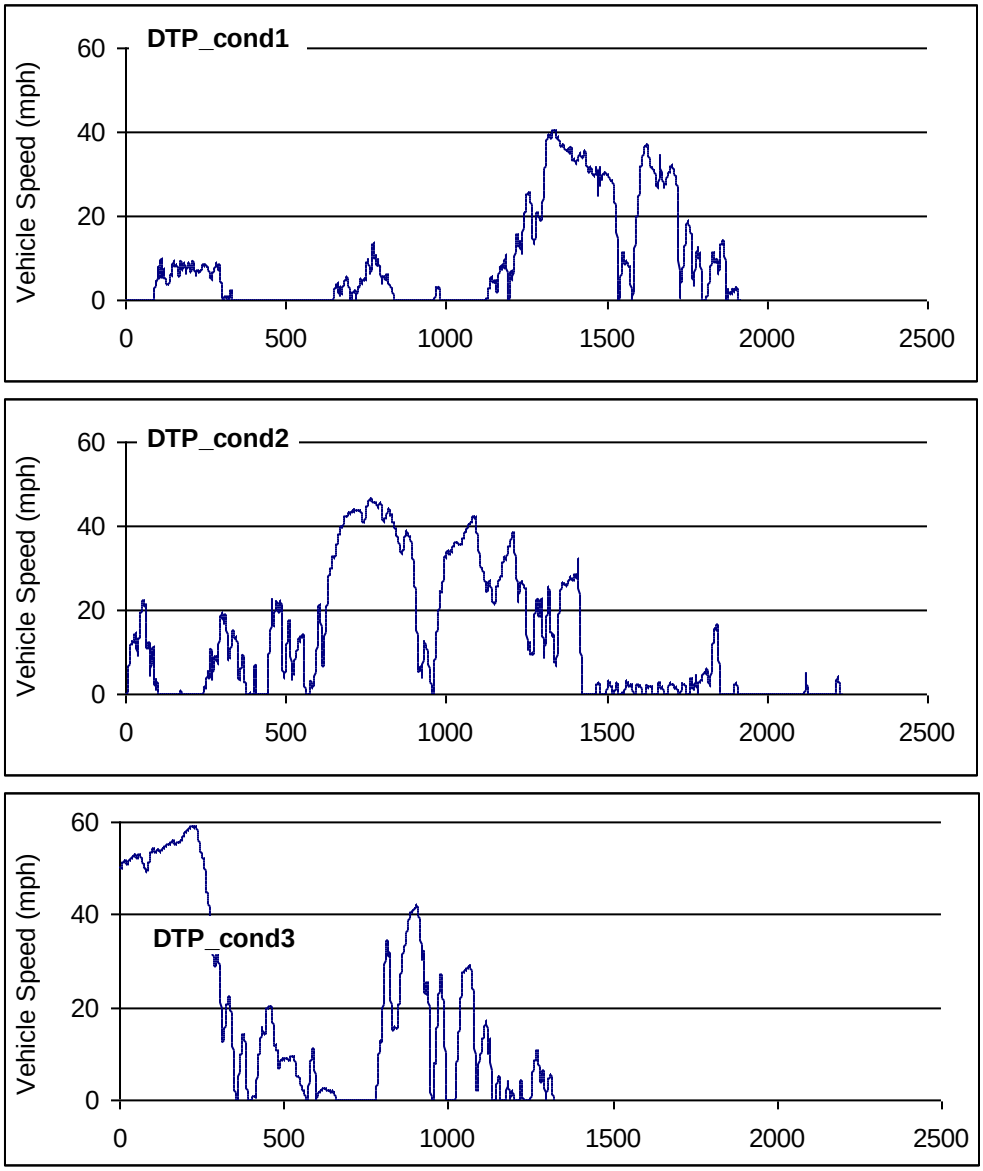

Figure A-5 Drayage truck port cycle conditioning segments consisting of phase 3 parts

UDDS Description

The Federal heavy-duty vehicle Urban Dynamometer Driving Schedule (UDDS) is a cycle commonly used to collect emissions data on engines already in heavy, heavy-duty diesel (HHD) trucks. This cycle covers a distance of 5.55 miles with an average speed of 18.8 mph, sample time of 1061 seconds, and maximum speed of 58 mph. This cycle will be performed as a double UDDS (2xUDDS) to collect sufficient sample for the batched media (exg. PM, BTEX, and DNPH) where the total sample time will be 2122 seconds. The 1x speed/time trace for the UDDS is provided below in Figures A-5.

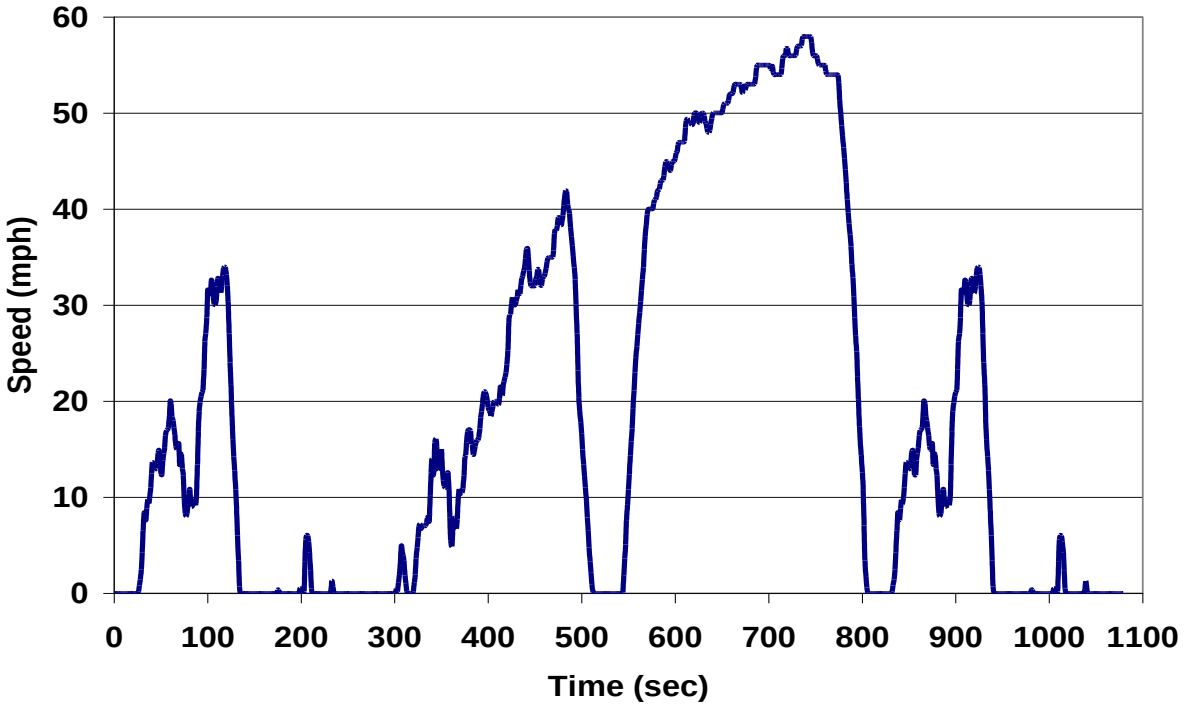

Figure A-5. Speed/Time Trace for a 1xUDDS cycle for the chassis dynamometer.

Attachment B: Brake Specific Emissions

This attachment includes the brake specific emission for all the vehicles tested. They are organized by emissions species.

Attachment C: ECM Download and Inspection Summary

This appendix lists each of the vehicles tested and provides selected ECM down load information, fleet maintenance information, and other as-received information on the vehicle. The vehicles are listed in the order they were tested. All vehicles were inspected for MIL lamp issues and none were found. IN all but one case the vehicles appeared to have reasonable emissions results.
All vehicles inspected showed proper tire pressure, fluids, and operational capabilities to perform the desired cycles. No overheating or gross PM emitters were identified that would suggest eliminating the vehicle from the program.

The Navistar (12WZJ-B/2009) did show signs of drivability issues. The vehicle was not able to shift gears properly while performing the traces. This was a shared vehicle so WVU, UCR and AQMD were in discussion on how to proceed. WVU operated the vehicle on UCR's dyno and agreed there was a problem with shifting. The vehicle was driven on the roads with similar difficulties. UCR and WVU consulted with the leasing agency to find out the vehicle had low RPM torque and need to be shifted at lower RPM conditions. Once this was understood the vehicle was tested. The low RPM shifting is unusual and does not represent the normal operational modes as used by other diesel class 8 vehicles. Some issues in the emissions were discovered and are described in the results section.

The emission results for the propane goods movement vehicle suggest there may be an issue with the operation of the vehicle not identified by the fleet, MIL capabilities, or other indicators from the vehicle during preparations.

01_Vehicle Index C8.3 MY2010

- No faults from when the vehicle was received or as it left.
- Fleet maintains good records on vehicle maintenance.
- ECM down load is below

02_Vehicle Index Vol_12.8 MY 2011 Mack/MP8445C

- No faults from when the vehicle was received or as it left.
- Leased vehicle by WVU and thus all pre inspection of vehicle records were done by WVU.
- WVU has ECM down load in their records

03_Vehicle Index Navistar/12WZJ-B/2009

- No faults from when the vehicle was received or as it left.
- Leased vehicle by UCR and thus all pre inspection of vehicle records were done by leasing company and met DOT inspection requirements.

04_Vehicle Index GM/8.1/2008

- No faults from when the vehicle was received or as it left.
- Loaded vehicle by UCR and thus all pre inspection of vehicle records were done by fleet company and met DOT inspection requirements.

05_Vehicle Index Navistar/A475/2011

- No faults from when the vehicle was received or as it left.
- Leased vehicle by UCR and thus all pre inspection of vehicle records were done by leasing company and met DOT inspection requirements.

06_Vehicle Index Cummins/ISX11.9/2011

- No faults from when the vehicle was received or as it left.
- Leased vehicle by UCR and thus all pre inspection of vehicle records were done by leasing company and met DOT inspection requirements.

07_Vehicle Index Cummins/ISB 220/2007

- No faults from when the vehicle was received or as it left.

- Leased vehicle by UCR and thus all pre inspection of vehicle records were done by leasing company and met DOT inspection requirements.

08_Vehicle Index Bi-Phase/8.1l GM/2009

- No faults from when the vehicle was received or as it left.
- Loaned vehicle by UCR
- No ECM interface was possible thus, utilized fleet records and dash MIL lights for maintenance information.
- The vehicle did appear to run hot. No over temperature issues were identified. Fleet owner was asked about maintained records and no issues were identified.
- Vehicle had in excess of 1,000,000 miles. The engine was repowered to propane about 60,000 miles ago and sees 3,000 to 4,000 miles per year
- All fluids and tire pressures were suitable.

09_Vehicle Index Navistar/GDT260/2008

- No faults from when the vehicle was received or as it left.
- Fluids, tire pressure and other details all met UCR's inspection report logs
- Leased vehicle by UCR and thus all pre inspection of vehicle records were done by leasing company and met DOT inspection requirements.

10_Vehicle Index Navistar/A430/2011

- No faults from when the vehicle was received or as it left.
- Fluids, tire pressure and other details all met UCR's inspection report logs
- Leased vehicle by UCR and thus all pre inspection of vehicle records were done by leasing company and met DOT inspection requirements.

11_Vehicle Index DDC/60 14L/2008 SN = 06R1019569

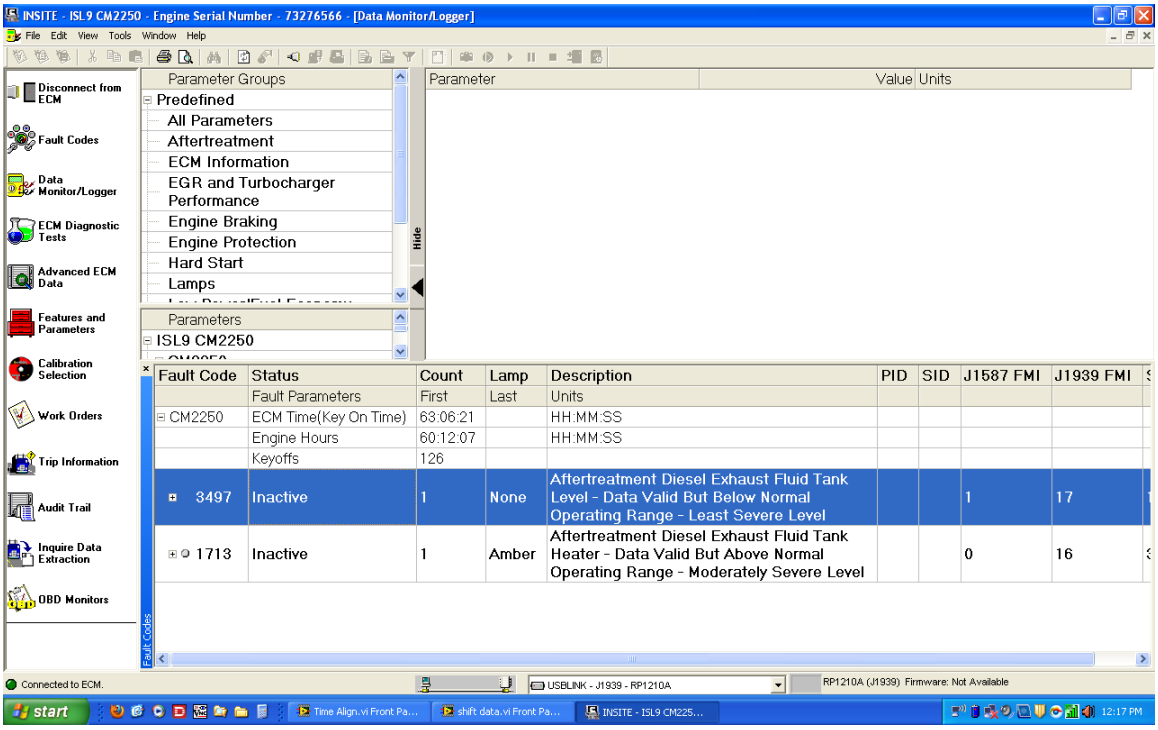
- No faults from when the vehicle was received or as it left.
- Loaned vehicle to UCR where fleet owner maintained good vehicle records

12_Vehicle Index DDC/60 14L/2008 SN = 06R1019704

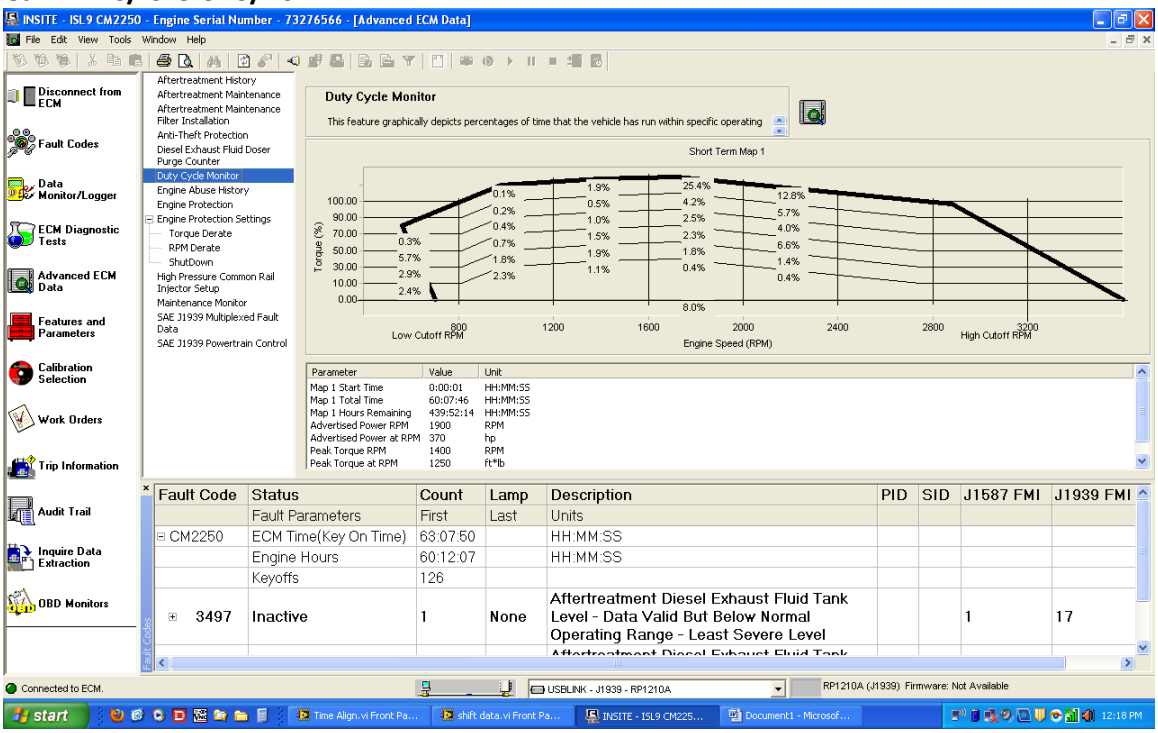
- No faults from when the vehicle was received or as it left.
- Loaned vehicle to UCR where fleet owner maintained good vehicle records

13 Refuse hauler Cummins/ISL9 370/2011

- No faults from when the vehicle was received or as it left.
- Leased vehicle by UCR and thus all pre inspection of vehicle records were done by leasing company and met DOT inspection requirements.
- ECM down load is below



Cummins/ISL9 370/2011



Cummins/ISL9 370/2011

14 Refuse hauler Navistar/A260/2011

- No faults from when the vehicle was received or as it left.
- Loaned vehicle to UCR

15 Refuse hauler Cummins/ISC 8.3/2012

- No faults from when the vehicle was received or as it left.
- Loaned vehicle to UCR

Attachment E. Detailed Test Schedule

The test schedule will be dependent on vehicle availability and application. UCR expects that the refuse and goods movement vehicles will be needed for 4-5 days and the school bus for 3-4 days see Table E-1. Each vehicle will probably take a full week suggesting that the 6-8 N_2O samples approved by CARB will be available for each application.

Table E-1 Vehicle Usage Times

Application	Drive Cycles			
	Transit	Refuse truck	Goods movement	School bus
Preparation days	n/a	2	2	1
Test days	n/a	2	4	1
Total days	n/a	4	6	2

Tables 5 – 9, below show the expected test sequences, conditioning times, soak times, regeneration schedule, and N_2O grab samples. The tables also show that UCR proposes pulling the N_2O grab samples for only two hot cycles and one cold cycle. Each grab sample includes one diluted exhaust sample and one ambient sample. The six grab samples by UCR assume that WVU is not testing for that same week. If both UCR and WVU are testing during a particular week then UCR will only sample for one cold and one hot cycle. If UCR and WVU are both testing the samples to CARB will increase to eight which can also be managed according to ARB staff.

Attachment F: Quality Control Checks

This attachment discusses the data that was inspected for possible issues. Issues ranged from PM typo's, high standard deviations, and other checks. The purpose of this verification is to check the quality and consistency of the data. The final data set is validated by this procedure and includes all the regulated and not regulated emissions.. Below were investigated based on outlier stdev between replicate test.

Table A-1 Reregulated species evaluated for possible data issues

Test Article				Comment
1	Cummins/ISX11.9/2011	PDT_1	PM	High PM standard deviation could be due to measurement sensitivity. Possible high PM standard deviation on test, but filter weights were between 25 ug and 10 ug with a 5-10 ug uncertainty (tunnel blanks).
2	Navistar/12WZJ-B/2009	PDT_2	PM	High PM standard deviation could be due to measurement sensitivity. Possible high PM standard deviation on test, but filter weights were between 25 ug and 10 ug with a 5-10 ug uncertainty (tunnel blanks). PM spike observed by real time instruments. **DMM shows an outlier due to real** measurement on one test and not others.
3	Navistar/A430/2011	PDT_1	CO	High stdev on CO. The CO decreased from test 1 to test 3 (same for backup instrument). PM, although, showed a slight increase from test 1 to test 3, but filter weights were light 3 ug to 16 ug so it is hard to quantify.
c)	Bi-Phase/8.1l GM/2009	PDT_1	PM	Engine running very hot and may be creating PM. Variability high due to possible poor operation. No ECM codes or dash codes. Data represents in-use operation.
d)	Navistar/12WZJ-B/2009	PDT_1	CO2	Higher variability may be due to the Navistar drivability issue raised during testing. See Appendix xx for description of the drivability for the Navistar engine. **See presentation 2012.04.11 AQMD meeting 02d_CARB for details**. Put in the appendix.
e)	Bi-Phase/8.1l GM/2009	PDT_2	PM	Engine running very hot and may be creating PM. Variability high due to

				possible poor operation. No ECM codes or dash codes. Data represents in-use operation.
f)	Cummins/M2/2010	PDT_3	PM	PM filter weights over 100ug (easy to measure) and the PM increased from test 1 to test 3 (low to high). The measurable increasing trend suggests the PM for this test could be coming from the exhaust tubing surfaces and due to the high sustained loads of the Port3 cycle the PM attached to the surfaces could be released from the exhaust surfaces. This released PM then would enter into the CVS and be collected on the MEL gravimetric filter and TOX sampling probes. This would also happen in the environment and is real. The MEL was cleaned as described in the Experimental section and was not a contributing source of PM.
g)	Mack/MP8445C/2011	PDT_3	PM	The higher variability for this cycle/vehicle may be due to light filter weights. Light filter weights so variability would be higher (40 to 90 ug). PM was random and suggests from the engine and not the exhaust surfaces.
h)	Bi-Phase/8.1l GM/2009	PDT_3	NOx and PM	Engine running very hot and may be creating PM. Variability high due to possible poor operation. No ECM codes or dash codes. Data represents in-use operation. NOx looks real since both NOx and NO analyzer showed same response. Thus no changes were made.
i)	Navistar/A430/2011	UDDS	CO	High stdev on CO. The CO increased from test 1 to test 3 (same for backup instrument). PM also showed a slight increase from test 1 to test 3, but filter weights were light 3 ug to 16 ug so it is hard to quantify.
j)	Bi-Phase/8.1l GM/2009	UDDS	NOx and PM	Selected different UDDS cycle (did 5 only used 3). Others were aborted for MEL operational reasons.
k)	Cummins/ISB 220/2007	CS-CBD	PM	High PM standard deviation could be due to measurement sensitivity. Possible high PM standard deviation on test, but filter

l)	**Navistar/A260/2011**	UDDS	NOx	weights were between 60 ug (1) and 10 ug (2) with a 5-10 ug uncertainty (tunnel blanks). DMM showed same trend, but could decaying from first to last. PM could be hang-up from previous in-use operation. This is the test where two high frequency regenerations occurred. Two with regens and two without regens. Every other cycle they were occurring. The regens did not increase the PM mass, but did affect NOx and CO2. Analyze separately **UDDS** and **UDDS-regen.** Regens also occurred on the refuse truck cycle. Every test. Could not avoid them. Thus, in-use emissions should include regens for this vehicle.

Preface

The draft of the *Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments* (Guidance Manual) is a description of the algorithms, recommended exposure variates, cancer and noncancer health values, and the air modeling protocols needed to perform a health risk assessment (HRA) under the Air Toxics Hot Spots Information and Assessment Act of 1987(Health and Safety Code Section 44300 et seq., see Appendix B). The Children's Environmental Health Protection Act of 1999 (Health and Safety Code Section 39606, also contained in Appendix B), which requires explicit consideration of infants and children in assessing risks from air toxics, necessitated revisions of the methods for both noncancer and cancer risk assessment, and of the exposure variates. This draft version of the Guidance Manual updates the previous version (OEHHA, 2003), and reflects advances in the field of risk assessment along with explicit consideration of infants and children.

The information presented in the draft manual is compiled from three technical support documents (TSDs) released by the Office of Environmental Health Hazard Assessment (OEHHA) for the Hot Spots Program. The three TSDs (which are also revised versions, replacing the original four Hot Spots TSDs adopted between 1999 and 2003) underwent public comment and peer review and were adopted for use in the Air Toxics Hot Spots program by the Director of OEHHA. The Technical Support Document for the Derivation of Noncancer Reference Exposure Levels (June, 2008) addressed the methodology for deriving acute, chronic and eight hour Reference Exposure Levels. The Technical Support Document for Cancer Potency Factors (May 2009) addresses the methodology for deriving cancer potency factors and adjusting cancer potency to account for the increased sensitivity of early-in-life exposure to carcinogens. The Technical Support Document for Exposure Assessment and Stochastic Analysis (June 2012) presents the exposure model for the Hot Spots program and reviews the available literature on exposure and relevant fate and transport variates. All three TSDs are available on OEHHA's web site at: http://www.oehha.ca.gov/air/hot_spots/index.html. Excerpts of these three TSDs are presented in this document. There is relatively little new information in the Guidance Manual since the adoption of the TSDs.

The draft Guidance Manual was released for public review. Public comments were received and changes were made in response to some comments. Responses were developed to all public comments. Both the Guidance Manual and OEHHA's response to comments were then reviewed by the State's Scientific Review Panel on Toxic Air Contaminants (SRP), who previously reviewed the three TSDs upon which this guidance is based. Following review by the SRP, OEHHA finalized this Guidance Manual. This Guidance Manual supersedes the risk assessment methods presented in the Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments (OEHHA, 2003), which in turn replaced earlier guidance provided by the California Air Pollution Control Officer's Association (CAPCOA, 1993). This manual updates health effects values, exposure pathway variates (e.g., breathing rates), and

continues to use a tiered approach for performing HRAs based on current science and policy assessment. The Technical Support Document for Cancer Potency Factors (OEHHA, 2009) recommends a tenfold early-in-life potency factor adjustment for the third trimester and ages zero to less than two, and a threefold adjustment factor for ages two to less than sixteen. In addition, we recommend evaluating residency periods of nine, thirty and seventy years. This means that exposure variates are needed for the third trimester, ages zero to less than two, ages two to less than nine, ages two to less than 16, ages 16 to less than 30, and ages 16 to 70.

The tiered approach presented in this draft manual provides a risk assessor with flexibility and allows consideration of site-specific differences. Furthermore, risk assessors can tailor the level of effort and refinement of an HRA by using the point-estimate exposure variates or the stochastic treatment of distributions of exposure variates. The four-tiered approach to risk assessment primarily applies to residential cancer risk assessment. Compared to the OEHHA 2003 document, the exposure pathways in the Guidance Manual remain the same. The exposure and risk algorithms are similar, but they have been revised to accept new data or variables that are used in the tiered risk assessment approach.

The draft manual also contains example calculations and an outline for a modeling protocol and an HRA report. A software program, the Hot Spots Analysis and Reporting Program (HARP), has been developed by the Air Resources Board in consultation with OEHHA and Air Pollution Control/Air Quality Management District representatives. The HARP software, which is being updated with the new exposure variates and health values, is the recommended model for calculating and presenting HRA results for the Hot Spots Program. Information on obtaining the HARP software can be found on the ARB's web site at *www.arb.ca.gov* under the Hot Spots Program.

The intent of the Guidance Manual and the HARP software is to incorporate children's health concerns, update risk assessment practices, and to provide consistent risk assessment procedures. The use of consistent risk assessment methods and report presentation has many benefits, such as expediting the preparation and review of HRAs, minimizing revision and resubmission of HRAs, allowing a format for facility comparisons, and cost-effective implementation of HRAs and the Hot Spots Program. Risk assessments prepared with this Guidance Manual may be used for permitting new or modified stationary sources, or public notification, and risk reduction requirements of the Hot Spots Program. The use of uniform procedures allows comparison of risks from different facilities and enables identification of facilities that are problematic from a public health perspective. OEHHA reviews the HRAs to insure they are adequate for decision making, but does not play a role in permitting decisions that may result from the HRAs. OEHHA will provide advice to the Districts when requested on any of the risk assessment methods or health values they have used.

1 - Introduction

1.1 Development of Guidelines

The Air Toxics Hot Spots Information and Assessment Act is designed to provide information to state and local agencies and to the general public on the extent of airborne emissions from stationary sources and the potential public health impacts of those emissions. The Hot Spots Act requires that the Office of Environmental Health Hazard Assessment (OEHHA) develop risk assessment guidelines for the Hot Spots program (Health and Safety Code (HSC) Section 44360(b)(2)) (see Appendix B for the text of the HSC). In addition, the Hot Spots Act specifically requires OEHHA to develop a "likelihood of risks" approach to health risk assessment. In response, OEHHA developed a tiered approach to risk assessment where a point estimate approach is first employed. If a more detailed analysis is needed, OEHHA has developed a stochastic, or probabilistic, approach using exposure factor distributions that can be applied in a stochastic estimate of the exposure. A detailed presentation of the tiered approach, risk assessment algorithms, selected exposure variates (e.g., breathing rate), and distributions with a literature review is presented in the *Air Toxics Hot Spots Program Risk Assessment Guidelines*; *Technical Support Document for Exposure Assessment and Stochastic Analysis* (OEHHA, 2012). A summary of this information can be found in Chapter 5 of this document.

The Technical Support Document for the Derivation of Noncancer Reference Exposure Levels (OEHHA, 2008) addresses dose response relationships for noncancer health effects and the methodology for deriving acute, chronic and 8-hour Reference Exposure Levels (RELs). Currently there are 53 acute RELs, 82 chronic RELs, and 10 eight-hour RELs. Review and revision of RELs to take into account new information and sensitive subpopulations including infants and children is an ongoing process. All draft RELs for individual chemicals revised under the current noncancer methodology will undergo public comment and peer review, as mandated by the Hot Spots Act. The Technical Support Document for Cancer Potency Factors (OEHHA, 2009) addresses the methodology for deriving cancer potency factors and adjusting cancer potency to account for the increased sensitivity to early-in-life exposure to carcinogens. This document contains inhalation cancer potency factors and oral cancer potency factors for 142 toxicants and toxicant compound classes developed by OEHHA or developed by other authoritative bodies and endorsed by OEHHA. The OEHHA website (*www.oehha.ca.gov*) should be consulted for the most current adopted chronic, acute and 8-hour RELs and cancer potency factors. In addition, for a small subset of these substances that are subject to airborne deposition and hence human oral and dermal exposure, oral chronic RELs and oral cancer potency factors have been developed by OEHHA. A summary of cancer and noncancer health effects values can be found in Appendix L and Chapters 6 and 7 of the Guidance Manual. All three Technical Support Documents have undergone public and peer review and have been approved by the state's Scientific Review Panel on Toxic Air Contaminants and adopted by OEHHA. The Guidance Manual is undergoing the same public and peer review process.

The Guidance Manual contains a description of the algorithms, recommended exposure variates, and cancer and noncancer health values, and modeling protocols needed to perform a Hot Spots risk assessment under the Hot Spots Act (see Appendix B). The information for the Guidance Manual is taken from the three TSDs. The Guidance Manual supersedes the risk assessment methods presented in the Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments (OEHHA, 2003).

The Guidance Manual is intended to address health risks from airborne contaminants released by stationary sources. Some of the methodology used is common to other regulatory risk assessment applications, particularly for California programs. However, if the reader needs to prepare a Health Risk Assessment (HRA) under another program, the HRA may need additional analyses. Therefore, appropriate California and federal agencies should be contacted. For example, if a facility must comply with HRA requirements under the Resource Conservation and Recovery Act (RCRA) or the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), the California Department of Toxic Substances Control (DTSC) must be contacted to determine if an HRA written to comply with AB 2588 will also satisfy RCRA/CERCLA requirements.

1.2 Use of the Guidance Manual

The intent in developing this Guidance Manual is to provide HRA procedures for use in the Air Toxics Hot Spots Program or for the permitting of existing, new, or modified stationary sources. The Air Resources Board (ARB) website (*www.arb.ca.gov*) provides more information on the Hot Spots Program and risk management guidelines, including recommendations for permitting existing, new, or modified stationary sources. The use of consistent risk assessment procedures and report presentation allows comparison of one facility to another, expedites the review of HRAs by reviewing agencies, and minimizes revision and resubmission of HRAs.

OEHHA recognizes that no one risk assessment procedure or set of exposure variates could perfectly address the many types of stationary facilities in diverse locations in California. Therefore a tiered risk assessment approach was developed to provide flexibility and allow consideration of site-specific differences. The tiered approach to risk assessment is discussed in detail in Chapter 8 of this Guidance.

These guidelines should be used in conjunction with the emission data collected and reported pursuant to requirements of the ARB's *Emission Inventory Criteria and Guidelines Regulations (Title 17, California Code of Regulations, Sections 93300-93300.5*), and the *Emission Inventory Criteria and Guidelines Report for the Air Toxics "Hot Spots" Program* (EICG Report), which is incorporated by reference therein (see ARB's web site: http://www.arb.ca.gov/ab2588/2588guid.htm for the most current version, which was approved on August 27, 2007). This regulation outlines requirements for the collection of emission data, based on an inventory plan, which must be approved by the Air Pollution Control or Air Quality Management District (District). The emissions reported under this program are routine or predictable and include continuous

and intermittent releases and predictable process upsets or leaks. Emissions for unpredictable releases (e.g., accidental catastrophic releases) are not reported under this program.

For landfill sites, these guidelines should be applied to the results of the landfill testing required under Health and Safety Code Section 41805.5 as well as to any emissions reported under the emission inventory requirements of the Air Toxics Hot Spots Act (e.g., from flares or other on-site equipment). Districts should be consulted to determine the specific landfill testing data to be used.

1.3 Who is Required to Conduct a Risk Assessment

The Hot Spots Act requires that each local Air Pollution Control District or Air Quality Management District (hereinafter referred to as District) determine which facilities will prepare an HRA. As defined under the Hot Spots Act, an HRA includes a comprehensive analysis of the dispersion of hazardous substances in the environment, their potential for human exposure, and a quantitative assessment of both individual and population-wide health risks associated with those levels of exposure.

Districts are to determine which facilities will prepare an HRA based on a prioritization process outlined in the law. The process by which Districts identify priority facilities for risk assessment involves consideration of potency, toxicity, quantity of emissions, and proximity to sensitive receptors such as hospitals, daycare centers, schools, work-sites, and residences. The District may also consider other factors that may contribute to an increased potential for significant risk to human receptors. As part of this process Districts categorize facilities as high, intermediate, or low priority. The District prioritization process is described in the *CAPCOA Air Toxics Hot Spots Program Facility Prioritization Guidelines, July 1990* (CAPCOA, 1990), although some Districts may have adopted their own method for prioritizing facilities for the purposes of AB2588, permitting, etc. Consult the District for updates to the Prioritization Guidelines. See the Hot Spots Program on ARB's web site at *www.arb.ca.gov* for more information on facility prioritization procedures.

Facilities designated by a District as "high priority" are required to submit an HRA to the District within 150 days of designation. Districts may grant a 30-day extension. However, a District may require any facility to prepare and submit an HRA according to the District priorities established for purposes of the Hot Spots Act.

1.4 The Hot Spots Analysis and Reporting Program (HARP) Software

The ARB and the Districts have identified a critical need for software to assist with the programmatic aspects of the Hot Spots Program. HARP is computer software used by the ARB, OEHHA, Districts, and facility operators to promote statewide consistency, efficiency, and cost-effective implementation of HRAs and the Hot Spots Program. The HARP software package includes: 1) an Emissions Inventory Database Module, 2) an Air Dispersion Modeling Module, and 3) a Risk Analysis Module. The user-friendly Windows-based package provides for:

1. Electronic implementation of the risk assessment methods presented in the OEHHA guidelines (Guidance Manual);
2. Electronic data transfer from facilities and Districts;
3. The production of reports;
4. Facility prioritization;
5. Air dispersion modeling (AERMOD) of multiple emission releases or facilities for cumulative impact evaluations;
6. A summary report of acute, 8-hour, and chronic health hazard quotients or indices, and cancer risk at the point of maximum impact (PMI), maximally exposed individual resident (MEIR), maximally exposed individual worker (MEIW) and other receptors to be evaluated as needed;
7. Mapping displays of facility property boundaries, risk isopleths, and elevation contours;
8. The ability to display combined risk contours from multiple emission sources;
9. Output of data for use in other “off-the-shelf” Geographic Information Systems (GIS) programs for additional types of analysis; and
10. Census data for determining population-related health impacts showing the number of people exposed at various cancer risk levels and cancer burden.

1.5 Risk Assessment Review Process

The Hot Spots Act risk assessments are reviewed by the local District and by OEHHA. The Districts focus their review on the emissions data and the air dispersion modeling. OEHHA provides comments on the HRA’s general concordance with the Guidelines Manual and the completeness of the reported health risks. The District, taking into account the comments of OEHHA, approves the HRA or returns it to the facility for revision and resubmission. If the HRA is not revised and resubmitted by the facility within 60 days, the District may modify the HRA and approve it as modified. Based on the approved HRA, the District determines if there is a significant health risk associated with emissions from the facility. If the District determines that facility emissions pose a significant health risk, the facility operator provides notice to all exposed individuals regarding the results of the HRA and may be required to take steps to reduce emissions by implementing a risk reduction audit and plan. Notification is to be made according to

procedures specified by the District. Each District determines its own levels of significance for cancer and noncancer health effects for notification and risk reduction. See the Hot Spots Program on ARB's web site at *www.arb.ca.gov* for more information on significance levels selected by each District.

1.6 Uncertainty in Risk Assessment

OEHHA has striven to use the best science available in developing these risk assessment guidelines. However, there is a great deal of uncertainty associated with the process of risk assessment. The uncertainty arises from lack of data in many areas necessitating the use of assumptions. The assumptions used in these guidelines are designed to err on the side of health protection in order to avoid underestimation of risk to the public. Sources of uncertainty, which may overestimate or underestimate risk, include: 1) extrapolation of toxicity data in animals to humans, 2) uncertainty in the estimation of emissions, 3) uncertainty in the air dispersion models, and 4) uncertainty in the exposure estimates. In addition to uncertainty, there is a natural range or variability in measured parameters defining the exposure scenario. Scientific studies with representative sampling and large enough sample sizes can characterize this variability. In the specific context of a Hot Spots risk assessment, the source of variability with the greatest quantitative impact is variation among the human population in such properties as height, weight, food consumption, breathing rates, and susceptibility to chemical toxicants. OEHHA captures at least some of the variability in exposure by developing data driven distributions of intake rates, where feasible, in the TSD for Exposure Assessment (OEHHA, 2012).

Interactive effects of exposure to more than one carcinogen or toxicant are addressed in the risk assessment with default assumptions of additivity. Cancer risks from all carcinogens addressed in the HRA are added. Similarly, non-cancer hazard quotients for substances impacting the same target organ/system are added to determine the hazard index (HI). Although such effects of multiple chemicals are assumed to be additive by default, several examples of synergism (interactive effects greater than additive) are known. For substances that act synergistically, the HRA could underestimate the risks. Some substances may have antagonistic effects (lessen the toxic effects produced by another substance). For substances that act antagonistically, the HRA could overestimate the risks.

Other sources of uncertainty, which may underestimate or overestimate risk, can be found in exposure estimates where little or no data are available (e.g., soil half-life and dermal penetration of some substances from a soil matrix).

The differences among species and within human populations usually cannot be easily quantified and incorporated into risk assessments. Factors including metabolism, target site sensitivity, diet, immunological responses, and genetics may influence the response to toxicants. The human population is much more diverse both genetically and culturally (e.g., lifestyle, diet) than inbred experimental animals. The intraspecies variability among humans is expected to be much greater than in laboratory animals.

In most cases, cancer potency values have been estimated only for the single most affected tumor site. This represents a source of uncertainty in the cancer risk assessment. Adjustment for tumors at multiple sites induced by some carcinogens may result in a higher potency. Some recent assessments of carcinogens include such adjustments. Other uncertainties arise 1) in the assumptions underlying the dose-response model used, and 2) in extrapolating from large experimental doses, where other toxic effects may compromise the assessment of carcinogenic potential, to usually much smaller environmental doses.

When occupational epidemiological data are used to generate a carcinogenic potency or a health protective level for a non-carcinogen, less uncertainty is involved in the extrapolation from workplace exposures to environmental exposures. When using human data, no interspecies extrapolation is necessary eliminating a significant source of uncertainty. However, children are a subpopulation with hematological, nervous, endocrine, and immune systems that are still developing and may be more sensitive to the effects of toxicants. The worker population and risk estimates based on occupational epidemiological data are more uncertain for children than adults. Current risk assessment guidelines include procedures designed to address the possibly greater sensitivity of infants and children, but there are only a few compounds for which these effects have actually been measured experimentally. In most cases, the adjustment relies on default assumptions which may either underestimate or overestimate the true risks faced by infants and children exposed to toxic substances or carcinogens.

Risk estimates generated by an HRA should not be interpreted as the expected rates of disease in the exposed population but rather as estimates of potential for disease, based on current knowledge and a number of assumptions.

In the Hot Spots program, cancer risk is often expressed as the maximum number of new cases of cancer projected to occur in a population of one million people due to exposure to the cancer-causing substance over a 30-year residential period. However, there is uncertainty associated with the cancer risk estimate. An individual's risk of contracting cancer from exposure to facility emissions may be less or more than the risk calculated in the risk assessment. An individual's risk not only depends on the individual's exposure to a specific chemical but also on his or her genetic background, health, diet, lifestyle choices and other environmental and workplace exposures. OEHHA uses health-protective exposure assumptions to avoid underestimating risk. For example, the risk estimate for airborne exposure to chemical emissions uses the health-protective assumption that the individual has a high breathing rate and exposure began early in life when cancer risk is highest.

A Reference Exposure Level (REL) is the concentration level at or below which no adverse non-cancer health effects are anticipated for the specified exposure duration. RELs are based on the most sensitive, relevant, adverse health effect reported in the medical and toxicological literature. RELs are designed to protect the most sensitive individuals in the population by the inclusion of factors that account for uncertainties as well as individual differences in human susceptibility to chemical exposures. The factors used in the calculation of RELs are meant to err on the side of public health

protection in order to avoid underestimation of non-cancer hazards. Exceeding the REL does not automatically indicate an adverse health impact. However, increasing concentrations above the REL value increases the likelihood that the health effect will occur.

Risk assessments under the Hot Spots program are often used to compare one source with another and to prioritize concerns. Consistent approaches to risk assessment are necessary to fulfill this function.

1.7 Tiered Approach to Risk Assessment

OEHHA developed a tiered approach to accommodate consideration of site-specific data that may be more appropriate for a given facility than the default variate. The first tier is the simplest point estimate approach to estimating exposure to facility emissions. Tier 1 is the first step in conducting a comprehensive risk assessment using algorithms and point estimates of input values described in the *Technical Support Document for Exposure Assessment and Stochastic Analysis*. (OEHHA, 2012) Each facility conducts a Tier 1 risk assessment to promote consistency across the state in facility risk assessments and facilitate comparisons across facilities. To be health-protective, high-end estimates for the key intake exposure variates are used for the dominant exposure pathways.

Tier 2 allows use of site-specific point estimates of exposure variates as long as these estimates can be justified. For example, if there are data indicating that consumption of fish from an impacted body of water is lower than the OEHHA-recommended fish consumption rate, then the facility can use that data to generate a point estimate for sport-fish consumption from that body of water. The risk assessor must supply the data and methods used for the site-specific estimates, and the site-specific estimates must be reproducible and approved by both the District and OEHHA.

Tier 3 risk assessment involves stochastic analysis of exposure using data-based distributions for the key exposure variates compiled in the OEHHA (2012) *Technical Support Document*. Since a stochastic approach to risk assessment provides more information about the range of risk estimates based on the range of exposures, Tier 3 can serve as a useful supplement to the Tier 1 and 2 approaches. Variance propagation methods (e.g., Monte Carlo analysis) are used to derive a range of cancer risk estimates reflecting the known variability in the inputs. Finally, a Tier 4 approach would use distributions of exposure variates that may be more appropriate for a site, such as the distribution of fish consumption rates for a specific body of water impacted by a facility. As in a Tier 2 approach, the risk assessment must supply the data and methods used for the site-specific distributions for exposure variates, and the site-specific estimates must be justified to and reproducible by the Districts and OEHHA.

2 - Overview of Health Risk Assessment

2.1 The Model for Risk Assessment

The standard approach currently used for health risk assessment (HRA) was originally proposed by the National Academy of Sciences in the 1983 book: *Risk Assessment in the Federal Government: Managing the Process* (NAS, 1983) and was updated in the Academy's 1994 book: *Science and Judgment in Risk Assessment* (NAS, 1994). In 2009 the National Academy published *Science and Decisions: Advancing Risk Assessment* (NAS, 2009), in which a number of recommendations are made on improving the risk assessment process and expanding it to include community concerns and cumulative risks. The four steps involved in the risk assessment process are 1) hazard identification, 2) exposure assessment, 3) dose-response assessment, and 4) risk characterization. These four steps are briefly discussed below.

2.2 Hazard Identification

For air toxics sources, hazard identification involves the pollutant(s) of concern emitted by a facility, and the types of adverse health effects associated with exposure to the chemical(s), including whether a pollutant is a potential human carcinogen or is associated with other types of adverse health effects. For the Air Toxics Hot Spots Program (Hot Spots), the emitted substances that are addressed in a risk assessment are found in the list of substances designated in the ARB's *Emission Inventory Criteria and Guidelines Regulations (Title 17, California Code of Regulations, Sections 93300-93300.5), and the Emission Inventory Criteria and Guidelines Report* (EICG Report), which is incorporated by reference therein (ARB, 2007*)*. This list of substances is contained in Appendix A of this document and the EICG Report. The list of substances also identifies those substances that are considered human carcinogens or potential human carcinogens.

2.3 Exposure Assessment

The purpose of the exposure assessment is to estimate the extent of public exposure to emitted substances. For the Hot spots program, in practice this means estimating exposures for those emitted substances for which potential cancer risk or noncancer health hazards for acute, repeated 8-hour, and chronic exposures will be evaluated. This involves emission quantification, modeling of environmental transport, evaluation of environmental fate, identification of exposure routes, identification of exposed populations, and estimation of short-term (e.g., 1-hour maximum), 8-hour average, and long-term (annual) exposure levels. These activities are described in Chapters 4 and 5. Chapter 5 also discusses the tiered approach to risk assessment.

The ARB's Emission Inventory Criteria and Guidelines (EICG) Report provides assistance in determining those substances that must be evaluated in an HRA and the reporting requirements of facilities, while the Hot Spots Analysis and Reporting Program (HARP) software can be used to model ground level concentrations at specific off-site

locations resulting from facility emissions. The United States Environmental Protection Agency (U.S. EPA) has adopted the AERMOD air dispersion model into its list of regulatory approved models, in place of the previously used ISCST3 model. AERMOD is a steady-state plume model that incorporates air dispersion based on planetary boundary layer turbulence structure and scaling concepts, including treatment of both surface and elevated sources, and both simple and complex terrain (U.S. EPA, 2009). The Air Resources Board recommends AERMOD for Hot Spots risk assessments. The AERMOD air modeling software will be incorporated into the HARP software, which allows the user to input all dispersion parameters directly into the program to generate air dispersion data. Alternatively, the air dispersion data may be generated separately from HARP using other air dispersion models, and then imported into HARP to generate risk estimates. Data imported into HARP must already be in the format required by HARP. HARP has the flexibility to generate a summary of the risk data necessary for an HRA by either of the above approaches.

Most of the toxicants assessed under the Hot Spots program are volatile organic compounds that remain as gases when emitted into the air. These chemicals are not subject to appreciable deposition to soil, surface waters, or plants. Therefore, human exposure via ingestion or dermal exposure, at least at concentrations typically encountered in the ambient air, is not considered for volatile organic compounds in the Hot Spots risk assessments. While some models indicate potential for dermal exposure to certain volatile organic compounds, at this time, the Hot spots program does not consider this pathway. Significant exposure to volatile organic toxicants emitted into the air occurs through the inhalation pathway, and this pathway is the primary consideration in the Hot Spots risk assessments. A small subset of Hot Spots substances consists of semi-volatile organic and metal toxicants emitted partially or totally as particles subject to deposition. Ingestion and dermal pathways as well as the inhalation pathway must be evaluated for these chemicals. A few of these semi-volatile organic and metal toxicants must also include the breast milk ingestion pathway. Additional ingestion pathways may also need to be evaluated depending on the pathways of exposure for the specific receptor of interest. Table 5.1 in Chapter 5, Table 6.4 in Chapter 6, and Table 7.1 in Chapter 7 list the substances that must be evaluated for multipathway impacts. HARP is designed to assess potential health impacts posed by substances that must be analyzed by a multipathway approach.

2.4 Dose-Response Assessment

Dose-response assessment is the process of characterizing the relationship between exposure to an agent and incidence of an adverse health effect in exposed populations. In quantitative carcinogenic risk assessment, the dose-response relationship is expressed in terms of a potency slope that is used to calculate the probability or risk of cancer associated with an estimated exposure. Cancer potency factors are expressed as the 95^{th} percent upper confidence limit of the slope of the dose response curve estimated assuming continuous lifetime exposure to a substance. Typically, potency factors are expressed as units of inverse dose (e.g., $(mg/kg\ BW/day)^{-1}$) or inverse concentration (e.g., $(\mu g/m^3)^{-1}$). It is assumed in cancer risk assessments that risk is directly proportional to dose and that there is no threshold for carcinogenesis.

The Office of Environmental Health Hazard Assessment (OEHHA) has compiled cancer potency factors, which should be used in risk assessments for the Hot Spots program, in Table 7.1. Cancer potency factors listed in Table 7.1 were derived either by the U.S. EPA or by OEHHA, underwent public and peer-review, and were adopted for use in the program. Chapter 8 describes procedures for use of potency values in estimating excess cancer risk. For a detailed description of cancer potency factors, refer to the *Technical Support Document for Cancer Potency Factors* (OEHHA, 2009).

For noncarcinogenic effects, dose-response data developed from animal or human studies are used to develop acute, 8-hour, and chronic noncancer Reference Exposure Levels (RELs). The acute, 8-hour and chronic RELs are defined as the concentration at which no adverse noncancer health effects are anticipated even in sensitive members of the general population, with infrequent one hour exposures, repeated 8-hour exposures over a significant fraction of a lifetime, or continuous exposure over a significant fraction of a lifetime, respectively. The most sensitive health effect is chosen to develop the REL if the chemical affects multiple organ systems. Unlike cancer health effects, noncancer health effects are generally assumed to have thresholds for adverse effects. In other words, injury from a pollutant will not occur until exposure to that pollutant has reached or exceeded a certain concentration (i.e., threshold) and/or dose. The acute, 8-hour, and chronic RELs are air concentrations intended to be below the threshold for health effects for the general population.

The actual threshold for health effects in the general population is generally not known with any precision. Uncertainty factors are applied to the Lowest Observed Adverse Effects Level (LOAEL) or No Observed Adverse Effects Level (NOAEL) or Benchmark Concentration values from animal or human studies to help ensure that the chronic, 8-hour and acute REL values are below the threshold for human health for nearly all individuals. This guidance manual provides the acute, 8-hour, and chronic Reference Exposure Levels in Tables 6.1 through 6.3. Some substances that pose a chronic or repeated 8-hour inhalation hazard may also present a chronic hazard via non-inhalation routes of exposure (e.g., ingestion of contaminated water, foods, or soils, and dermal absorption). The oral RELs for these substances are presented in Table 6.4. The methodology and derivations for acute, 8-hour, and chronic, RELs are described in the *Technical Support Document for the Derivation of Noncancer Reference Exposure Levels* (OEHHA, 2008).

2.5 Risk Characterization

This is the final step of risk assessment. In this step, modeled concentrations and exposure information, which are determined through exposure assessment, are combined with potency factors and RELs that are developed through dose-response assessment. The use of cancer potency factors to assess total cancer risk and the use of the hazard index approach for evaluating the potential for noncarcinogenic health effects are described in Chapter 8. Example calculations for determining (inhalation) cancer risk and noncancer acute, 8-hour, and chronic hazard quotients and hazard indices are presented in Appendix I. Chapter 9 provides an outline that specifies the content and recommended format of HRA results.

Under the Hot Spots Act, health risk assessments are to quantify both individual and population-wide health impacts (Health and Safety Code, Section 44306) (Appendix B). The health risk assessments are facility specific and the calculated risk should be combined for all pollutants emitted by a single facility. For example, cancer risk from multiple carcinogens is considered additive. For exposures to multiple non-carcinogen pollutants, a hazard index approach is applied for air contaminants affecting the same organ system. All substances emitted by the facility that are on the Hot Spots Act list of substances must be identified in the HRA, including those on the list that do not have a potency value or REL.

For assessing risk, OEHHA has developed two methods for determining dose via inhalation, dermal absorption, and ingestion pathways. These two methods, the point estimate approach and the stochastic exposure assessment approach, are described below and in Chapters 5 and 8. Detailed presentations of these methods can be found in*: Technical Support Document for Exposure Assessment and Stochastic Analysis* (OEHHA, 2012*)*.

2.5.1 *Point Estimate Approach*

OEHHA provides information in this document on average and high-end values for key exposure pathways (e.g., breathing rate for the inhalation exposure pathway). The average and high-end of point estimates in this document are defined in terms of the probability distribution of values for that variate. The mean represents the average values for point estimates and the 95th percentiles represent the high-end point estimates from the distributions identified in OEHHA (2012). Thus, within the limitations of the data, average and high-end point estimates are supported by the distribution.

Tier 1 of the tiered approach to risk assessment, which is briefly discussed in Section 2.5.3 and presented in more detail in Chapter 8, utilizes a combination of the average and high-end point estimates to more realistically estimate exposure in multipathway risk assessments. This method uses high-end exposure estimates for the pathways that are the main drivers of exposure and the average point estimate for the other non-driving exposure pathways. This approach will lessen the issue of compounding high-end exposure estimates, while retaining a health-protective approach for the more important exposure pathways. It is unlikely that an individual receptor would be on the high-end of exposure for all exposure pathways. See Chapter 8 for detailed discussions of how this multipathway methodology is applied to cancer and noncancer calculations. The HARP software can perform this analysis (referred to as the derived approach in the HARP software).

In addition to using an estimate of average and high-end consumption rates, cancer risk evaluations at individual receptors are presented for 9, 30, and 70-year exposure durations. The 9 and 30-year durations correspond to the average and high-end of residency time recommended by U.S. EPA (1997). The California data presented in Appendix L of the Exposure TSD (OEHHA, 2012) are generally supportive of the nationwide data. The 9 and 70-year exposure durations present potential impacts over the range of residency periods, while the 30-year exposure duration is recommended

for use as the basis for estimating cancer risk at the MEIR in all HRAs. Population-wide impacts should use the 70-year exposure duration.

The parameters used for all exposure durations assume exposure begins in the last trimester of pregnancy and progresses through the exposure duration of interest (e.g., 9, 30, or 70 years). These assumptions are thus protective of children. Children have higher intake rates on a per kilogram body weight basis (e.g., they breathe, drink and eat more per kg body weight than adults) and thus receive a higher dose from contaminated media. See Chapter 5 for the point estimates that can be used to estimate impacts for children. Chapters 5 and 8 discuss how to calculate cancer risk based on various exposure durations and point estimates. Appendix I contains an example calculation and Chapter 9 clarifies how to present the findings in an HRA.

2.5.2 *Stochastic Exposure Assessment*

OEHHA was directed under the Air Toxics "Hot Spots" program (SB 1731, Calderon, stat. 1992; Health and Safety Code Section 44360(b)(2)) to develop a "likelihood of risk" approach to risk assessment. To satisfy this requirement, OEHHA developed a stochastic approach to risk assessment that utilizes distributions for exposure variates such as breathing rate and water consumption rate rather than a single point estimate. The variability in exposure can be propagated through the risk assessment model using the distributions as input and a Monte Carlo or similar method. The result of such an analysis is a range of risks that at least partially characterizes variability in exposure.

Distributions of key exposure variates that are presented in the *Technical Support Document for Exposure Assessment and Stochastic Analysis* (OEHHA, 2012) were taken from the literature, if adequate, or developed from raw data of original studies. Intake variates such as vegetable consumption are relatively data rich; for these variates reasonable probability distributions can be constructed. However, the data necessary to characterize the variability in risk assessment variates are not always available. For example, for the fate and transport variates (e.g., fish bioaccumulation factors), there are only a few measurements for a given chemical available which precludes the adequate characterization of a probability distribution. We only developed distributions for those key exposure variates that were adequately characterized by data. Development of distributions is described in detail in the *Technical Support Document for Exposure Assessment and Stochastic Analysis* (OEHHA, 2012).

2.5.3 *Tiered Approach to Risk Assessment*

OEHHA recommends using a tiered approach to risk assessment. Tier 1 is a standard point estimate approach using the recommended point estimates presented in this document. If site-specific information is available to modify some point estimates developed in the *Technical Support Document for Exposure Assessment and Stochastic Analysis* (OEHHA, 2012) and is more appropriate to use than the recommended point estimates in this document, then Tier 2 allows use of that site-specific information. Site-specific information should be presented to the District before being used. The District may contact OEHHA for additional advice. Note that all non-default variates need to be adequately justified to OEHHA and the Districts to be used. In Tier 3, a stochastic approach to exposure assessment is used with the data distributions developed in the TSD (OEHHA, 2012) and presented in this document. Tier 4 is also a stochastic approach but allows for utilization of site-specific distributions, if they are justifiable (to OEHHA and the Districts) and more appropriate for the site under evaluation than those recommended in this document. Persons preparing an HRA that has a Tier 2 through Tier 4 evaluation must also include the results of a Tier 1 evaluation. Tier 1 evaluations are required for all HRAs prepared for the Hot Spots Program to promote consistency across the state for all facility risk assessments and allow comparisons across facilities. Chapter 8 provides a summary of the tiered approach and the TSD (OEHHA, 2012) discusses it in detail. Chapter 9 provides an outline that specifies the content and recommended format of HRA results.

3 - Hazard Identification - Air Toxics Hot Spots Emissions

3.1 The Air Toxics Hot Spots List of Substances and Emissions Inventory

For air toxics sources, hazard identification involves identifying pollutants of concern and whether these pollutants are potential human carcinogens or associated with other types of adverse health effects. For the Air Toxics Hot Spots (Hot Spots) Program, the emitted substances that are addressed in a health risk assessment (HRA) are found in the list of hazardous substances designated in the Air Resources Board's (ARB's) *Emission Inventory Criteria and Guidelines Regulations (Title 17, California Code of Regulations, Sections 93300-93300.5), and the Emission Inventory Criteria and Guidelines Report* (EICG Report), which is incorporated by reference therein (ARB, 2007). This list of substances is contained in both Appendix A of this document and the EICG Report. The list of substances also identifies those substances that are considered human carcinogens or potential human carcinogens.

The substances included on the Hot Spots Program list of substances are defined in the statute as those substances found on lists developed by the following sources:

- International Agency for Research on Cancer (IARC);
- U.S. Environmental Protection Agency (U.S. EPA);
- U.S. National Toxicology Program (NTP);
- ARB Toxic Air Contaminant Identification Program List;
- Hazard Evaluation System and Information Service (HESIS) (State of California);
- Proposition 65 (Safe Drinking Water and Toxic Enforcement Act of 1986) list of carcinogens and reproductive toxicants (State of California);
- Any additional substance recognized by the State Board as presenting a chronic or acute threat to public health when present in the ambient air.

All substances emitted by the facility that are on the Hot Spots Act list of substances must be identified in the HRA.

The ARB EICG Report (ARB, 2007) specifies that each facility subject to the Hot Spots Act must submit an Emission Inventory Report to the local air pollution control or air quality management district. This Emission Inventory Report must identify and account for all listed substances used, manufactured, formulated, or released by the facility. All routine, predictable releases must be reported. These inventory reports include the emission data necessary to estimate off-site levels of facility-released Hot Spots substances. These inventory reports will be discussed in further detail in Chapter 4. See Chapter 9 for an outline that specifies the content and recommended format for presenting the air dispersion modeling and HRA results. As presented in Appendix A, the EICG Report divides the list into three groups for reporting purposes. Potency or severity of toxic effects and potential for facility emission were considered in placing compounds into the three groups.

For the first group (listed in these guidelines in Appendix A-I), all emissions of these substances must be quantified in the HRA. For substances in the second group (listed in these guidelines in Appendix A-II), emissions are not quantified; however, facilities must report whether the substance is used, produced, or otherwise present on-site (i.e., these substances are simply listed in a table in the HRA). Lastly, substances in the third group (Appendix A-III) also only need to be reported in a table in the HRA if they are manufactured by the reporting facility.

Facilities that must comply with the Resource Conservation and Recovery Act and Comprehensive Environmental Response, Compensation and Liability Act (RCRA/CERCLA) requirements for risk assessment need to consult the California Department of Toxic Substances Control (DTSC) Remedial Project Manager to determine which substances must be evaluated in their risk assessment. Some RCRA/CERCLA facilities may emit substances which are not currently listed under the Hot Spots Program but which may require evaluation in a RCRA/CERCLA risk assessment.

4 - Air Dispersion Modeling

The information contained in this section is primarily an abbreviated version of the material found in Chapter 2 of the Air Toxics Hot Spots Risk Assessment Guidelines; Exposure Assessment and Stochastic Analysis Technical Support Document (OEHHA, 2012). Several references have been included in this section to indicate those areas that are covered in more detail in Chapter 2 of the Technical Support Document. However, some air dispersion concepts and procedures have been added to assist the reader in the health risk assessment (HRA) process. In particular, a brief summary of the Hot Spots Analysis and Reporting Program (HARP) software applicability to air dispersion analysis has been included. The HARP software has been developed by the Air Resources Board (ARB), in consultation with OEHHA and Air Pollution Control or Air Quality Management District (District) representatives. The HARP software is the recommended model for calculating and presenting HRA results for the Air Toxics Hot Spots Program (Hot Spots). Information on obtaining the HARP software can be found under the Hot Spots Program on the ARB's web site at *www.arb.ca.gov*. See Chapter 9 for an outline that specifies the content and recommended format for presenting the air dispersion modeling and HRA results.

The U.S. EPA has adopted the AERMOD air dispersion model into their list of regulatory approved models, in place of the previously used ISCST3 model. AERMOD is a steady-state plume model that incorporates air dispersion based on planetary boundary layer turbulence structure and scaling concepts, including treatment of both surface and elevated sources, and both simple and complex terrain (U.S. EPA, 2009). The Air Resources Board recommends AERMOD for Hot Spots risk assessments.

4.1 Air Dispersion Modeling in Exposure Assessment: Overview

Estimates of air concentrations of emitted toxicants in the surrounding community from a facility's air emissions are needed in order to determine cancer and noncancer risks. One approach to determining the concentration of air pollutants emitted from the facility is to do air monitoring in the surrounding community. However, there are a number of disadvantages to this approach. Ambient air monitoring is costly because good estimates of an annual average concentration typically require monitoring at least one day in six over a year. Because it is costly, monitoring is usually limited to a select number of pollutants, and a limited number of sites. There can be significant risks from some chemicals at or even below the monitoring detection limit, which can add considerable uncertainty to risk estimates if many of the measurements are below or near the detection limit. Monitoring measures not only facility emissions but also general ambient background as well. It can be difficult and expensive to distinguish between the two using monitoring, particularly if general ambient background levels are high relative to the contribution of facility emissions. These limitations often make it impractical to use monitoring in a program such as the Air Toxics Hot Spots program with hundreds of facilities.

Air dispersion models have several advantages over monitoring. Modeling can provide greater spatial detail and the costs are relatively cheap by comparison. For example, dispersion models can estimate the pollutant concentration in air at many receptor locations (hundreds to thousands) and for a multitude of averaging periods. Air dispersion models have been validated using air monitoring.

There are, however, uncertainties associated with the typical usage of air dispersion modeling. The use of meteorological data from the nearest airport may not ideally be the best representation of localized conditions. Gaussian plume air dispersion models ignore calm hours. This can bias model predictions towards underestimation. Some dispersion models offer limited chemical reactions within the algorithms; however, we generally assume the pollutant is inert for the near-field atmospheric travel time. This may bias estimated concentrations towards over-prediction for those pollutants that are highly reactive in the atmosphere. Air dispersion model results are only as good as the emissions estimates and emissions estimates can be uncertain. However, on the whole, the advantages of air dispersion modeling for a program like the Air Toxics Hot Spots far outweigh the disadvantages.

Professional judgment is required throughout the dispersion modeling process. The local air quality district has final authority on modeling protocols. The following guidance is intended to assist in the understanding of dispersion modeling for risk assessments.

Air dispersion modeling includes the following steps (see Figure 1):

1. Create an emission inventory of the toxic releases (Section 4.2)
2. Identify the source types (Section 4.3)
3. Identify the terrain type and land use (Section 4.4)
4. Determine the detail needed for the analysis: screening or refined (Section 4.5)
5. Identify the population exposure (Section 4.6)
6. Identify the receptor network (Section 4.7)
7. Obtain meteorological data (for refined air dispersion modeling only) (Section 4.8)
8. Select an air dispersion model (Section 4.9)
9. Prepare a modeling protocol and submit to the local Air District (hereafter referred to as “the District”) (Section 4.14)
10. Complete the air dispersion analysis
11. If necessary, redefine the receptor network and return to Step 10

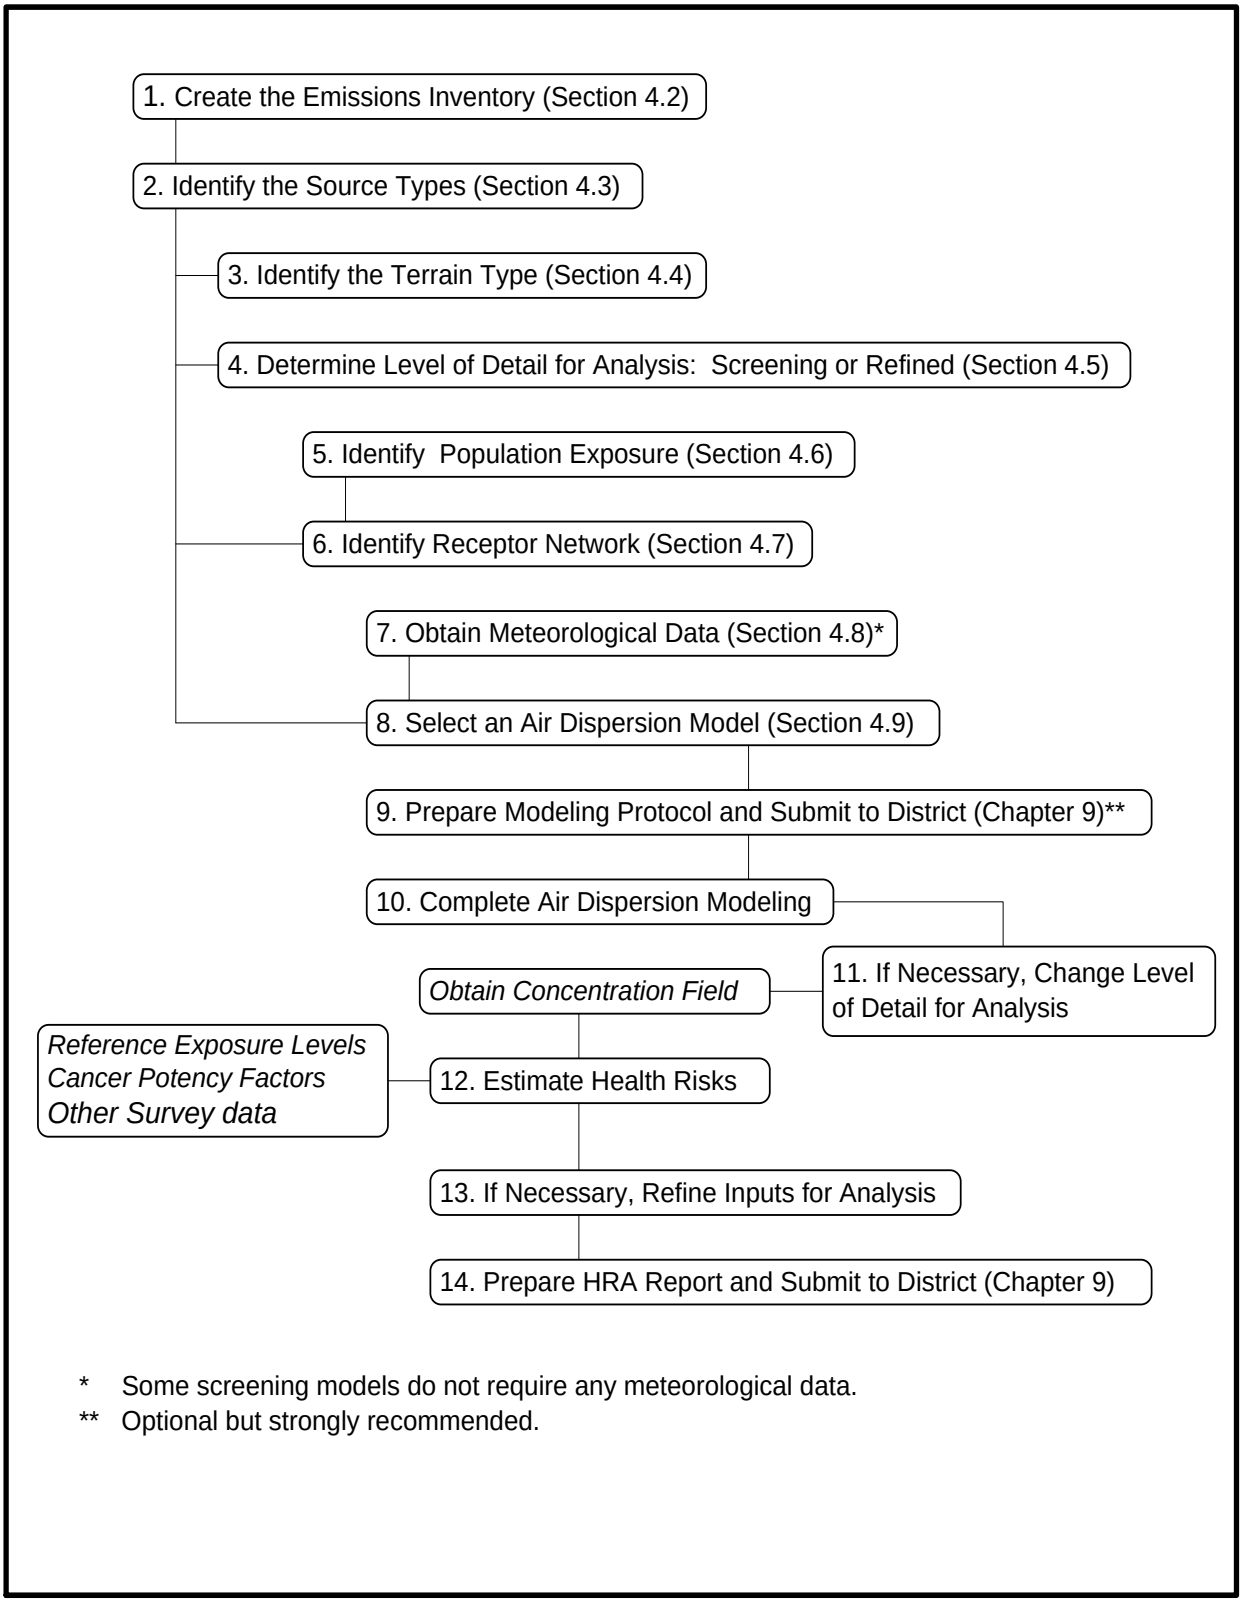
12. Complete the risk assessment

13. If necessary, refine the inputs and/or the model selection and return to Step 8

14. Present the HRA results (Chapter 9 provides an outline that specifies the content and recommended format of HRA results).

The output of the air dispersion modeling analysis includes a receptor field of ground level concentrations of the pollutant in ambient air. These concentrations can be used to estimate an inhaled or ingested dose for the estimation of multipathway cancer risk, or used to determine a hazard index for acute (inhalation), and chronic noncancer multipathway risks. It should be noted that in the Air Toxics "Hot Spots" program, facilities simulate the dispersion of the chemical emitted as an inert compound, and do not model any atmospheric transformations or dispersion of products from such reactions. The U.S. EPA Guideline on Air Quality Models (U.S. EPA, 2005) should be consulted when evaluating reactive pollutants for other regulatory purposes.

Figure 1 Overview of the Air Dispersion Modeling Process.



* Some screening models do not require any meteorological data.
** Optional but strongly recommended.

4.2 Emission Inventories

The Emission Inventory Reports (Inventory Reports) developed under the Hot Spots Program provide data to be used in the HRA and in the air dispersion modeling process. The Inventory Reports contain information regarding emission sources, emitted substances, emission rates, emission factors, process rates, and release parameters (area and volume sources may require additional release data beyond that generally available in Emissions Inventory reports). This information is developed according to the ARB's *Emission Inventory Criteria and Guidelines Regulations (Title 17, California Code of Regulations, Sections 93300-93300.5)*, and the *Emission Inventory Criteria and Guidelines Report* (EICG Report), which is incorporated by reference therein (ARB, 2007*)*.

Updated emission data for process changes, emission factor changes, material/fuel changes, or shutdown must be approved by the District prior to the submittal of the health risk assessment (HRA). Ideally, the District review of updated emissions could be completed within the modeling protocol. In addition, it must be stated clearly in the risk assessment if the emission estimates are based on updated or revised emissions (e.g., emission reductions). This section summarizes the requirements that apply to the emission data which are used for Air Toxics "Hot Spots" Act risk assessments.

4.2.1 *Air Toxics Hot Spots Emissions*

As noted in Chapter 3, Hazard Identification, the HRA should identify all substances emitted by the facility, which are on the Hot Spots Act list of substances (see Appendix A of the Guidance Manual or the EICG Report). The EICG Report specifies that Inventory Reports must identify and account for all listed substances used, manufactured, formulated, or released by the facility. All routine, predictable releases must be reported. Under the regulations, the list is divided into three groups for reporting purposes. The first group (listed in Appendix A-I of the Inventory Guidelines Report) has all pollutants whose emissions must be quantified. The second group (listed in Appendix A-II of the Inventory Guidelines Report) includes substances where emissions do not need to be quantified; however, facilities must report whether the substance is used, produced, or otherwise present on-site. The third group (listed in Appendix A-III of the Emissions Inventory Guidelines Report) includes substances whose emissions need not be reported unless the substance is manufactured by the facility. Chemicals or substances in the second and third groups should be listed in a table in the risk assessment.

Facilities that must comply with the Resource Conservation and Recovery Act and Comprehensive Environmental Response, Compensation and Liability Act (RCRA/CERCLA) requirements for risk assessment need to consult the Department of Toxic Substances Control (DTSC) Remedial Project Manager to determine which substances must be evaluated in their risk assessment in addition to the list of "Hot Spots" chemicals. Some RCRA/CERCLA facilities may emit chemicals that are not currently listed under the "Hot Spots" Program. Chapter 9 provides an outline that specifies the content and recommended format of HRA results.

4.2.1.1 Emission Estimates Used in the Risk Assessment

The HRA must include emission estimates for all substances that are required to be quantified in the facility's emission inventory report. Specifically, HRAs should include both annual average emissions and maximum 1-hour emissions for each pollutant. Maximum 1-hour emissions are used for acute noncancer health impacts while annual emissions are used for chronic exposures (i.e., chronic and 8-hour noncancer health impacts or cancer risk assessment).

Emissions for each substance must be reported for individual emitting processes associated with unique devices within a facility. Total facility emissions for an individual air contaminant will be the sum of emissions, reported by process, for that facility. Information on daily and annual hours of operation, and relative monthly activity, must be reported for each emitting process. Devices and emitting processes must be clearly identified and described and must be consistent with those reported in the emissions inventory report.

The HRA should include tables that present the emission information (i.e., emission rates for each substance released from each process) in a clear and concise manner. The District may allow the facility operator to base the HRA on more current emission estimates than those presented in the previously submitted emission inventory report (i.e., actual enforceable emission reductions realized by the time the HRA is submitted to the District). If the District allows the use of more current emission estimates, the District must review and approve the new emissions estimates prior to use in the HRA. The HRA report must clearly state what emissions are being used and when any reductions became effective. Specifically, a table presenting emission estimates included in the previously submitted emission inventory report as well as those used for the HRA should be presented. The District should be consulted concerning the specific format for presenting the emission information. Chapter 9 provides an outline that specifies the content and recommended format of HRA results. A revised emission inventory report must be submitted to the District prior to submitting the HRA and forwarded by the District to the ARB, if revised emission data are used.

4.2.1.1.1 Molecular Weight Adjustments for the Emissions of Metal Compounds

For most of the Hot Spots toxic metals, the OEHHA cancer potency factors, acute and chronic RELs apply to the weight of the toxic metal atom contained in the overall compound. Some of the Hot Spots compounds contain various elements along with the toxic metal atom (e.g., "Nickel hydroxide", CAS number 12054-48-7, has a formula of H_2NiO_2). Therefore, an adjustment to the reported pounds of the overall compound is needed before applying the OEHHA cancer potency factor for "Nickel and compounds" to such a compound. This ensures that the cancer potency factor, acute or chronic REL is applied only to the fraction of the overall weight of the emissions that are associated with health effects of the metal. In other cases, the Hot Spots metals are already reported as the metal atom equivalent (e.g., CAS 7440-02-0, "Nickel"), and these cases do not use any further molecular weight adjustment. (Refer to Note [7] in Appendix A,

List of Substances in the EICG Report for further information on how the emissions of various Hot Spots metal compounds are reported.)

The appropriate molecular weight adjustment factors (MWAF) to be used along with the OEHHA cancer potency factors, acute and chronic RELs for Hot Spots metals can be found in the MWAF column[1] of the table containing OEHHA/ARB Approved Health Values for use in Hot Spots Facility Risk Assessments that is in Appendix L of this document.

As an example, the compound "Nickel hydroxide" has a molecular formula of H_2NiO_2. The atomic weight of each of the elements in this compound, and the fraction they represent of the total weight, are therefore as follows:

Element	Number of atoms	Atomic Weight	Fraction of Total Weight = MWAF
1 x Nickel (Ni)	1 x	58.70	58.70 / 92.714 = **0.6332** (MWAF for Nickel)
2 x Oxygen (O)	2 x	15.999	
2 x Hydrogen (H)	2 x	1.008	
Total Molecular Weight of H_2NiO_2:		92.714	

So, for example, assume that 100 pounds of "Nickel hydroxide" emissions are reported under CAS number 12054-48-7. To get the Nickel atom equivalent of these emissions, multiply by the listed MWAF (0.6332) for Nickel hydroxide:

- 100 pounds x 0.6332 = 63.32 pounds of Nickel atom equivalent.

This step should be completed prior to applying the OEHHA cancer potency factor for "Nickel and compounds" in a calculation for a prioritization score or risk assessment calculation. (Note - The HARP software automatically applies the appropriate MWAF for each Hot Spots chemical (by CAS number), so the emissions should not be manually adjusted when using HARP. Therefore, if using HARP, you would use 100 pounds for Nickel hydroxide and HARP will make the MWAF adjustment for you. If not using HARP, you would use 63.32 pounds.)

[1] The value listed in the MWAF column for Asbestos is not a molecular weight adjustment. This is a conversion factor for adjusting mass and fibers or structures. See Appendix C for more information on Asbestos reporting and risk assessment information or see the EICG report for reporting guidance.

4.2.1.2 Release Parameters

Emission release parameters (e.g., stack height and inside diameter, stack gas exit velocity, release temperature and emission source location in UTM coordinates) are needed as inputs to the air dispersion model. The Inventory Guidelines specify the release parameters that must be reported for each stack, vent, ducted building, exhaust site, or other site of exhaust release. Additional information may be required to characterize releases from non-stack (volume and area) sources; see U.S. EPA dispersion modeling guidelines or specific user's manuals. This information should also be included in the air dispersion section of the risk assessment. This information must be presented in tables included in the risk assessment. Note that some dimensional units needed for the dispersion model may require conversion from the units reported in the Inventory Report (e.g., Kelvin (K) vs. degrees Fahrenheit (°F)). Chapter 9 provides an outline that specifies the content and recommended format of HRA results.

4.2.1.3 Operation Schedule

The HRA should include a discussion of the facility operation schedule and daily emission patterns. For AB2588 purposes, emissions should be reported based on routine and predictable operations. Weekly or seasonal emission patterns may vary and should be discussed. This is especially important in a refined HRA. Diurnal emission patterns should be simulated in the air dispersion model because of diurnal nature of meteorological observations. Diurnal evaluations are important to include since diurnal weather patterns and emission releases may cause significant differences in the concentration at a receptor of interest.

A table should be included listing the emission schedule on an hourly and yearly basis. In addition, the emission schedule and exposure schedule should corroborate any exposure adjustment factors used for approximating an inhaled dose. For more information about exposure adjustment factors, see Section 4.8.1. Alternatively, exposure adjustments can be made through refining the air dispersion analysis. See Section 4.11.1.2(h) for special case modeling or Appendix M. An alternative to including modeling that addresses diurnal influences would be to include a sensitivity study showing, and/or text explaining, the reason(s) why there are no significant differences due to diurnal influences on the emissions from the facility or at the receptor(s) of interest. For more guidance, you can contact the district or reviewing authority**.** Chapter 9 provides an outline that specifies the content and recommended format of HRA results.

4.2.1.4 Emission Controls

The HRA should include a description of control equipment, the emitting processes it serves, and its efficiency in reducing emissions of substances on the Air Toxics “Hot Spots” list. The EICG Report requires that this information be included in the Inventory Reports, along with the emission data for each emitting process. If the control equipment did not operate full-time throughout the year, then the reported overall control efficiency must be adjusted to account for any predictable downtime of the

control equipment. Any entrainment of toxic substances to the atmosphere from control equipment should be accounted for; this includes fugitive releases during maintenance and cleaning of control devices (e.g., baghouses and cyclones). Contact the District for guidance with control equipment adjustments. Recommended default deposition rates that are used when calculating potential noninhalation health impacts are listed in Section 5.3.2. Chapter 9 provides an outline that specifies the content and recommended format of HRA results.

4.2.2 *Landfill Emissions*

Emission estimates for landfill sites should be based on testing required under Health and Safety Code, Section (HSC) 41805.5 (AB 3374, Calderon) and any supplemental AB 2588 source tests or emission estimates used to characterize air toxics emissions from landfill surfaces or through off-site migration. The District should be consulted to determine the specific Calderon data to be used in the HRA. The "Hot Spots" Program HRA for landfills should also include emissions of listed substances for all applicable power generation and maintenance equipment at the landfill site. Processes that need to be addressed include stationary internal combustion engines, flares, evaporation ponds, composting operations, boilers, and gasoline dispensing systems.

4.3 Source Characterization

Pollutants are released into the atmosphere in many different ways. The release conditions need to be properly identified and characterized to appropriately use the air dispersion models.

4.3.1 *Source Type*

Source types can be identified as point, line, area, or volume sources for input to the air dispersion model. Several air dispersion models have the capability to simulate more than one source type.

4.3.1.1 Point Sources

Point sources are probably the most common type of source and most air dispersion models have the capability to simulate them. Typical examples of point sources include exhaust stacks. Isolated vents from buildings are special examples of point sources.

4.3.1.2 Line Sources

The version 12345 or newer of the AERMOD can accommodate line sources. Line sources can be also treated as a special case of either an area or a volume source. Examples of line sources include: conveyor belts and rail lines, freeways, and busy roadways. Not all mobile sources may be subject to the Hot Spots program; however, non-motor vehicles that operate within a facility (e.g., ships, trains, and cranes, etc.) are subject to the Hot Spots program. For more information, see the ARB's Emission Inventory and Criteria Guidelines document or ARB's interpretation and guidance

memorandum to CAPCOA regarding mobile sources which are subject to the "Hot Spots" program. This memo can be found at http://www.arb.ca.gov/ab2588/motorv.pdf.

Mobile sources and rail lines are required to be evaluated under SB 352. SB 352 requires a risk assessment performed under the Hot Spots risk assessment guidance for proposed school sites within 500 feet of a busy roadway. Dedicated air dispersion models are available for motor vehicle emissions from roadways which are a special type of line source. These models (i.e., CALINE3, CAL3QHCR, and CALINE4) are designed to simulate the mechanical turbulence and thermal plume rise due to the motor vehicle activity on the roadway. However, these dedicated models use the Pasquill-Gifford dispersion stability classes for dispersion; the AERMOD dispersion model uses a more advanced continuous stability estimation method based on observations. The limitation with AERMOD is that the user needs to estimate initial mixing (Szo and Syo) for mechanical turbulence and thermal plume rise. Consult with the District prior to conducting roadway modeling to determine model use.

For practical information on how to simulate roadway emission dispersion using these models, see the California Air Pollution Control Officer's Association (CAPCOA) website at http://www.capcoa.org or the Sacramento Metropolitan AQMD (SMAQMD) website at http://www.airquality.org/ceqa/RoadwayProtocol.shtml. The SMAQMD has a document titled, "Recommended Protocol for Evaluating the Location of Sensitive Land Uses Adjacent to Major Roadways"(January, 2010). The ARB recommends this document for SB-352 risk assessments.

4.3.1.3 Area Sources

Emissions that are to be modeled as area sources are typical of fugitive sources characterized by non-buoyant emissions containing negligible vertical extent (e.g., no plume rise or emissions distributed over a large horizontal area).

Fugitive particulate (PM2.5, PM10, TSP) emission sources include areas of disturbed ground (e.g., open pits, parking lots) which may be present during operational phases of a facility's life. Also included are areas of exposed material (e.g., storage piles and slag dumps) and segments of material transport where potential fugitive emissions may occur (uncovered haul trucks or rail cars, emissions from unpaved roads). Fugitive emissions may also occur during stages of material handling where particulate material is exposed to the atmosphere (uncovered conveyors, hoppers, and crushers).

Other fugitive emissions emanating from many points of release may be modeled as area sources. Examples include fugitive emissions from valves, flanges, venting, and other connections that occur at ground level or at an elevated level or deck if on a building or structure. Modern dispersion models include an option for an initial vertical extent (Szo) where needed.

Modeling portable equipment as an area source is a case-by-case situation that should be discussed with the District or reviewing authority. Situations may exist where this type of operation is best represented as another type of release.

4.3.1.4 Volume Sources

Non-point sources with emissions containing an initial vertical extent should be modeled as volume sources. The initial vertical extent may be due to plume rise or a vertical distribution of numerous smaller sources over a given area. Examples of volume sources include buildings with natural fugitive or passive ventilation, and line sources such as conveyor belts and rail lines.

4.3.2 *Quantity of Sources*

The number of sources at a facility may influence the selection of the air dispersion model. Some dispersion models are capable of simulating only one source at a time, and are therefore referred to as single-source models (e.g., AERSCREEN).

In some cases, for screening purposes, single-source models may be used in situations involving more than one source using one of the following approaches:

- Combining all sources into one single “representative” source

In order to be able to combine all sources into one single source, the individual sources must have similar release parameters. For example, when modeling more than one stack as a single “representative” stack, the stack gas exit velocities and temperatures must be similar. In order to obtain a conservative estimate, the values leading to the higher concentration estimates should typically be used (e.g., the lowest stack gas exit velocity and temperature, the height of the shortest stack, and a receptor distance and spacing that will provide maximum concentrations, etc.).

- Running the model for each individual source and superimposing results

Superimposition of results of single sources of emissions is the actual approach followed by all the Gaussian models capable of simulating more than one source. Simulating sources in this manner may lead to conservative estimates if worst-case meteorological data are used or if the approach is used with a model that automatically selects worst-case meteorological conditions, especially wind direction. The approach will typically be more conservative the farther apart the sources are because each run would use a different worst-case wind direction.

Additional guidance regarding source merging is provided by the U.S. EPA (1995a). It should be noted that depending upon the population distribution, the total burden can actually increase when pollutants are more widely dispersed. If the total burden from the facility or zone of impact (see Section 4.6.1) could increase for the simplifying modeling assumptions described above, the District should be consulted.

4.4 Terrain Type

Two types of terrain characterizations are required to select the appropriate model. One classification is made according to land type and another one according to terrain topography.

4.4.1 *Terrain Type – Land Use*

Some air dispersion models (e.g., CALINE) use different dispersion coefficients (sigmas) depending on the land use over which the pollutants are being transported. The land use type is also used by some models to select appropriate wind profile exponents. Traditionally, the land type has been categorized into two broad divisions for the purposes of dispersion modeling: urban and rural. Accepted procedures for determining the appropriate category are those suggested by Irwin (1978): one based on land use classification and the other based on population.

The land use procedure is generally considered more definitive. Population density should be used with caution and should not be applied to highly industrialized areas where the population density may be low. For example, in low population density areas a rural classification would be indicated, but if the area is sufficiently industrialized the classification should already be "urban" and urban dispersion parameters should be used.

If the facility is located in an area where land use or terrain changes abruptly, for example, on the coast, the District should be consulted concerning the classification. If need be, the model should be run in both urban and rural modes and the District may require a classification that biases estimated concentrations towards over prediction. As an alternative, the District may require that receptors be grouped according to the terrain between source and receptor.

AERMOD is the U.S. EPA's preferred dispersion model for a wide range of applications in rural or urban conditions. The users should refer to section 5.0 of the AERMOD Implementation Guide to determine urban or rural conditions.

The Land Use and the Population Density Procedures discussed above are described as follows.

4.4.1.1 Land Use Procedure

(1) Classify the land use within the total area A, circumscribed by a 3 km radius circle centered at the source using the meteorological land use typing scheme proposed by Auer (1978) and shown in Table 4.1.

(2) If land use types I1, I2, C1, R2 and R3 account for 50 percent or more of the total area *A* described in (1), use urban dispersion coefficients. Otherwise, use appropriate rural dispersion coefficients.

4.4.1.2 Population Density Procedure

(1) Compute the average population density (*p*) per square kilometer with *A* as defined in the Land Use procedure described above. (Population estimates are also required to determine the exposed population; for more information see Section 4.6.3.)

(2) If *p* is greater than 750 people/km^2 use urban dispersion coefficients, otherwise, use appropriate rural dispersion coefficients.

Table 4.1 Identification and classification of land use types (Auer, 1978)

Used to define rural and urban dispersion coefficients in certain models.

Type	Use and Structures	Vegetation
I1	*Heavy Industrial* Major chemical, steel and fabrication industries; generally 3-5 story buildings, flat roofs	Grass and tree growth extremely rare; <5% vegetation
I2	*Light-moderate industrial* Rail yards, truck depots, warehouses, industrial parks, minor fabrications; generally 1-3 story buildings, flat roofs	Very limited grass, trees almost totally absent; <5% vegetation
C1	*Commercial* Office and apartment buildings, hotels; >10 story heights, flat roofs	Limited grass and trees; <15% vegetation
R1	*Common residential* Single family dwelling with normal easements; generally one story, pitched roof structures; frequent driveways	Abundant grass lawns and light-moderately wooded; >70% vegetation
R2	*Compact residential* Single, some multiple, family dwelling with close spacing; generally <2 story, pitched roof structures; garages (via alley), no driveways	Limited lawn sizes and shade trees; <30% vegetation
R3	*Compact residential* Old multi-family dwellings with close (<2 m) lateral separation; generally 2 story, flat roof structures; garages (via alley) and ashpits, no driveways	Limited lawn sizes, old established shade trees; <35% vegetation
R4	*Estate residential* Expansive family dwelling on multi-acre tracts	Abundant grass lawns and lightly wooded; >80% vegetation
A1	*Metropolitan natural* Major municipal, state, or federal parks, golf courses, cemeteries, campuses; occasional single story structures	Nearly total grass and lightly wooded; >95% vegetation
A2	Agricultural rural	Local crops (e.g., corn, soybean); >95% vegetation
A3	*Undeveloped* Uncultivated; wasteland	Mostly wild grasses and weeds, lightly wooded; >90% vegetation
A4	Undeveloped rural	Heavily wooded; >95% vegetation
A5	*Water surfaces* Rivers, lakes	

4.4.2 *Terrain Type - Topography*

Surface conditions and topographic features generate turbulence, modify vertical and horizontal winds, and change the temperature and humidity distributions in the boundary layer of the atmosphere. These in turn affect pollutant dispersion and models differ in their need to take these factors into account.

The classification according to terrain topography should ultimately be based on the topography at the receptor location with careful consideration of the topographical features between the receptor and the source. Differentiation of simple versus complex terrain is unnecessary with AERMOD. In complex terrain, AERMOD employs the well-known dividing-streamline concept in a simplified simulation of the effects of plume-terrain interactions. For other plume models, topography can be classified as follows:

4.4.2.1 Simple Terrain (also referred to as "Rolling Terrain")

Simple terrain is all terrain located below stack height including gradually rising terrain (i.e., rolling terrain). Note that *Flat Terrain* also falls in the category of simple terrain.

4.4.2.2 Intermediate Terrain

Intermediate terrain is terrain located above stack height and below plume height. The recommended procedure to estimate concentrations for receptors in intermediate terrain is to perform an hour-by-hour comparison of concentrations predicted by simple and complex terrain models. The higher of the two concentrations should be reported and used in the risk assessment.

4.4.2.3 Complex Terrain

Complex terrain is terrain located above plume height. Complex terrain models are necessarily more complicated than simple terrain models. There may be situations in which a facility is "overall" located in complex terrain but in which the nearby surroundings of the facility can be considered simple terrain. In such cases, receptors close to the facility in this area of simple terrain will "dominate" the risk analysis and there may be no need to use a complex terrain model. It is unnecessary to determine which terrain dominates the risk analysis for users of AERMOD.

4.5 Level of Detail: Screening vs. Refined Analysis

Air dispersion models can be classified according to the level of detail which is used in the assessment of the concentration estimates as "screening" or "refined". Refined air dispersion models use more robust algorithms capable of using representative meteorological data to predict more representative and usually less conservative estimates. Refined air dispersion models are, however, more resource intensive than their screening counterparts. It is advisable to first use a screening model to obtain conservative concentration estimates and calculate health risks. If the health risks are estimated to be above the threshold of concern, then use of a refined model to calculate

more representative concentration and health risk estimates would be warranted. There are situations when screening models represent the only viable alternative (e.g., when representative meteorological data are not available). The district or reviewing authority should be consulted to determine the appropriate method for determining the level of detail in the modeling analysis. The HARP software will incorporate the capability of using either representative meteorological data from AERMOD or the default meteorological conditions from the AERSCREEN model.

It is acceptable to use a refined air dispersion model in a "screening" mode for this program's health risk assessments. In this case, a refined air dispersion model is used:

- with worst-case meteorology instead of representative meteorology;

- with a conservative averaging period conversion factor to calculate longer term concentration estimates (see Section 4.10 for more discussion on screening air dispersion models and adjustments factors).

Note that use of worst case meteorology in a refined model is not the normal practice in New Source Review or Ambient Air Quality Standard evaluation modeling.

4.6 Population Exposure

The level of detail required for the analysis (e.g., screening or refined), and the procedures to be used in determining geographic resolution and exposed population require case-by-case analysis and professional judgment. The District should be consulted before beginning the population exposure estimates, and as results are generated, further consultation may be necessary. Some suggested approaches and methods for handling the breakdown of population and performance of a screening or detailed risk analysis are provided in this section.

In addition to estimating individual cancer risk at specific points such as the MEI (maximally exposed individual), OEHHA recommends determining the number of people who reside within the 1×10^{-6}, 1×10^{-5}, $1x\ 10^{-4}$, and higher cancer risk isopleths. For noncancer population evaluations, the number of people who reside within the 0.5, one, five, or higher hazard index isopleths should be reported. The HARP software can provide population exposure estimates as cancer burden or as the number of persons exposed to a selected (user identified) health risk/impact level. Information on obtaining the HARP software can be found under the Hot Spots Program on the ARB's web site at *www.arb.ca.gov*. Chapter 9 provides an outline that specifies the content and recommended format of HRA results.

4.6.1 *Zone(s) of Impact*

As part of the estimation of the population exposure for the cancer risk analysis, it is necessary to determine the geographic area affected by the facility's emissions. An initial approach to define a "zone of impact" surrounding the source is to generate an isopleth where the total excess lifetime cancer risk from inhalation exposure to all emitted carcinogens is greater than 10^{-6} (one in 1,000,000).

For noncarcinogens, a second, third, and fourth isopleth (to represent the chronic, 8-hour, and acute impacts) should be created to define the zone of impact for the hazard index from both inhalation and noninhalation pathways greater than or equal to 1.0. For clarity these isopleths may need to be presented on separate maps in the HRA.

Contact the District or reviewing authority to discuss inclusion of isopleth maps if all potential health risks fall within the facility boundary and no receptors have, or will ever, be present within the boundary (also see Section 4.7.1 for a discussion of on-site receptors).

The initial "zone of impact" can be determined as follows:

- Use a screening dispersion model (e.g., AERSCREEN) to obtain concentration estimates for each emitted pollutant at varying receptor distances from the source. Several screening models feature the generation of an automatic array of receptors which is particularly useful for determining the zone of impact. In order for the model to generate the array of receptors the user needs to provide some information normally consisting of starting distance, increment and number of intervals.

- Calculate total cancer risk and hazard index (HI) for each receptor location by using the methods provided in the risk characterization sections in Chapter 8 of the Air Toxics Hot Spots Risk Assessment Guidance Manual.

- Find the distance where the total inhalation cancer risk is equal to 10^{-6}; this may require redefining the receptor array in order to have two receptor locations that bound a total cancer risk of 10^{-6}. Next, find the distance where the chronic, 8-hour, and acute health hazard indices are declared significant by the District (e.g., acute, 8-hour, or chronic HI = 1.0).

Some Districts may prefer to use a cancer risk of 10^{-7} or an HI of 0.5 as the zone of impact. Therefore, the District should be consulted before modeling efforts are initiated. If the zone of impact is greater than 25 km from the facility at any point, then the District should be consulted. The District may specify limits on the area of the zone of impact. Ideally, these preferences would be presented in the modeling protocol (see Section 4.14).

Note that when depicting the risk assessment results, risk isopleths must present the total cancer and noncancer risk from both inhalation and noninhalation pathways. The zone of impact should be clearly shown on a map with geographic markers of adequate resolution (see Section 4.6.3.1). The text below discusses methodology for defining the zone of impact and has format recommendations. Chapter 9 provides an outline that specifies the content and recommended format of all HRA results.

The zone of impact can be defined once the exposure assessment (air dispersion modeling) process has determined the pollutant concentrations at each designated off-site receptor and a risk analysis (see Chapter 8) has been performed. For clarity, the cancer and noncancer zone(s) of impact should be presented on separate maps. A

map illustrating the carcinogenic zone of impact is required. The District may at its discretion ask for the map illustrating the potential carcinogenic zone of impact to identify the zone of impact for the minimum exposure pathways (inhalation, soil, dermal, and mother's milk) and the zone of impact for all applicable pathways of exposure (minimum pathways plus site/route dependent pathways). Two maps may be needed to accomplish this. The legend of these maps should state the level(s) used for the zone of impact and identify the exposure pathways that were included in the assessment.

The noncancer maps should also clearly identify the noncancer zones of impact. These include the acute (inhalation) zone of impact, 8-hour (inhalation) zone of impact and the chronic (including both inhalation, multipathway) zone of impact. The District may at its discretion require separate chronic inhalation and chronic multipathway zones of impact maps. For clarity, presentation of the two chronic zones of impact may also require two or more maps. The legend of these maps should state the level(s) used for the zone of impact and identify the exposure pathways (and target organs) that were included in the assessment. Further information regarding the methods for determination of hazard indices and cancer risk are discussed in Chapter 8 and Appendix I.

4.6.2 *Screening Population Estimates for Risk Assessments*

A screening risk assessment should include an estimate of the maximum exposed population. For screening risk assessments, a detailed description of the exposed population is not required. The impact area to be considered should be selected to be health protective (i.e., will not underestimate the number of exposed individuals). A health-protective assumption is to assume that all individuals within a large radius of the facility are exposed to the maximum concentration. If a facility must also comply with the RCRA/CERCLA risk assessment requirements, health effects to on-site workers may also need to be addressed. The DTSC's Remedial Project Manager should be consulted on this issue. The District should be consulted to determine the population estimate that should be used for screening purposes. Guidance for one screening method is presented here.

1. Use a screening dispersion model (e.g., AERSCREEN) to obtain concentration estimates for each emitted pollutant at varying receptor distances from the source. Several screening models feature the generation of an automatic array of receptors that is particularly useful for determining the zone of impact. In order for the model to generate the array of receptors, the user needs to provide some information normally consisting of starting distance, increment, and number of intervals.

2. Calculate the potential cancer risk and hazard index for each receptor location by using the methods provided in the risk characterization sections of this document (Chapter 8).

3. Find the distance where the potential cancer risk is equal to District specified levels (e.g., 10^{-6}); this may require redefining the receptor array in order to have

two receptor locations that bound a total cancer risk of 10^{-6}. This exercise should be repeated for the noncancer health impacts.

4. Calculate cancer burden by estimating the number of people in the grid and stipulate that all are exposed at the highest level.

4.6.3 *Refined Population Estimates for Risk Assessments*

The refined HRA requires a detailed analysis of the population exposed to emissions from the facility. Where possible, a detailed population exposure analysis provides estimates of the number of individuals in residences and offsite workplaces, as well as at sensitive receptor sites such as schools, daycare centers and hospitals. The District may require that locations with high densities of sensitive individuals be identified (e.g., schools, daycare centers, hospitals). These population analyses can include exposure estimates for workers and residents through the use of land use maps or other tools. The overall exposed residential and worker populations should be apportioned into smaller geographic subareas. The information needed for each subarea is:

1. The number of exposed persons, and
2. The receptor location at which the calculated ambient air concentration is assumed to be representative of the exposure to the entire population in the subarea.

A multi-tiered approach is suggested for the population analysis. Census tracts, which the facility could significantly impact, should be identified (see Section 4.6.3.1). A census tract should be divided into smaller subareas if it is close to the facility where ambient concentrations vary widely. The District may determine that census tracts provide sufficient resolution near the facility to adequately characterize population exposure or they may prefer the census information to be evaluated using smaller blocks. Further downwind where ambient concentrations are less variable, the census tract level may be acceptable to the District. The District may determine that the aggregation of census tracts (e.g., when the census tracts making up a city are combined) is appropriate for receptors that are considerable distances from the facility.

If a facility must also comply with the RCRA/CERCLA HRA requirements, health effects to on-site workers may also need to be addressed. The DTSC's Remedial Project Manager should be consulted on this issue. In some cases it may be appropriate to evaluate risks to on-site receptors. The district should be consulted about special cases for which evaluation of on-site receptors is appropriate, such as facilities frequented by the public or where people may reside (e.g., military facilities).

4.6.3.1 Census Tracts

For a refined risk assessment, the boundaries of census tracts can be used to define the geographic area to be included in the population exposure analysis. Digital maps showing the census tract boundaries in California can be obtained from "The Thomas

Guide"® on the World Wide Web. Statistics for each census tract can be obtained from the U.S. Census Bureau. The website address for the U.S. Census Bureau is http://www.census.gov. Numerous additional publicly accessible or commercially available sources of census data can be found on the World Wide Web. A specific example of a census tract is given in Appendix K. The HARP software includes U.S. census data and is a recommended tool for performing population exposure estimates.

The two basic steps in defining the area under analysis are:

(1) Identify the "zone of impact" (as defined previously in Section 4.6.1) on a map detailed enough to provide for resolution of the population to the subcensus tract level. (The U.S. Geological Survey (USGS) 7.5-minute series maps and the maps within the HARP software provide sufficient detail.) This is necessary to clearly identify the zone of impact, location of the facility, and sensitive receptors within the zone of impact. If significant development has occurred since the USGS survey, this should be indicated. A specific example of a 7.5-minute series map is given in Appendix K.

(2) Identify all census tracts within the zone of impact using a U.S. Bureau of Census or equivalent map (e.g., Thomas Brothers, HARP Software). If only a portion of the census tract lies within the zone of impact, then only the population that falls within the isopleth should be used in the population estimate or burden calculation. To determine this level of detail, local planning and zoning information may need to be collected. When this more detailed information is not available, then a less refined approach is to include the census data if the centroid of the census block falls within the isopleths of interest. The census tract boundaries should be transferred to a map, such as a USGS map (referred to hereafter as the "base map".)

An alternative approach for estimating population exposure in heavily populated urban areas is to apportion census tracts to a Cartesian grid cell coordinate system. This method allows a Cartesian coordinate receptor concentration field to be merged with the population grid cells. This process can be computerized and minimizes manual mapping of centroids and census tracts. The HARP software includes this function and will provide population estimates that are consistent with the methodology discussed here.

The District may determine that aggregation of census tracts (e.g., which census tracts making up a city can be combined) is appropriate for receptors that are located at considerable distances from the facility. If the District permits such an approach, it is suggested that the census tract used to represent the aggregate be selected in a manner to ensure that the approach is health protective. For example, the census tract included in the aggregate that is nearest (downwind) to the facility should be used to represent the aggregate.

4.6.3.1.1 Subcensus Tract

Within each census tract are smaller population units. These units [urban block groups (BG) and rural enumeration districts (ED)] contain about 1,100 persons. BGs are

further broken down into statistical units called blocks. Blocks are generally bounded by four streets and contain an average of 70 to 100 persons. However, this range in population is an average and population units may vary significantly. In some cases, the EDs are very large and identical to a census tract.

The area requiring detailed (subcensus tract) resolution of the exposed residential and worker population will need to be determined on a case-by-case basis through consultation with the District. The District may determine that census tracts provide sufficient resolution near the facility to adequately characterize population exposure.

Employment population data can be obtained at the census tract level from the U.S. Census Bureau or from local planning agencies. This degree of resolution will generally not be sufficient for most risk assessments. For the area requiring detailed analysis, zoning maps, general plans, and other planning documents should be consulted to identify subareas with worker populations.

The boundaries of each residential and employment population area should be transferred to the base map.

4.6.4 *Sensitive Receptor Locations*

Individuals who may be more sensitive to toxic exposures than the general population are distributed throughout the total population. Sensitive populations may include young children and chronically ill individuals. The District may require that locations with high densities of sensitive individuals be identified (e.g., schools, nursing homes, residential care facilities, daycare centers, and hospitals). The HRA should state what the District requirements are regarding identification of sensitive receptor locations.

Although protection of sensitive individuals is incorporated into OEHHA's risk assessment methodology in both cancer risk and noncancer risk assessment, the assessment of risk at the specific location of such sensitive individuals (e.g., schools, hospitals, or nursing homes) may be useful to assure the public that such individuals are being considered in the analysis. For some chemicals (e.g., mercury and manganese) children have been specifically identified as the sensitive subpopulation for noncancer health impacts, so it can be particularly appropriate to assess school sites.

4.7 Receptor Siting

4.7.1 *Receptor Points*

The modeling analysis should contain a network of receptor points with sufficient detail (in number and density) to permit the estimation of the maximum concentrations. Locations that must be identified include:

- The maximum estimated off-site impact or point of maximum impact (PMI),
- The maximum exposed individual at an existing residential receptor (MEIR),
- The maximum exposed individual at an existing occupational worker receptor (MEIW).

Note that some situations may also require that on-site receptor (worker or residential) locations be evaluated. The risk assessor can contact the District or reviewing authority for guidance if on-site exposure situations are present at the emitting facility. However, these on-site locations should be included in the HRA. Some examples where the health impacts of on-site receptors may be appropriate could be military base housing, prisons, universities, day care facilities, or locations where the public may have regular access for the appropriate exposure period (e.g., a lunch time café or museum for acute exposures). When a receptor lives and works on the facility, site, or property, then these receptors should be evaluated and reported under both residential and worker scenarios and the one that is most health protective should be used for risk management decisions. The cancer risk estimates for the onsite residents may use a 30-year exposure duration while the 25-year exposure duration is used for a worker. Under a Tier 2 analysis, alternate exposure durations may be evaluated and presented with all assumptions supported.

All of these locations (i.e., PMI, MEIR, and MEIW) must be identified for potential multipathway carcinogenic and noncarcinogenic effects. It is possible that the estimated PMI, MEIR, and MEIW risk for cancer, chronic noncancer, 8-hour, and acute noncarcinogenic risks occur at different locations or that some of these evaluations may not be necessary (e.g., the receptor does not exist). For example, some facilities will not have off-site workers in the vicinity of the facility and will not need to evaluate worker exposure, or the exposure situation may only require the evaluation of short-term carcinogenic or acute noncancer impacts (see Section 8.2.10 for a discussion of short-term projects). The approval to revise the exposure assessment for a receptor, or to omit the MEIW receptor, should be verified in writing with the District or reviewing authority and included in the HRA.

Other sensitive receptor locations may also be of interest and required to be included in the HRA. The District or reviewing authority should be consulted to determine which sensitive receptor locations must be included.

The results from a screening model (if available) can be used to identify the area(s) where the maximum concentrations are likely to occur. Receptor points should also be located at the population centroids (see Section 4.7.2) and sensitive receptor locations (see Section 4.6.4). The exact configuration of the receptor array used in an analysis will depend on the topography, population distribution patterns, and other site-specific factors. All receptor locations should be identified in the HRA using UTM (Universal Transverse Mercator) coordinates and receptor number. The receptor numbers in the summary tables should match receptor numbers in the computer output (e.g., HARP output files). In addition to actual UTM coordinates, the block/street locations (i.e., north side of 3,000 block of Smith Street) should be provided in the HRA for the PMI, MEIR, and MEIW for carcinogenic and noncarcinogenic health effects. Chapter 9 provides an outline that specifies the content and recommended format of HRA results.

4.7.1.1 Receptor Height

To evaluate localized impacts, receptor height should be taken into account at the point of maximum impact on a case-by-case basis. For example, receptor heights may have to be included to account for receptors significantly above ground level. Flagpole receptors at the height of the breathing zone of a person may need to be considered when the source receptor distance is less than a few hundred meters. Consideration must also be given to the noninhalation pathway analysis which requires modeling of chemical deposition onto soil or water at ground level. For the inhalation pathway, a health protective approach is to select a receptor height from 0 meters to 1.8 meters that will result in the highest predicted downwind concentration. Final approval of this part of the modeling protocol should be with the District or reviewing authority.

4.7.2 *Centroid Locations*

For each subarea analyzed, a centroid location (the location at which a calculated ambient concentration is assumed to represent the entire subarea) should be determined. When population is uniformly distributed within a population unit, a geographic centroid based on the shape of the population unit can be used. If only a portion of the census tract lies within the isopleth or area of interest, then only the population that falls within the isopleth should be used in the calculation for population exposure. To determine this level of detail, local planning and zoning information may need to be collected. Where populations are not uniformly distributed, a population-weighted centroid may be used. Another alternative uses the concentration at the point of maximum impact within that census tract as the concentration to which the entire population of that census tract is exposed. While this less refined approach is commonly accepted, Districts should be contacted to approve this method prior to its use in a risk assessment.

The centroids represent locations that should be included as receptor points in the dispersion modeling analysis. Annual average concentrations should be calculated at each centroid using the modeling procedures presented in this chapter.

For census tracts and BG/EDs, judgments can be made using census tracts maps and street maps to determine the centroid location. At the block level, a geographic centroid is sufficient.

4.7.3 *Spatial Averaging*

Since the inception of the “Hot Spots” and California’s Air Toxics Programs, HRA results for an individual receptor have typically been based on air dispersion modeling results at a single point or location. With a few exceptions, this method has been traditionally used for all types of receptors (e.g., PMI, MEIR, MEIW, pathway receptors, etc.). The assumptions used in risk assessment are designed to prevent underestimation of health impacts to the public resulting in a health protective approach. However, basing risk estimates on a single highest point (PMI, MEIR, or MEIW) does not take into account that a person does not remain at one location on their property, or in one location at the

workplace over an extended period of time. Therefore, the average air concentration over a small area is likely to be more representative than using the air concentration at a single point, particularly in those situations where concentrations fall off rapidly around that single point. The concept of averaging air concentrations over a small area is known as spatial averaging.

In order to understand how spatial averaging can impact air dispersion modeling results with various types of facilities, the ARB, in conjunction with the OEHHA, performed sensitivity analyses to evaluate the impacts of spatially averaging air dispersion modeling results (see Appendix C of the Air Toxics Hot Spots Program Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis (EASA)). Based on these sensitivity analyses, it is reasonable and appropriate to include spatial averaging techniques in air toxic risk assessments as supplemental information to Tier 1 information (i.e., modeling results that are based on the air concentration from a single point or location). While all risk assessments must include results based on Tier 1 methodology, the spatially averaged concentrations around the point of interest (e.g., PMI, MEIR, MEIW, multipathway exposure evaluations, etc.) could also be included as an option in risk assessments and acceptable for risk management decisions subject to approval by the District or reviewing agency. Spatial averaging is an option for the purpose of additional refinement to the risk assessment.

A few reasons that support the inclusion of spatially averaged modeled concentrations in risk assessment include the following:

- Averaging results over a small domain will give a more representative picture of individual exposure and risk than an estimate based on one single location within their property.
- Spatial averaging will allow air dispersion modeling and risk assessment results to be characterized as the estimated concentration and risk in a discrete area of interest, rather than an exact value for a single location.
- From a risk communication standpoint, the ARB and OEHHA feel it is more appropriate to present the modeling output and the calculated health impacts as the potential impacts within a small or discrete area, rather than an exact value at a specific point on a grid or map.
- Spatial averaging is the recommended procedure in ARB's Lead Risk Management Guidelines (2001) and has been used in several complex source HRAs [e.g., Roseville Railyard (2004), Ports of LA/LB (2006), Port of Oakland (2008)].
- Spatially averaging the deposition concentrations over pasture land, a garden, or a water body for multipathway exposure scenarios is a planned upgrade for the HARP Software. This will provide an option that will refine multipathway exposure assessments. Average deposition on these types of areas (e.g., a water body) is not necessarily well represented by the single highest point of deposition, or deposition at the geographic center of the water body. Likewise, since produce is grown over the entire surface of the garden and cows graze the

entire pasture, deposition is better estimated by evaluating the entire area rather than using a single point.

4.7.3.1 Spatial Averaging Methodology

The spatial averaging sensitivity study in Appendix C of the EASA is based on simulating emissions from point, volume, area, and line sources. Most source types (e.g., point) are simulated as a small, medium or large source. Line sources are only simulated as small and large. In addition, meteorological data collected at five different locations in California were used. Nested spatial average grids of various domains were used to study the differences on the spatial average concentration. In the case of the 20 meter by 20 meter spatial average nested grid, the spatial average concentration showed little change over the PMI for medium and large sources. In the case for small sources, the spatial average concentration is approximately 45% to 80% of the PMI concentration. Individual source type and meteorological conditions will cause variations in these results.

The results of the spatial averaging sensitivity study in Appendix C of the EASA shows that sources with low plume rise that result in a PMI, MEIW, or MEIR located at or near the property fence line are most sensitive to spatial averaging. Source types with high plume rise (e.g., tall stacks) show a PMI far downwind where the concentration gradient is more gradual and therefore spatial averaging has a lesser effect. While spatial averaging can be used regardless of source size or the location of the PMI, the following conditions generally apply when a source is a good candidate for spatial averaging:

- The MEIR, MEIW, or PMI is located at the fence line or close to the emission source.
- The concentration gradient is high near the PMI. This is more associated with low level plumes such as fugitive, volume, area, or short stacks.
- A long term average is being calculated to represent a multi-year risk analysis based on one to five years of meteorological data. Note that spatial averaging should **not** be used for short term (acute) calculations.

In general, the method for calculating the spatial average in air toxic risk assessments includes the following steps:

1. Locate the point(s) of interest and receptor(s) (i.e., PMI, MEIW, MEIR, and any additional receptor locations of interest or concern) with a grid resolution spacing of no greater than five meters. To achieve this, two or more modeling runs with successively finer nested grid resolutions may be needed to find the final location where the nested grid that will be used for spatial averaging will be placed.

2. Center the spatial average nested grid on the each receptor's location of interest determined in step 1. Limit the nested grid to no larger than 20 meters by 20 meters or 400 square meters. Note that if a portion of the centered and nested grid falls within the facility boundary and the receptor location of interest is outside of the boundary, then adjustments to the nested grid to obtain the spatially-averaged concentration for the offsite receptor are reasonable. This may be done by either repositioning the nested grid to cover 400 square meters of off-boundary area surrounding the receptor or center the nested grid and delete any on-site grid points so that only the offsite grid points surrounding the receptor are used in the spatially averaged concentration. The grid resolution spacing should be no greater than five meters. With a five meter grid resolution, the 20 meter by 20 meter domain will result in 25 receptors. The size, shape, and placement of the domain and the resolution of points are subject to approval by the District, ARB, or other reviewing authority. See the Sections 4.7.3.1.2 and 4.7.3.1.3 below for additional discussion on domain sizing and grid spacing at worksites, pastures, gardens, and water bodies.

3. Some configurations of source activity and meteorological conditions result in a predominant downwind plume center line that is significantly askew from one of the four ordinate directions. In this case, a tilted nested grid is necessary to coincide with the dominant plume centerline. Polar receptors are easier to implement than a tilted rectangular grid. The domain of the polar receptor field should be limited to a 15 meter radius. See Appendix C of the EASA for detailed instructions on tilted polar receptors.

4. Calculate the arithmetic mean of the long term period average concentration (e.g., annual average) of the nested grid of receptors to represent the spatial average. This average is used in the risk calculations.

5. Document and include all methods, assumptions, data, maps, and files used in the spatial averaging analysis and clearly present this information in the risk assessment following the requirements of the District or reviewing authority. Note that in the update to the HARP software, functionality will be included that will assist with spatial averaging and the methodology discussed.

The following sections discuss the use of spatial averaging for various receptor types and exposure pathways.

4.7.3.1.1 Residential Receptors

Follow the steps in Section 4.7.3 outlining the spatial averaging methodology. To remain health protective when evaluating a residential receptor, spatial averaging should not take place using large nested domains. The domain used for spatial averaging should be no larger than 20 meters by 20 meters with a maximum grid spacing resolution of equal to or less than five meters. This domain represents an area

that is approximately the size of a small urban lot. The size of the domain and resolution of points shall be subject to approval by the District, ARB, or other reviewing authority.

4.7.3.1.2 Worker Receptors

Offsite worker locations (e.g. MEIW) may also be a candidate for spatial averaging. However, workers can be at the same location during almost their entire daily work shift (e.g., desk/office workers). When this is the situation, then the traditional method of using a single location and corresponding modeled concentration is appropriate. If spatial averaging is used, care should be taken to determine the proper domain size and grid resolution. Follow the steps in Section 4.7.3 outlining the spatial averaging methodology. To be consistent with the residential receptor assumptions and remain health protective, a modeling domain size no larger than 20 meters by 20 meters is recommended with a grid spacing resolution of equal to or less than five meters. However, if workers routinely and continuously move throughout the worksite over a space greater than 20 meters by 20 meters, then a larger domain may be considered.

The HRA or modeling protocol shall support all assumptions used, including, but not limited to, documentation for all workers showing the area where each worker routinely performs their duties and the percentage of time spent in those areas. The final domain size should not be greater than the smallest area of worker movement. Other considerations for determining domain size and grid spacing resolution may include an evaluation of the concentration gradients across the worker area. The grid spacing used within the domain to find the concentration that will be used to calculate health impacts should be sufficient in number and detail to obtain a representative concentration across the area of interest. The size of the domain and resolution of points shall be subject to approval by the District, ARB, or other reviewing authority.

4.7.3.1.3 Pastures, Gardens, or Water Bodies

The simplified approach of using the concentration (deposition rate) at the centroid, a specific point of interest, or the PMI location for an area being evaluated for noninhalation exposures (e.g., a body of water used for fishing, a pasture used for grazing, area of a garden, etc.) is acceptable for use in HRA. However, evaluating deposition concentrations over pasture land, a garden, or a water body for multipathway exposure scenarios using spatial averaging could give more representative estimates of the overall deposition rate. Use of spatial averaging in this application is subject to approval by the District, ARB, or other reviewing authority.

If spatial averaging will be done, follow the steps in Section 4.7.3.1 outlining the spatial averaging methodology. When using spatial averaging over the deposition area, care should be taken to determine the proper domain size to make sure it includes all reasonable areas of potential deposition. The size and shape of the area of interest (e.g., pasture or water body) should be identified and used for the modeling domain. The grid spacing or resolution used within the domain should be sufficient in detail to obtain a representative deposition concentration across the area of interest. One way

to determine the grid resolution is to include an evaluation of the concentration gradients across the deposition area. The HRA or modeling protocol shall support all assumptions used, including, but not limited to, documentation of the deposition area (e.g., size and shape of the pasture, garden, or water body, maps, representative coordinates, grid resolution, concentration gradients, etc.). The size of the domain and grid resolution is subject to approval by the reviewing authority.

In lieu of following the details in the paragraph above, the approach used for the other receptors (e.g., MEIR, MEIW) that uses a domain size not greater than 20 meters by 20 meters, located on the PMI within the area of interest, with a maximum grid spacing resolution of five meters, can be used. This default refined approach would apply to deposition areas greater than 20 meters by 20 meters. For smaller deposition areas, the simplified approach of using the PMI for the area, the concentration at the centroid or a specific point of interest, or averaging over the actual smaller domain can be used. This again is subject to approval by the reviewing authority.

The HRA or modeling protocol shall support all assumptions used, including, but not limited to, documentation of the deposition area (e.g., size and shape of the water body, pasture, or garden; all data; maps; representative coordinates, and etc.), and the details clarifying how and where the averaging was done (e.g., location and magnitude of concentration gradients, the grid spacing used).

4.8 Meteorological Data

Refined air dispersion models require hourly meteorological data. The first step in obtaining meteorological data should be to check with the District and the ARB for data availability. Other sources of data include the National Weather Service (NWS), National Climatic Data Center (NCDC), Asheville, North Carolina, ARB meteorological database (METDB), military stations and private networks. Meteorological data for a subset of NWS stations are available from the U.S. EPA Support Center for Regulatory Air Models (SCRAM). The SCRAM can be accessed at www.epa.gov/scram001/main.htm. All meteorological data sources should be approved by the District. Data not obtained directly from the District or the ARB should be checked for quality, representativeness, and completeness. It should be approved by the District before use. U.S. EPA provides guidance (U.S. EPA, 1995e) for these data. Meteorological data may need further processing. Data users can consult with the District or the ARB on how to process the raw meteorological data. The risk assessment should indicate if the District required the use of a specified meteorological data set. All memos indicating District approval of meteorological data should be attached in an appendix. If no representative meteorological data are available, screening procedures should be used as indicated in Section 4.10.

The analyst should acquire enough meteorological data to ensure that the worst-case meteorological conditions are represented in the model results. The US-EPA Guideline on Air Quality Models (U.S. EPA 2005) prefers that the latest five years of consecutive meteorological data be used to represent long term averages (i.e., cancer and chronic impacts). Previous OEHHA guidance allowed the use of the worst-case year to save

computer time. The processing speed of modern computers has increased to the point where processing five years of data over one year is no longer burdensome. However, the District may determine that one year of representative meteorological data is sufficient to adequately characterize the facility's impact. This may especially be the case when five years of quality consecutive data are not available.

To determine long term average concentrations the data can be averaged. For calculation of the one-hour maximum concentrations needed to evaluate acute effects, the worst-case year should be used in conjunction with the maximum hourly emission rate. For example, the long term average concentration and one-hour maximum concentration at a single receptor for five years of meteorological data are calculated below:

Year	Annual Average ($\mu g/m^3$)	Maximum One-Hour ($\mu g/m^3$)
1	7	100
2	5	80
3	9	90
4	8	110
5	6	90
5-year average	7	

In the above example, the long-term average concentration over five years is 7 $\mu g/m^3$. Therefore, 7 $\mu g/m^3$ should be used to evaluate carcinogenic and chronic effects (i.e., annual average concentration). The one-hour maximum concentration is the highest one-hour concentration in the five-year period. Therefore, 110 $\mu g/m^3$ is the peak one-hour concentration that should be used to evaluate acute effects.

The higher hourly concentration usually occurs when meteorological dispersion conditions become worse, such as, calm or light wind, inversion, etc. Inversion usually happens in late afternoon through early morning. As the sun goes down, the atmospheric temperature near surface starts to fall, usually faster than the temperature in the upper atmosphere causing a temperature inversion layer to form and extend downward. This inversion layer usually sustains throughout the night, and remains until early morning. Because of the inversion (cold air sitting on warm air at the top of the inversion layer), pollutant vertical mixing is very low in the morning.

When predicted concentrations are high and the mixing height is very low for the corresponding averaging period, the modeling results deserve additional consideration. For receptors in the near field, it is within the model formulation to accept a very low mixing height for short durations. However, it would be unlikely that the very low mixing height would persist long enough for the pollutants to travel into the far field. In the

event that the analyst identifies any of these time periods, they should be discussed with the District on a case-by-case basis.

4.8.1 *Meteorological Data Formats*

Most short-term dispersion models require input of hourly meteorological data in a format which depends on the model. U.S. EPA provides software for processing meteorological data for use in U.S. EPA recommended dispersion models. U.S. EPA recommended meteorological processors include the Meteorological Processor for Regulatory Models (MPRM), PCRAMMET, and AERMET. Use of these processors will ensure that the meteorological data used in an U.S. EPA recommended dispersion model will be processed in a manner consistent with the requirements of the model.

Meteorological data for a subset of NWS stations are available on the World Wide Web at the U.S. EPA SCRAM address, http://www.epa.gov/scram001.

4.8.2 *Treatment of Calms*

Calms are hours when the wind speed is below the starting threshold of the anemometer. Gaussian plume models require a wind speed and direction to estimate plume dispersion in the downwind direction.

U.S. EPA's policy is to disregard calms until such time as an appropriate analytical approach is available. The recommended U.S. EPA models contain a routine that eliminates the effect of the calms by nullifying concentrations during calm hours and recalculating short-term and annual average concentrations. Certain models lacking this built-in feature can have their output processed by U.S. EPA's CALMPRO program (U.S. EPA, 1984a) to achieve the same effect. Because the adjustments to the concentrations for calms are made by either the models or the postprocessor, actual measured on-site wind speeds should always be input to the preprocessor. These actual wind speeds should then be adjusted as appropriate under the current U.S. EPA guidance by the preprocessor.

Following the U.S. EPA methodology, measured on-site wind speeds of less than 1.0 m/s, but above the instrument threshold, should be set equal to 1.0 m/s by the preprocessor when used as input to Gaussian models. Calms are identified in the preprocessed data file by a wind speed of 1.0 m/s and a wind direction equal to the previous hour. For input to AERMOD, no adjustment should be made to the site specific wind data. AERMOD can produce model estimates for conditions when the wind speed may be less than 1 m/s but still greater than the instrument threshold. Some air districts provide pre-processed meteorological data for use in their district that treats calms differently. Local air districts should be consulted for available meteorological data. In addition, to reduce the number of calms and missing winds in the surface data, EPA has developed a pre-processor – AERMINUTE – to process 1-minute ASOS wind data for generating hourly average wind speed and directions for input to AERMET in Stage 2. The details can be found in the EPA's AERMINUTE User's Instructions at:

http://www.epa.gov/ttn/scram/models/aermod/aerminute_userguide_v11059_draft.pdf

If the fraction of calm hours is excessive, then an alternative approach may need to be considered to characterize dispersion. The Calpuff model modeling system can simulate calm winds as well as complex wind flow and therefore is a viable alternative. The local air district should be consulted for alternative approaches.

4.8.3 *Treatment of Missing Data*

Missing data refer to those hours for which no meteorological data are available from the primary on-site source for the variable in question. When missing values arise, they should be handled in one of the following ways listed below, in the following order of preference:

(1) If there are other on-site data, such as measurements at another height, they may be used when the primary data are missing. If the height differences are significant, corrections based on established vertical profiles should be made. Site-specific vertical profiles based on historical on-site data may also be appropriate to use if their determination is approved by the reviewing authority. If there is question as to the representativeness of the other on-site data, they should not be used.

(2) If there are only one or two missing hours, then linear interpolation of missing data may be acceptable, however, caution should be used when the missing hour(s) occur(s) during day/night transition periods.

(3) If representative off-site data exist, they may be used. In many cases this approach may be acceptable for cloud cover, ceiling height, mixing height, and temperature. This approach will rarely be acceptable for wind speed and direction. The representativeness of off-site data should be discussed and agreed upon in advance with the reviewing authority.

(4) An imputation methodology may be acceptable, provided it is well-documented, sufficiently justified, and properly applied.

(5) Failing any of the above, the data field should be coded as missing using missing data codes appropriate to the applicable meteorological pre-processor.

Appropriate model options for treating missing data, if available in the model, should be employed. Substitutions for missing data should only be made in order to complete the data set for modeling applications, and should not be used to attain the “regulatory completeness” requirement of 90%. That is, the meteorological data base must be 90% complete on a monthly basis (before substitution) in order to be acceptable for use in air dispersion modeling. The use of any data substitution technique should be thoroughly documented to provide the District or reviewing authority with all the information necessary to determine its approvability.

If the recommended methods for addressing missing meteorological data cannot be achieved as described, then alternative approaches should be discussed and developed in conjunction with the District or reviewing authority.

4.8.4 *Representativeness of Meteorological Data*

The atmospheric dispersion characteristics at an emission source need to be evaluated to determine if the collected meteorological data can be used to adequately represent atmospheric dispersion for the project.

Such determinations are required when the available meteorological data are acquired at a location other than that of the proposed source. In some instances, even though meteorological data are acquired at the location of the pollutant source, they still may not correctly characterize the important atmospheric dispersion conditions.

Considerations of representativeness are always made in atmospheric dispersion modeling whether the data base is "on-site" or "off-site." These considerations call for the judgment of a meteorologist or an equivalent professional with expertise in atmospheric dispersion modeling. If in doubt, the District should be consulted.

4.8.4.1 Spatial Dependence

The location where the meteorological data are acquired should be compared to the source location for similarity of terrain features. For example, in complex terrain, the following considerations should be addressed in consultation with the District:

- Aspect ratio of terrain, i.e., ratio of:
    - Height of valley walls to width of valley;
    - Height of ridge to length of ridge; and
    - Height of isolated hill to width of hill at its base
- Slope of terrain
- Ratio of terrain height to stack/plume height
- Distance of source from terrain (i.e., how close to valley wall, ridge, isolated hill)
- Correlation of terrain feature to prevailing meteorological conditions

Likewise, if the source is located on a plateau or plain, the source of meteorological data used should be from a similar plateau or plain.

Judgments of representativeness should be made only when sites are climatologically similar. Sites in nearby, but different air sheds, often exhibit different weather patterns. For instance, meteorological data acquired along a shoreline are not normally representative of inland sites and vice versa.

Meteorological data collected need to be examined to determine if drainage, transition, and synoptic flow patterns are characteristics of the source, especially those critical to the regulatory application. Consideration of orientation, temperature, and ground cover should be included in the review.

An important aspect of space dependence is height above the ground. Where practical, meteorological data should be acquired at the release height, as well as above or below, depending on the buoyancy of the source's emissions. AERMOD at a minimum requires wind observations at a height above ground between seven times the local surface roughness height and 100 meters.

4.8.4.2 Temporal Dependence

To be representative, meteorological data must be of sufficient duration to define the range of sequential atmospheric conditions anticipated at a site. As a minimum, one full year of on-site meteorological data is necessary to prescribe this time series. Multiple years of data are used to describe variations in annual and short-term impacts. Consecutive years from the most recent, readily available 5-year period are preferred to represent these yearly variations.

4.8.4.3 Further Considerations

It may be necessary to recognize the non-homogeneity of meteorological variables in the air mass in which pollutants disperse. This non-homogeneity may be essential in correctly describing the dispersion phenomena. Therefore, measurements of meteorological variables at multiple locations and heights may be required to correctly represent these meteorological fields. Such measurements are generally required in complex terrain or near large land-water body interfaces.

It is important to recognize that, although certain meteorological variables may be considered unrepresentative of another site (for instance, wind direction or wind speed), other variables may be representative (such as temperature, dew point, cloud cover). Exclusion of one variable does not necessarily exclude all. For instance, one can argue that weather observations made at different locations are likely to be similar if the observers at each location are within sight of one another - a stronger argument can be made for some types of observations (e.g., cloud cover) than others. Although by no means a sufficient condition, the fact that two observers can “see” one another supports a conclusion that they would observe similar weather conditions.

Other factors affecting representativeness include change in surface roughness, topography and atmospheric stability. Currently there are no established analytical or statistical techniques to determine representativeness of meteorological data. The establishment and maintenance of an on-site data collection program generally fulfills the requirement for “representative” data. If in doubt, the District should be consulted.

4.8.5 *Alternative Meteorological Data Sources*

It is necessary, in the consideration of most air pollution problems, to obtain data on site-specific atmospheric dispersion. Frequently, an on-site measurement program must be initiated. As discussed in Section 4.8.3, representative off-site data may be used to substitute for missing periods of on-site data. There are also situations where current or past meteorological records from a National Weather Service station may suffice. These considerations call for the judgment of a meteorologist or an equivalent professional with expertise in atmospheric dispersion modeling. More information on Weather Stations including: National Weather Service (NWS), military observations, supplementary airways reporting stations, upper air and private networks, is provided in "On-Site Meteorological Program Guidance for Regulatory Modeling Applications" (U.S. EPA, 1995e).

4.8.5.1 Recommendations

On-site meteorological data should be processed to provide input data in a format consistent with the particular models being used. The input format for U.S. EPA short-term regulatory models is defined in U.S. EPA's MPRM. The input format for AERMOD is defined in the AERMET meteorological pre-processor. Processors are available on the SCRAM web site. The actual wind speeds should be coded on the original input data set. Wind speeds less than 1.0 m/s but above the instrument threshold should be set equal to 1.0 m/s by the preprocessor when used as input to Gaussian models. Wind speeds below the instrument threshold of the cup or vane, whichever is greater, should be considered calm, and are identified in the preprocessed data file by a wind speed of 1.0 m/s and a wind direction equal to the previous hour. For input to AERMOD, no adjustment should be made to the site specific wind data. AERMOD can produce model estimates for conditions when the wind speed may be less than 1 m/s but still greater than the instrument threshold.

If data are missing from the primary source, they should be handled as follows, in order of preference: (1) substitution of other representative on-site data; (2) linear interpolation of one or two missing hours; (3) substitution of representative off-site data; (4) use of a well-documented and justified imputation methodology; or (5) coding as a missing data field, according to the discussions in Section 4.8.3. The use of any data substitution technique should be thoroughly documented to provide the District or reviewing authority with all the information necessary to determine its approvability.

If the data processing recommendations in this section cannot be achieved, then alternative approaches should be discussed and developed in conjunction with the District or reviewing authority.

4.8.6 *Quality Assurance and Control*

The purpose of quality assurance and maintenance is the generation of a representative amount (90% of hourly values for a year on a monthly basis) of valid data. For more information on data validation consult reference U.S. EPA (1995e). Maintenance may

be considered the physical activity necessary to keep the measurement system operating as it should. Quality assurance is the management effort to achieve the goal of valid data through plans of action and documentation of compliance with the plans.

Quality assurance (QA) will be most effective when following a QA Plan which has been signed-off by appropriate project or organizational authority. The QA Plan should contain the following information (paraphrased and particularized to meteorology from Lockhart):

1. Project description - how meteorology data are to be used
2. Project organization - how data validity is supported
3. QA objective - how QA will document validity claims
4. Calibration method and frequency - for data
5. Data flow - from samples to archived valid values
6. Validation and reporting methods - for data
7. Audits - performance and system
8. Preventive maintenance
9. Procedures to implement QA objectives - details
10. Management support - corrective action and reports

It is important for the person providing the quality assurance (QA) function to be independent of the organization responsible for the collection of the data and the maintenance of the measurement systems. Ideally, the QA auditor works for a separate company.

4.9 Model Selection

There are several air dispersion models that can be used to estimate pollutant concentrations and new ones are likely to be developed. U.S. EPA added AERMOD, which incorporates the PRIME downwash algorithm, to the list of preferred models in 2005 as a replacement to ISCST3. CalPuff was added in 2003. The latest version of the U.S. EPA recommended models can be found at the SCRAM Bulletin board located at http://www.epa.gov/scram001. However, any model, whether a U.S. EPA guideline model or otherwise, must be approved for use by the local air district. Recommended models and guidelines for using alternative models are presented in this section. All air dispersion models used to estimate pollutant concentrations for risk assessment analyses must be in the public domain. Classification according to terrain, source type and level of analysis is necessary before selecting a model (see Section 4.4). The selection of averaging times in the modeling analysis is based on the health effects of concern. Annual average concentrations are required for an analysis of carcinogenic or other chronic effects. One-hour maximum concentrations are required for analysis of acute effects.

4.9.1 *Recommended Models*

Recommended air dispersion models to estimate concentrations for risk assessment analyses are generally referenced in US EPA's Guideline on Air Quality Models

available at http://www.epa.gov/scram001. Currently AERMOD is recommended for most refined risk assessments in flat or complex terrain and in rural or urban environments[1]. In addition, CalPuff is available where spatial wind fields are highly variable or transport distances are large (e.g., 50 km). AERSCREEN is a screening model based on AERMOD. AERSCREEN can be used when representative meteorological data are unavailable. CTSCREEN is available for screening risk assessments in complex terrain. The most current version of the models should be used for risk assessment analysis. Some facilities may also require models capable of special circumstances such as dispersion near coastal areas. For more information on modeling special cases see Sections 4.12 and 4.13.

Most air dispersion models contain provisions that allow the user to select among alternative algorithms to calculate pollutant concentrations. Only some of these algorithms are approved for regulatory application such as the preparation of health risk assessments. The sections in this guideline that provide a description of each recommended model contain information on the specific switches and/or algorithms that must be selected for regulatory application.

To further facilitate the model selection, the District should be consulted for additional recommendations on the appropriate model(s) or a protocol submitted for District review and approval (see Section 4.14.1).

4.9.2 *Alternative Models*

Alternative models are acceptable if applicability is demonstrated or if they produce results identical or superior to those obtained using one of the preferred models referenced in Section 4.9.1. For more information on the applicability of alternative models refer to the following documents:

- U.S. EPA (2005). "Guideline on Air Quality Models" Section 3.2.2
- U.S. EPA (1992). "Protocol for Determining the Best Performing Model"
- U.S. EPA (1985a). "Interim Procedures for Evaluating Air Quality Models – Experience with Implementation"
- U.S. EPA (1984b). "Interim Procedures for Evaluating Air Quality Models (Revised)"

4.10 Screening Air Dispersion Models

A screening model may be used to provide a maximum concentration that is biased toward overestimation of public exposure. Use of screening models in place of refined modeling procedures is optional unless the District specifically requires the use of a refined model. Screening models are normally used when no representative meteorological data are available and may be used as a preliminary estimate to determine if a more detailed assessment is warranted.

[1] AERMOD was promulgated by U.S. EPA as a replacement to ISCST3 on November 9, 2006.

Some screening models provide only 1-hour average concentration estimates. Other averaging periods can be estimated based on the maximum 1-hour average concentration in consultation and approval of the responsible air district. Because of variations in local meteorology, the exact factor selected may vary from one district to another. Table 4.2 provides guidance on the range and typical values applied. The conversion factors are designed to bias predicted longer term averaging periods towards overestimation.

Table 4.2 Recommended Factors to Convert Maximum 1-hour Avg. Concentrations to Other Averaging Periods (U.S. EPA, 2011, 1995a; ARB, 1994).

Averaging Time	Range	Typical SCREEN3 Recommended	AERSCREEN Recommended
3 hours	0.8 - 1.0	0.9	1.0
8 hours	0.5 - 0.9	0.7	0.9
24 hours	0.2 - 0.6	0.4	0.6
30 days	0.2 - 0.3	0.3	
Annual	0.06 - 0.1	0.08	0.1

AERSCREEN automatically provides the converted concentration for longer than 1-hour averaging periods. For area sources, the AERSCREEN 3, 8, and 24-hour average concentration are equal to the 1-hour concentration. No annual average concentration is calculated. SCREEN3 values are shown for comparison purposes.

4.10.1 *AERSCREEN*

The AERSCREEN (U.S. EPA, 2011) model is now available and should be used in lieu of SCREEN3 with approval of the local District. AERSCREEN is a screening level air quality model based on AERMOD. AERSCREEN does not require the gathering of hourly meteorological data. Rather, AERSCREEN requires the use of the MAKEMET program which generates a site specific matrix of meteorological conditions for input to the AERMOD model. MAKEMET generates a matrix of meteorological conditions based on local surface characteristics, ambient temperatures, minimum wind speed, and anemometer height.

AERSCREEN is currently limited to modeling a single point, capped stack, horizontal stack, rectangular area, circular area, flare, or volume source. More than one source may be modeled by consolidating the emissions into one emission source.

4.10.2 *Valley Screening*

The Valley model is designed to simulate a specific worst-case condition in complex terrain, namely that of a plume impaction on terrain under stable atmospheric conditions. The algorithms of the VALLEY model are included in other models such as SCREEN3 and their use is recommended in place of the VALLEY model. The usefulness of the VALLEY model and its algorithms is limited to pollutants for which only long-term average concentrations are required. For more information on the Valley model consult the user's guide (Burt, 1977).

4.10.2.1 Regulatory Options

Regulatory application of the Valley model requires the setting of the following values during a model run:

- Class F Stability (rural) and Class E Stability (urban)
- Wind Speed = 2.5 m/s
- 6 hours of occurrence of a single wind direction (not exceeding a 22.5 deg sector)
- 2.6 stable plume rise factor

4.10.3 *CTSCREEN*

The CTSCREEN model (Perry et al., 1990) is the screening mode of the Complex Terrain Dispersion Model (CTDMPLUS). CTSCREEN can be used to model single point sources only. It may be used in a screening mode for multiple sources on a case by case basis in consultation with the District. CTSCREEN is designed to provide conservative, yet theoretically sounder, worst-case 1-hour concentration estimates for receptors located on terrain above stack height. Internally-coded time-scaling factors are applied to obtain other averages (see Table 4.3). These factors were developed by comparing the results of simulations between CTSCREEN and CTDMPLUS for a variety of scenarios and provide conservative estimates (Perry et al., 1990). CTSCREEN produces identical results as CTDMPLUS if the same meteorology is used in both models. CTSCREEN accounts for the three-dimensional nature of the plume and terrain interaction and requires detailed terrain data representative of the modeling domain. A summary of the input parameters required to run CTSCREEN is given in Table 4.4. The input parameters are provided in three separate text files. The terrain topography file (TERRAIN) and the receptor information file (RECEPTOR) may be generated with a preprocessor that is included in the CTSCREEN package. In order to generate the terrain topography file the analyst must have digitized contour information.

Table 4.3 Time-scaling factors internally coded in CTSCREEN

Averaging Period	Scaling Factor
3 hours	0.7
24 hour	0.15
Annual	0.03

Table 4.4 Input Parameters Required to Run CTSCREEN

Parameter	File
Miscellaneous program switches	CTDM.IN
Site Latitude and Longitude (degrees)	CTDM.IN
Site TIME ZONE	CTDM.IN
Meteorology Tower Coordinates (user units)	CTDM.IN
Source Coordinates: x and y (user units)	CTDM.IN
Source Base Elevation (user units)	CTDM.IN
Stack Height (m)	CTDM.IN
Stack Diameter (m)	CTDM.IN
Stack Gas Temperature (K)	CTDM.IN
Stack Gas Exit Velocity (m/s)	CTDM.IN
Emission Rate (g/s)	CTDM.IN
Surface Roughness for each Hill (m)	CTDM.IN
Meteorology: Wind Direction (optional)	CTDM.IN
Terrain Topography	TERRAIN
Receptor Information (coordinates and associated hill number)	RECEPTOR

4.11 Refined Air Dispersion Models

Refined air dispersion models are designed to provide more representative concentration estimates than screening models. In general, the algorithms of refined models are more robust and have the capability to account for site-specific meteorological conditions. For more information regarding general aspects of model selection see Section 4.9.

4.11.1 *AERMOD*

For a wide variety of applications in all types of terrain, the recommended model is AERMOD. AERMOD is a steady-state plume dispersion model for assessment of pollutant concentrations from a variety of sources. AERMOD simulates transport and dispersion from multiple point, area, or volume sources based on an up-to-date characterization of the atmospheric boundary layer. Sources may be located in rural or urban areas and receptors may be located in simple or complex terrain. AERMOD accounts for building wake effects (i.e., plume downwash) based on the PRIME building downwash algorithms. The model employs hourly sequential preprocessed meteorological data to estimate concentrations for averaging times from one hour to one year (also multiple years). AERMOD is designed to operate in concert with two pre-processor codes: AERMET processes meteorological data for input to AERMOD, and AERMAP processes terrain elevation data and generates receptor information for input to AERMOD. Guidance on input requirements may be found in the AERMOD Users Guide.

4.11.1.1 Regulatory Options

U.S. EPA regulatory application of AERMOD requires the selection of specific switches (i.e., algorithms) during a model run. All the regulatory options can be set by selecting the DFAULT keyword. The U.S. EPA regulatory options, automatically selected when the DFAULT keyword is used, are:

- Stack-tip downwash
- Incorporates the effects of elevated terrain
- Includes calms and missing data processing routines
- Does not allow for exponential decay for applications other than a 4-hour half life for SO_2

Additional information on these options is available in the AERMOD User's Guide.

4.11.1.2 Special Cases

a. Building Downwash:
AERMOD automatically determines if the plume is affected by the wake region of buildings when their dimensions are given. The specification of building dimensions does not necessarily mean that there will be downwash. See

Section 4.13.1 for guidance on how to determine when downwash is likely to occur.

b. Area Sources:
The area source algorithm in AERMOD estimates source emission strength by integrating an area upwind of the receptor location. Receptors may be placed within the area itself, downwind of the area or adjacent to the area. However, since the vertical distribution parameter (σ_z) goes to zero as the downwind distance goes to zero, the plume function solution is infinite for a downwind receptor distance of zero. In order to avoid such singularity in the plume function solution, the AERMOD model arbitrarily sets the plume function to zero when the receptor distance is less than one meter. As a result, the area source algorithm will not provide reliable solutions for receptors located within or adjacent to very small areas, with dimensions on the order of a few meters across. In these cases, the receptor should be placed at least one meter outside of the area.

c. Volume Sources:
The volume source algorithms in AERMOD require an estimate of the initial distribution of the emission source. The initial distribution of emissions for a volume source is in the horizontal and vertical directions. When modeling volume source emissions, one needs to provide initial horizontal (σ_{y0}) and vertical (σ_{z0}) dimensions as accurate as possible so that pollutant buoyancy and dispersion are also calculated accurately. US EPA's AERMOD User Guide provides suggested procedures to estimate these initial dimensions based on source type (Table 3-1) (U.S. EPA, 2004a).

d. Line Sources:
Examples of line sources include conveyor belts or roads. Depending on the source, these can be modeled three ways; as a line source, as a series of volume sources, or as an elongated area source. Where the emission source is neutrally buoyant, such as a conveyor belt, AERMOD can be used according to the user guide. In the event that the line source is a roadway, then additional considerations are required.

At the present time, CALINE (CALINE3, CAL3QHCR, and CALINE4) is the only model dedicated to modeling the enhanced mechanical and thermal turbulence created by motor vehicles traveling on a roadway. Of these, CAL3QHCR is the only model that accepts hourly meteorological data and can estimate annual average concentrations. However, CALINE uses the Pasquill-Gifford stability categories which are used in the ISCST model. AERMOD is now the preferred plume model over ISCST3 with continuous plume dispersion calculations based on observations but AERMOD does not include the enhanced roadway turbulence. Therefore, in the case where roadway emissions dominate the risk assessment, it may be most important to simulate the enhanced thermal and mechanical turbulence from motor vehicles with the CAL3QHCR model.

In the case where roadway emissions are a subset of all emissions for the risk assessment, including roadway emissions along with facility emissions, it may be best to use AERMOD for all emissions, roadway and facility, in order to maintain continuity with one dispersion model for the risk assessment. If AERMOD is used, it is important to consider that a major freeway may act similar to a large building which can cause some mixing and therefore initial vertical dispersion. This dispersion could be estimated with sensitivity studies based on wind speed, wind angle, roadway orientation, roadway width, and etc. This could be a complex estimation and needs very adept modeling skills. Roadway modeling should be evaluated on a case-by-case basis in consultation with the District or the reviewing authority.

Line sources inputs include a composite fleetwide emission factor, roadway geometry, hourly vehicle activity (i.e., diurnal vehicle per hour pattern), hourly meteorological data, and receptor placement. For practical information on how to simulate roadway emissions using these models, see CAPCOA's website at http://www.capcoa.org or the Sacramento Metropolitan AQMD (SMAQMD) website at http://www.airquality.org/ceqa/RoadwayProtocol.shtml. The SMAQMD has a document titled, "Recommended Protocol for Evaluating the Location of Sensitive Land Uses Adjacent to Major Roadways"(January, 2010).

e. Complex Terrain:
AERMOD uses the Dividing Streamline (Hc) concept for complex terrain. Above Hc, the plume is assumed to be "terrain following" in the convective boundary layer. Below Hc, the plume is assumed to be "terrain impacting" in the stable boundary layer. AERMOD computes the concentration at any receptor as a weighted function between the two plume states (U.S. EPA, 2004b).

f. Deposition:
AERMOD contains algorithms to model settling and deposition and requires additional information to do so including particle size distribution. For more information consult the AERMOD User's Guide (U.S. EPA, 2004a).

g. Diurnal Considerations:
Systematic diurnal changes in atmospheric conditions are expected along the coast (or any large body of water) or in substantially hilly terrain. The wind speed and direction are highly dependent on time of day as the sun rises and begins to heat the Earth. The sun heats the surface of the land faster than the water surface. Therefore the air above the land warms up sooner than over water. This creates a buoyant effect of warm air rising over land and the cool air from over water moves in to fill the void. Near large bodies of water (e.g., the ocean) this is known as a sea breeze. In complex terrain this is known as upslope flow as the hot air follows the terrain upwards. When the sun sets and the surface of the land begins to cool, the air above also cools and creates a draining effect. Near the water this is the land breeze; in complex terrain this is known as downslope or drainage flow. In addition, for the sea breeze, the atmospheric

conditions change rapidly from neutral or stable conditions over water to unstable conditions over land.

Near the large bodies of water the sea breeze is typical in the afternoon and the land breeze is typical for the early morning before sunrise. In complex terrain upslope flow is typical in the afternoon, while drainage flow is typical at night. Diurnal profiles need to be evaluated in conjunction with the facility emissions since sources can have varied emission profiles (e.g., some sources are continuously emitting while others are intermittent). These intermittent emission profiles may be influenced by diurnal patterns; therefore, they need to be evaluated to properly estimate potential exposures. For these reasons, it is especially important to simulate facility emissions with a hourly diurnal pattern reflective of source activity so that the risk assessment is representative of daily conditions.

h. 8-hour Modeling for the Offsite Worker's Exposure and Residential Exposure: If the ground level air concentrations from a facility operating 5 days a week, 8 hours per day have been estimated by a 24 hour per day annual average, an adjustment factor can be applied to estimate the air concentration that an offsite worker with the same schedule would be exposed to. The 24-hour annual average concentration is multiplied times 4.2.

If the meteorology during the time that the facility is emitting is used, hourly model simulations need to be post-processed to cull out the data needed for the offsite worker exposure. See Appendix M for information on how to calculate the refined offsite worker concentrations using the hourly raw results from the AERMOD air dispersion model. For more discussion on worker exposure, see Section 4.8.1.

Eight-hour exposure modeling can be used to evaluate the potential for health impacts (including effects of repeated exposures) in children and teachers exposed during school hours. Although not required in the HRA, 8-hour exposure modeling could also be performed at the discretion of the District to a residential scenario (i.e., the MEIR) where a facility operates only a portion of the day and exposure to residences are not adequately reflected by averaging concentrations over a 24 hour day.

4.11.1.3 HARP Dispersion Analysis

It is highly recommended that air dispersion analysis be performed using the HARP software. HARP can perform refined dispersion analysis by utilizing the U.S. EPA standard program AERMOD. In the future, the updated version of HARP will link the AERMOD outputs with risk assessment modules.

4.11.2 *CTDMPLUS*

CTDMPLUS is a Gaussian air quality model for use in all stability conditions in complex terrain. In comparison with other models, CTDMPLUS requires considerably more

detailed meteorological data and terrain information that must be supplied using specifically designed preprocessors. CTDMPLUS was designed to handle up to 40 point sources.

4.12 Modeling to Obtain Concentrations used for Various Health Impacts

The following section outlines how emissions and air dispersion modeling results are used or adjusted for a receptor that is exposed to either a non-continuous or continuously emitting source.

4.12.1 *Emission Rates for Cancer, Chronic, and Acute Health Impacts*

As discussed in Section 4.2.1.1, the HRA should include both annual average emissions and maximum 1-hour emissions for each pollutant emitted by the facility. Maximum 1-hour emissions are used for acute noncancer health impacts while annual emissions are used for chronic exposures (i.e., chronic and 8-hour noncancer health impacts or cancer risk assessment). When applying the emission rates in the air dispersion analysis, it is important not to artificially inflate or deplete the reported emission inventory.

For annual average emissions, the emissions are spread evenly over the entire year for continuous emitting sources. However, for sources where the emission patterns vary (i.e., non-continuous emitting sources), the emission rate should also account for the facility's emission schedule. If appropriate, the variable emissions rate option (e.g., hour-of-day) should be used in the air dispersion analysis. For more information consult the AERMOD User's Guide (U.S. EPA, 2004a). Also, when calculating emission rates for acute health impacts, it is important the emission rates never exceed the reported maximum 1-hour emissions.

4.12.2 *Modeling and Adjustments for Inhalation Cancer Risk at a Worksite*

Modeled long-term averages are typically used for cancer risk assessments for residents and workers. In an inhalation cancer risk assessment for an offsite worker, the long-term average should represent what the worker breathes during their work shift. However, the long-term averages calculated from AERMOD typically represent exposures for receptors that were present 24 hours a day and seven days per week (i.e., the schedule of a residential receptor). To estimate the offsite worker's concentration, there are two approaches. The more refined, complex, and time consuming approach is to post-process the hourly raw dispersion model output and examine the hourly concentrations that fall within the offsite worker's shift. See Appendix M for information on how to simulate the long-term concentration for the offsite worker that can be used to estimate inhalation cancer risk.

In lieu of post-processing the hourly dispersion model output, the more typical approach is to obtain the long-term average concentration as you would for modeling a residential receptor and approximate the worker's inhalation exposure using an adjustment factor. The actual adjustment factor that is used to adjust the concentration may differ from the example below based on the specifics of the source and worker receptor

(e.g., work-shift overlap). Once the worker's inhalation concentration is determined, the inhalation dose is calculated using additional exposure frequency and duration adjustments. See Chapter 5 for more information on the inhalation dose equation.

4.12.2.1 Non-Continuous Sources

When modeling a non-continuously emitting source (e.g., operating for eight hours per day and five days per week), the modeled long-term average concentrations are based on 24 hours a day and seven days per week for the period of the meteorological data set. Even though the emitting source is modeled using a non-continuous emissions schedule, the long-term concentration is still based on 24 hours a day and seven days per week. Thus, this concentration includes the zero hours when the source was not operating. For the offsite worker inhalation risk, we want to determine the long-term concentration the worker is breathing during their work shift. Therefore, the long-term concentration needs to be adjusted so it is based only on the hours when the worker is present. For example, assuming the emitting source and worker's schedules are the same, the adjustment factor is 4.2 = (24 hours per day/8 hours per shift)x(7 days in a week/5 days in a work week). In this example, the long term residential exposure is adjusted upward to represent the exposure to a worker. Additional concentration adjustments may be appropriate depending on the work shift overlap. These adjustments are discussed below.

The calculation of the adjustment factor from a non-continuous emitting source is summarized in the following steps.

a. Obtain the long-term concentrations from air dispersion modeling as is typical for residential receptors (all hours of a year for the entire period of the meteorological data set).

b. Determine the coincident hours per day and days per week between the source's emission schedule and the offsite worker's schedule.

c. Calculate the worker adjustment factor (WAF) using Equation 4.1. When assessing inhalation cancer health impacts, a discount factor (*DF*) may also be applied if the offsite worker's schedule partially overlaps with the source's emission schedule. The discount factor is based on the number of coincident hours per day and days per week between the source's emission schedule and the offsite worker's schedule (see Equation 4.2). The DF is always less than or equal to one.

Please note that worker adjustment factor does not apply if the source's emission schedule and the offsite worker's schedule do not overlap. Since the worker is not present during the time that the source is emitting, the worker is not exposed to the source's emission (i.e., the DF in Equation 4.2 becomes 0).

$$WAF = \frac{H_{residentid}}{H_{source}} \times \frac{D_{residentid}}{D_{source}} \times DF \qquad \text{Eq. 4.1}$$

Where:
WAF = the worker adjustment factor
$H_{residential}$= the number of hours per day the long-term residential concentration is based on (always 24 hours)
H_{source} = the number of hours the source operates per day
$D_{residential}$ = the number of days per week the long-term residential concentration is based on (always 7 days)
D_{source}= the number of days the source operates per week
DF = a discount factor for when the offsite worker's schedule partially overlaps the source's emission schedule. Use 1 if the offsite worker's schedule occurs within the source's emission schedule. If the offsite worker's schedule partially overlaps with the source's emission schedule, then calculate the discount factor using Equation 4.2 below.

$$DF = \frac{H_{coincident}}{H_{worker}} \times \frac{D_{coincident}}{D_{worker}} \qquad \text{Eq. 4.2}$$

Where:
DF = the discount factor for assessing cancer impacts
$H_{coincident}$ = the number of hours per day the offsite worker's schedule and the source's emission schedule overlap
$D_{coincident}$= the number of days per week the offsite worker's schedule and the source's emission schedule overlap
H_{worker} = the number of hours the offsite worker works per day
D_{worker}= the number of days the offsite worker works per week

d. The final step is to estimate the offsite worker's inhalation concentration by multiplying the worker adjustment factor with the long-term residential concentration. The worker's concentration is then plugged into the dose equation and risk calculation.

The HARP software has the ability to calculate worker impacts using an approximation factor and, in the future, it will have the ability to post-process refined worker concentrations using the hourly raw results from an air dispersion analysis.

4.12.2.2 Continuous Sources

If the source is continuously emitting, then the worker is assumed to breathe the long-term annual average concentration during their work shift. Equation 4.1 becomes one and no concentration adjustments are necessary in this situation when estimating the inhalation cancer risk. Note however, if an assessor does not wish to apply the assumption the worker breathes the long-term annual average concentration during the work shift, then a refined concentration can be post-processed as described in Appendix M. All alternative assumptions should be approved by the reviewing authority and supported in the presentation of results.

4.12.3 *Modeling and Adjustments for Noncancer 8-Hour RELs*

For 8-hour noncancer health impacts, we evaluate if the receptor (e.g., worker or resident) is exposed to an 8 hour average concentration, occurring daily, that exceeds the 8-hour REL. The 8 hour RELs were derived primarily for the offsite worker scenario. Although not required in an HRA, residential receptors can be evaluated with an 8-hour

REL at the discretion of the District or Reviewing authority. For ease, we use a worker receptor in this discussion and in the discussion below for a non-continuously emitting source. The daily average concentration is intended to represent the long-term average concentration the worker is breathing during the work shift. In general, there are two approaches for estimating the concentration used for the 8-hour hazard index. The more refined, complex, and time consuming approach is to post-process the hourly dispersion model output and use only the hourly concentrations that are coincident with the offsite worker hours to obtain the long-term concentration. See Appendix M for information on how to simulate the daily average concentration through air dispersion modeling.

Before proceeding through a refined analysis described in Appendix M, the assessor may wish to approximate the long-term concentration, as described below, and calculate the 8-hour hazard index. In lieu of post-processing the hourly dispersion model output described in Appendix M, the more typical approach is to obtain the long-term average concentration as you would for modeling a residential receptor and approximate the worker's inhalation concentration using an adjustment factor. The method for applying the adjustment factor is described in the section below.

The results from the 8-hour hazard index calculations should not be combined with the chronic or acute hazard indices. Each of the potential noncancer health impacts should be reported independently. See Chapter 8 for more discussion on calculating health impacts.

4.12.3.1 Non-Continuous Sources

When modeling a non-continuously emitting source (e.g., operating for eight hours per day and five days per week), the modeled long-term average concentrations are based on 24 hours a day and seven days per week for the period of the meteorological data set. Even though the emitting source is modeled using a non-continuous emissions schedule, the long-term concentration is still based on 24 hours a day and seven days per week. Thus, this concentration includes the zero hours when the source was not operating. For the offsite worker 8-hour hazard index, we want to determine the long-term average daily concentration the worker may be breathing during their work shift. This is similar to the cancer approximation adjustment method with one difference; there is no adjustment for partial overlap between the worker's schedule and the source's emission schedule. The reason for this difference in methodology is because the 8-hour REL health factors are designed for repeated 8-hour exposures and cannot readily be adjusted to other durations of exposure. The 8-hour RELs should be used for typical daily work shifts of 8-9 hours. For further questions, assessors should contact OEHHA, the District, or reviewing authority to determine if the 8-hour RELs should be used in your HRA. Any discussions or directions to exclude the 8-hour REL evaluation should be documented in the HRA.

When calculating the long-term average daily concentration for the 8-hour REL comparison, the long-term residential concentration needs to be adjusted so it is based only on the operating hours of the emitting source with the assumption the offsite

worker's shift falls within the emitting source's schedule. For example, assuming the emitting source operates 8 hours per day, 5 days per week and the offsite worker's schedules falls anywhere within this period of emissions, then the adjustment factor is 4.2 = (24 hours per day/8 hours of emissions per day)x(7 days in a week/5 days of emissions per week). In this example, the long term residential exposure is adjusted upward to represent the 8-hour exposure to a worker. No adjustments are applied for partial work shift overlap with the emitting source. If the source emits at night, then see Appendix N for additional recommendations.

Using the approximation factor is a screening method. If the 8-hour hazard index is above a threshold of concern with this method, the district or assessor should contact OEHHA for further guidance regarding the substance of concern. If necessary, further evaluation can be performed using the refined daily average modeling methodology discussed in Appendix M.

The calculation of the adjustment factor from a non-continuous emitting source is summarized in the following steps.

b. Obtain the long-term concentrations from air dispersion modeling as is typical for residential receptors (all hours of a year for the entire period of the meteorological data set).

c. Calculate the worker adjustment factor (WAF) using Equation 4.3. The source's emission schedule is assumed to overlap offsite worker's schedule. Note that the worker adjustment factor and the 8-hour inhalation REL do not apply if the source's emission schedule and the offsite worker's schedule do not overlap at some point.

$$WAF = \frac{H_{residentid}}{H_{source}} \times \frac{D_{residentid}}{D_{source}} \qquad \text{Eq. 4.3}$$

Where:

WAF = the worker adjustment factor
$H_{residential}$= the number of hours per day the long-term residential concentration is based on (always 24 hours)
H_{source} = the number of hours the source operates per day
$D_{residential}$ = the number of days per week the long-term residential concentration is based on (always 7 days).
D_{source}= the number of days the source operates per week.

d. The final step is to estimate the offsite worker's daily average inhalation concentration by multiplying the WAF with the long-term residential concentration. The worker's concentration is then used to calculate the 8-hour hazard index. This method using the approximation factor is a screening method. If the 8-hour hazard index is above a threshold of concern, the district or assessor should contact OEHHA for further guidance regarding the substance of concern.

In the future, the HARP software will have the ability to use 8-hour RELs, calculate worker impacts using an approximation factor, and to post-process worker concentrations using the hourly raw results from an air dispersion analysis.

4.12.3.2 Continuous Sources

If the source is continuously emitting, then the worker is assumed to breathe the long-term annual average concentration during their work shift and no concentration adjustments are made when estimating 8-hour health impacts. Note however, if an assessor does not wish to assume the worker breathes the long-term annual average concentration during the work shift, then a refined concentration can be post-processed as described in Appendix M. All alternative assumptions should be approved by the reviewing authority and supported in the presentation of results.

Note that 8-hour RELs are not typically used for continuously emitting sources for residential receptors. In this situation it is only necessary to estimate a chronic Hazard Index using the annual average concentrations and chronic RELs. However, there may be situations where the District may wish to assess an 8-hour Hazard Index, for example, where there are significant differences in modeled concentration of emissions during the day due to diurnal wind patterns.

4.12.4 *Modeling and Adjustment Factors for Noncancer Chronic RELs*

Potential chronic noncancer health impacts use the long-term annual average concentration regardless of the emitting facility's schedule. No adjustment factors should be used to adjust this concentration. Chronic RELs are used to assess not only residential health impacts, but in many cases worker health impacts as well. There are currently only a limited number of substances with an 8-hour inhalation REL, and a facility may emit only, or mostly, substances that currently have just a chronic REL. Until there are 8-hour RELs for all the Hot Spots substances emitted from a specified facility, we recommend determining the chronic HI for the MEIW to adequately protect the offsite worker.

The results from the chronic hazard index calculations are not combined with the 8-hour or acute hazard indices. All potential noncancer results should be reported independently. See Chapter 8 for more discussion on calculating health impacts.

4.12.5 *Modeling and Adjustments for Oral Cancer Potencies and Oral RELs*

When estimating the cancer risk or noncancer health impacts from noninhalation pathways, no adjustment is made to the long-term annual average concentration regardless of the emitting facility's schedule. Since the media (e.g., soil) at the receptor location where deposition takes place for noninhalation pathways is continuously present, the concentrations used for all noninhalation pathways are not adjusted (up or down) by an adjustment factor. However, some adjustments are made to the concentration once the pollutants reach the media, for example, pollutants undergo decay in soils. In addition, when the dose for each pathway is calculated, exposure adjustments may also be made. See Chapter 5 of this document and the Technical

Support Document for Exposure Assessment and Stochastic Analysis (OEHHA, 2012) to get more information on these types of adjustments. Oral cancer potencies and oral RELs are used to assess both residential or worker health impacts.

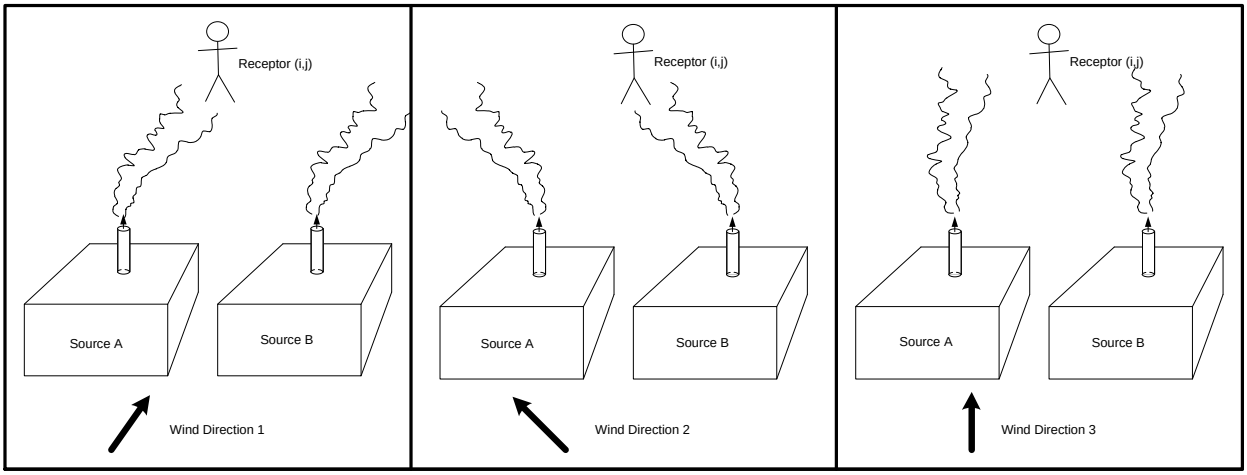
4.12.6 *Modeling One-Hour Concentrations using Simple and Refined Acute Calculations*

Modeled one-hour concentrations are needed for the acute health hazard index calculations. HARP has two methods to calculate this concentration: Simple and Refined. As an aid to understanding the differences between Simple and Refined, Figure 2 shows three possible conditions showing how wind direction may vary and impact a downwind receptor (i,j) differently from just two sources (A and B).

For the Simple calculation, HARP stores only the maximum one-hour concentration at each receptor (i,j) from each source (A and B) as the dispersion model marches down each hour of the simulation (e.g., one to five years of hourly data). At the end of the simulation period, HARP reports back only the maximum impacts at each receptor from each source regardless of which hour of the simulation period this occurred. For example, the Simple Maximum Acute Impacts would be the summation of Source A impacts from Wind Direction 1 and Source B impacts from Wind Direction 2 as shown in Figure 2.

For the Refined simulation, HARP stores each hourly concentration at each receptor (i,j) from each source. At the end of the simulation period, HARP evaluates the coincident impact at each receptor from all sources for each hour of the simulation period. In this case the maximum impacts will be identified by a particular hour of the period with associated wind speed, direction, and atmospheric conditions. For example, the Refined Maximum Acute impact from Sources A and B on receptor (i,j) could be from any wind direction (1,2, or 3) as shown in Figure 2. Since HARP stores all simulations for all sources – at all receptors – for all hours to calculate the refined impacts, there is great potential to fill large amounts of disk storage space. The Refined simulation provides a more representative picture of the maximum acute hazard index from a facility. The Simple calculation will provide an upper bound to the acute hazard index.

Figure 2 Acute Scenarios



4.13 Modeling Special Cases; Specialized Models

Special situations arise in modeling some sources that require considerable professional judgment; a few are outlined below. It is recommended that the reader consider retaining professional consultation services if the procedures are unfamiliar. The following sections, taken mostly from the document "On-Site Meteorological Program Guidance for Regulatory Modeling Applications" (U.S. EPA, 1995e), provide general information on data formats and representativeness. Some Districts may have slightly different recommendations from those given here.

4.13.1 *Building Downwash*

The entrainment of a plume in the wake of a building can result in the "downwash" of the plume to the ground. This effect can increase the maximum ground-level concentration downwind of the source. Therefore, stack sources must be evaluated to determine whether building downwash is a factor in the calculation of maximum ground-level concentrations.

The PRIME algorithm, included with AERMOD, has several advances in modeling building downwash effects including enhanced dispersion in the wake, reduced plume rise due to streamline deflection and increased turbulence, and continuous treatment of the near and far wakes (Schulman, 2000).

Complicated situations involving more than one building may necessitate the use of the Building Profile Input Program (BPIP) which can be used to generate the building dimension section of the input file of the ISC models (U.S. EPA, 1993). The BPIP program calculates each building's direction-specific projected width. The Building Profile Input Program for PRIME (BPIPPRM) is the same as BPIP but includes an algorithm for calculating downwash values for input into the PRIME algorithm which is contained in such models as AERMOD. The input structure of BPIPPRM is the same as that of BPIP.

4.13.2 *Deposition*

There are two types of deposition: wet deposition and dry deposition. Wet deposition is the incorporation of gases and particles into rain-, fog- or cloud water followed by a precipitation event and also rain scavenging of particles during a precipitation event. Wet deposition of gases is therefore more important for water soluble chemicals; particles (and hence particle-phase chemicals) are efficiently removed by precipitation events (Bidleman, 1988). Dry deposition refers to the removal of gases and particles from the atmosphere.

In the Air Toxics "Hot Spots" program, deposition is quantified for particle-bound pollutants and not gases. Wet deposition of water-soluble gas phase chemicals is thus not considered. When calculating pollutant mass deposited to surfaces without including depletion of pollutant mass from the plume, airborne concentrations remaining in the plume and deposition to surfaces can be overestimated, thereby resulting in overestimates of both the inhalation and multi-pathway risk estimates. However, neglecting deposition in the air dispersion model, while accounting for it in the multipathway health risk assessment, is a conservative, health protective approach (CAPCOA, 1987; Croes, 1988). Misapplication of plume depletion can also lead to possible underestimates of multi-pathway risk and for that reason no depletion is the default assumption. If plume depletion is incorporated, then some consideration for possible resuspension is warranted. An alternative modeling methodology accounting for plume depletion can be discussed with the Air District and used in an approved modeling protocol.

Although not generally used, several air dispersion models can provide downwind concentration estimates that take into account the upwind deposition of pollutants to surfaces and the consequential reduction of mass remaining in the plume. Air dispersion models having deposition and plume depletion algorithms require particle distribution data that are not always readily available. These variables include particle size, mass fraction, and density for input to AERMOD. In addition, the meteorological fields need to include additional parameters including relative humidity, precipitation, cloud cover, and surface pressure. Consequently, depletion of pollutant mass from the plume often is not taken into account.

In conclusion, multipathway risk assessment analyses normally incorporate deposition to surfaces in a screening mode, specifically by assigning a default deposition velocity of 2 cm/s for controlled sources and 5 cm/s for uncontrolled sources in lieu of actual measured size distributions (ARB, 1989). For particles (and particle-phase chemicals), the deposition velocity depends on particle size and is minimal for particles of diameter approximately 0.1-1 micrometer; smaller and larger particles are removed more rapidly.

4.13.3 *Short Duration Emissions*

Short-duration emissions (i.e., much less than an hour) require special consideration. In general, "puff models" provide a better characterization of the dispersion of pollutants having short-duration emissions. Continuous Gaussian plume models have traditionally

been used for averaging periods as short as about 10 minutes and are not recommended for modeling sources having shorter continuous emission duration.

4.13.4 *Fumigation*

Fumigation occurs when a plume that was originally emitted into a stable layer in the atmosphere is mixed rapidly to ground-level when unstable air below the plume reaches plume level. Fumigation can cause very high ground-level concentrations. Typical situations in which fumigation occurs are:

- Breaking up of a nocturnal radiation inversion by solar warming of the ground surface (rising warm unstable air); note that the break-up of a nocturnal radiation inversion is a short-lived event and should be modeled accordingly.

- Shoreline fumigation caused by advection of pollutants from a stable marine environment to an unstable inland environment

- Advection of pollutants from a stable rural environment to a turbulent urban environment

SCREEN3 incorporates concentrations due to inversion break-up and shoreline fumigation and is limited to maximum hourly evaluations. The Offshore and Coastal Dispersion Model incorporates overwater plume transport and dispersion as well as changes that occur as the plume crosses the shoreline – hourly meteorological data are needed from both offshore and onshore locations.

4.13.5 *Raincap on Stack*

The presence of a raincap or any obstacle at the top of the stack hinders the momentum of the exiting gas. The extent of the effect is a function of the distance from the stack exit to the obstruction and of the dimensions and shape of the obstruction.

On the conservative side, the stack could be modeled as having a non-zero, but negligible exiting velocity, effectively eliminating any momentum rise. Such an approach would result in final plume heights closer to the ground and therefore higher concentrations nearby. There are situations where such a procedure might lower the actual population-dose and a comparison with and without reduced exit velocity should be examined.

Plume buoyancy is not strongly reduced by the occurrence of a raincap. Therefore, if the plume rise is dominated by buoyancy, it is not necessary to adjust the stack conditions. (The air dispersion models determine plume rise by either buoyancy or momentum, whichever is greater.)

The stack conditions should be modified when the plume rise is dominated by momentum and in the presence of a raincap or a horizontal stack. Sensitivity studies with the SCREEN3 model, on a case-by-case basis, can be used to determine whether

plume rise is dominated by buoyancy or momentum. The District should be consulted before applying these procedures.

- Set exit velocity to 0.001 m/sec
- Turn stack tip downwash off
- Reduce stack height by 3 times the stack diameter

Stack tip downwash is a function of stack diameter, exit velocity, and wind speed. The maximum stack tip downwash is limited to three times the stack diameter in the AERMOD air dispersion model. In the event of a horizontal stack, stack tip downwash should be turned off and no stack height adjustments should be made. Note: This approach may not be valid for large (several meter) diameter stacks.

An alternative, more refined, approach could be considered for stack gas temperatures which are slightly above ambient (e.g., ten to twenty degrees Fahrenheit above ambient). In this approach, the buoyancy and the volume of the plume remain constant and the momentum is minimized.

- Turn stack tip downwash off
- Reduce stack height by 3 times the stack diameter ($3D_o$)
- Set the stack diameter (D_b) to a large value (e.g., 10 meters)
- Set the stack velocity to $V_b = V_o (D_o/D_b)^2$

Where V_o and D_o are the original stack velocity and diameter and V_b and D_b are the alternative stack velocity and diameter for constant buoyancy. This approach is advantageous when $D_b >> D_o$ and $V_b << V_o$ and should only be used with District approval.

In the presence of building downwash and in the event that PRIME downwash is being utilized in AERMOD, an alternative approach is recommended. PRIME algorithms use the stack diameter to define initial plume radius and to solve conservation laws. The user should input the actual stack diameter and exit temperature but set the exit velocity to a nominally low value (e.g., 0.001 m/s). Also since PRIME does not explicitly consider stack-tip downwash, no adjustments to stack height should be made.

Currently U.S. EPA is BETA testing options for capped and horizontal releases in AERMOD. It is expected that these options will replace the above guidance when BETA testing is complete.

4.13.6 *Landfill Sites*

Landfills should be modeled as area sources. The possibility of non-uniform emission rates throughout the landfill area should be investigated. A potential cause of non-uniform emission rates would be the existence of cracks or fissures in the landfill cap (where emissions may be much larger). If non-uniform emissions exist, the landfill should be modeled with several smaller areas assigning an appropriate emission factor to each one of them, especially if there are nearby receptors (distances on the same order as the dimensions of the landfill).

4.14 Specialized Models

Some models have been developed for application to very specific conditions. Examples include models capable of simulating sources where both land and water surfaces affect the dispersion of pollutants and models designed to simulate emissions from specific industries.

4.14.1 *Buoyant Line and Point Source Dispersion Model (BLP)*

BLP is a Gaussian plume dispersion model designed for the unique modeling problems associated with aluminum reduction plants, and other industrial sources where plume rise and downwash effects from stationary line sources are important.

4.14.1.1 Regulatory Application

Regulatory application of BLP model requires the selection of the following options:

- rural (IRU=l) mixing height option;
- default (no selection) for all of the following: plume rise wind shear (LSHEAR), transitional point source plume rise (LTRANS), vertical potential temperature gradient (DTHTA), vertical wind speed power law profile exponents (PEXP), maximum variation in number of stability classes per hour (IDELS), pollutant decay (DECFAC), the constant in Briggs' stable plume rise equation (CONST2), constant in Briggs' neutral plume rise equation (CONST3), convergence criterion for the line source calculations (CRIT), and maximum iterations allowed for line source calculations (MAXIT); and
- terrain option (TERAN) set equal to 0.0, 0.0, 0.0, 0.0, 0.0, 0.0.

For more information on the BLP model consult the user's guide (Schulman and Scire, 1980).

4.14.2 *Offshore and Coastal Dispersion Model (OCD)*

OCD (DiCristofaro and Hanna, 1989) is a straight-line Gaussian model developed to determine the impact of offshore emissions from point, area or line sources on the air quality of coastal regions. OCD incorporates "over-water" plume transport and dispersion as well as changes that occur as the plume crosses the shoreline. Hourly meteorological data are needed from both offshore and onshore locations. Additional data needed for OCD are water surface temperature, over-water air temperature, mixing height, and relative humidity.

Some of the key features include platform building downwash, partial plume penetration into elevated inversions, direct use of turbulence intensities for plume dispersion, interaction with the overland internal boundary layer, and continuous shoreline fumigation.

4.14.2.1 Regulatory Application

OCD has been recommended for use by the Minerals Management Service for emissions located on the Outer Continental Shelf (50 FR 12248; 28 March 1985). OCD is applicable for over-water sources where onshore receptors are below the lowest source height. Where onshore receptors are above the lowest source height, offshore plume transport and dispersion may be modeled on a case-by-case basis in consultation with the District.

4.14.3 *Shoreline Dispersion Model (SDM)*

SDM (PEI, 1988) is a hybrid multipoint Gaussian dispersion model that calculates source impact for those hours during the year when fumigation events are expected using a special fumigation algorithm and the MPTER regulatory model for the remaining hours.

SDM may be used on a case-by-case basis for the following applications:

- tall stationary point sources located at a shoreline of any large body of water;
- rural or urban areas;
- flat terrain;
- transport distances less than 50 km;
- 1-hour to 1-year averaging times.

4.15 Interaction with the District

The risk assessor must contact the District to determine if there are any specific requirements. Examples of such requirements may include, but are not limited to: specific receptor location guidance, specific usage of meteorological data, and specific report format (input and output). See Chapter 9 for more information on the format and content of modeling protocols and HRAs.

4.15.1 *Submittal of Modeling Protocol*

It is strongly recommended that a modeling protocol be submitted to the District for review and approval prior to extensive analysis with an air dispersion model. The modeling protocol is a plan of the steps to be taken during the air dispersion modeling process. Following is an example of the format that may be followed in the preparation of the modeling protocol. **Consult with the District to confirm format and content requirements or to determine the availability of District modeling guidelines before submitting the protocol.**

Outline for a Modeling Protocol

I. Introduction

Include the facility name, address, and a brief overview describing the facility's operations.

- Provide a description of the terrain and topography surrounding the facility and potential receptors.

- Indicate the format in which data will be provided. Ideally, the report and summary of data will be on paper and all data and model input and output files will be provided electronically (e.g., compact disk or CD).

- Identify the guidelines used to prepare the protocol (e.g., District Guidelines).

II. Emissions

For each pollutant and process whose emissions are required to be quantified in the HRA, list the annual average emissions (pounds/year and grams/second) and the maximum one-hour emissions (pounds/hour and grams/second)[2]. Maximum 1-hour emissions are used for acute noncancer health impacts while annual emissions are used for chronic exposures (i.e., chronic and 8-hour noncancer health impacts or cancer risk assessment).

- Identify the reference and method(s) used to determine emissions (e.g., source tests, emission factors, etc.). Clearly indicate any emission data that are not reflected in the previously submitted emission inventory report. In this event, a revised emission inventory report will need to be submitted to the District.

- Identify if this will be a multipathway assessment based on emitted substances.

III. Models / Modeling Assumptions

Specify the model and modeling assumptions

- Identify the model(s) to be used, including the version number.

- Identify the model options that will be used in the analysis.

---

[2] Except radionuclides, for which annual and hourly emissions are reported in Curies/year and millicuries/hour, respectively.

- Identify the modeling domain(s) and the spacing of receptor grid(s). Grid spacing should be sufficient in number and detail to capture the concentration at all of the receptors of interest.

- Indicate complex terrain options that may be used, if applicable.

- Identify the source type(s) that will be used to represent the facility's operations (e.g., point, area, or volume sources, flare options or other).

- Indicate the preliminary source characteristics (e.g., stack height, gas temperature, exit velocity, dimensions of volume source, etc.).

- Identify and support the use of urban or rural dispersion coefficients for those models that require dispersion coefficients. For other models, identify and support the parameters required to characterize the atmospheric dispersion due to land characteristics (e.g., surface roughness, Monin-Obukhov length).

IV. Meteorological Data

Specify the type, source, and year(s) of hourly meteorological data (e.g., hourly surface data, upper air mixing height information).

- State how the data are representative for the facility site.

- Describe QA/QC procedures.

- Identify any gaps in the data; if gaps exist, describe how the data gaps are filled.

V. Deposition

- Specify the method to calculate deposition (if applicable).

VI. Receptors

Specify the type and location of receptors. Include all relevant information describing how the individual and population-related receptors will be evaluated.

- Identify and describe the location(s) of known or anticipated potential sensitive receptors, the point of maximum impact (PMI), and the maximum exposed individual residential (MEIR) and worker (MEIW) receptors. Identify any special considerations or grids that will be used to model these receptors. This information should correspond with information provided in Section III (e.g., fine receptor spacing of 20 meters at the fence line and centered on the maximum impacts; coarse receptor spacing of 100 meters out to 2,000 meters; extra coarse spacing of 1,000 meters out to 20,000 meters).

- Identify if spatial averaging will be used. Include necessary background information on each receptor including how the domain and spacing will be determined for each receptor or exposure pathway.

- Describe how the cancer burden or population impact estimates are calculated. Clarify the same information for the presentation of noncancer population impacts (e.g., centroids of the census tracts in the area within the zone of impact).

- Specify that actual UTM coordinates and the block/street locations (i.e., north side of 3,000 block of Smith Street), where possible, will be provided for specified receptor locations.

- Identify and support the use of any exposure adjustments (e.g., time a location, diurnal).

- Include the list of anticipated exposure pathways that will be included and indicate which substance will be evaluated in the multipathway assessment. Identify if sensitive receptors are present and which receptors will be evaluated in the HRA.

VII. Maps

Identify how the information will be graphically presented.

- Indicate which cancer risk isopleths will be plotted for the cancer zone of impact (e.g., 10^{-7}, 10^{-6} see Section 4.6.1).

- Indicate the hazard quotients or hazard indices to be plotted for the noncancer acute, 8 hour, and chronic zones of impact (e.g., 0.5, 1.0, etc.).

4.16 Health Risk Assessment Report

This section describes the information related to the air dispersion modeling process that needs to be reported in the risk assessment. This section is also presented in Chapter 9, Summary of the Requirements for a Modeling Protocol and a Health Risk Assessment Report, in Section 9.2. The District may have specific requirements regarding format and content (see Section 4.15). Sample calculations should be provided at each step to indicate how reported emissions data were used. Reviewing agencies must receive input, output, and supporting files of various model analyses on computer-readable media (e.g., CD).

4.16.1 *Information on the Facility and its Surroundings*

Report the following information regarding the facility and its surroundings:

- Facility Name

- Location (UTM coordinates and street address)
- Land use type (see Section 2.4)
- Local topography
- Facility plot plan identifying:
  - source locations
  - property line
  - horizontal scale
  - building heights
  - emission sources

4.16.2 *Source and Emission Inventory Information*[3]

4.16.2.1 Release Parameters

Report the following information for each release location in table format:

- Release location identification number
- Release name
- Release type (e.g., point, volume, area, line, pit, etc.)
- Source identification number(s) used by the facility that emit out of this release location
- Release location using UTM coordinates
- Release parameters by release type (e.g., shown for point source):
  - Stack height (m), stack diameter (building dimensions for downwash), exhaust gas exit velocity (m/s), exhaust gas volumetric flow rate (ACFM), exhaust gas exit temperature (K), etc.

4.16.2.2 Source Description and Operating Schedule

The description and operating schedule for each source should be reported in table form including the following information:

- Source identification number used by the facility
- Source name
- Number of operating hours per day and per year (e.g., 0800-1700, 2700 hr/yr)
- Number of operating days per week (e.g., Mon-Sat)
- Number of operating days or weeks per year (e.g., 52 wk/yr excluding major holidays)
- Release point identification number(s) for where source emissions are released

[3] Health and Safety Code section 44346 authorizes facility operators to designate certain "Hot Spots" information as trade secret. Section 44361(a) requires districts to make health risk assessments available for public review upon request. Section 44346 specifies procedures to be followed upon receipt of a request for the release of trade secret information. See also the Inventory Guidelines Report regarding the designation of trade secret information in the Inventory Reports.

- Fraction of source emissions emitted at each release point by release point ID number

4.16.2.3 Emission Control Equipment and Efficiency

Report emission control equipment and efficiency by source and by substance

4.16.2.4 Emissions Data Grouped By Source

Report emission rates for each toxic substance, grouped by source (i.e., emitting device or process identified in Inventory Report), in table form including the following information:

- Source name
- Source identification number
- Substance name and CAS number (from Inventory Guidelines)
- Annual average emissions for each substance (lb/yr)
- Hourly maximum emissions for each substance (lb/hr)

4.16.2.5 Emissions Data Grouped by Substance

Report facility total emission rate by substance for all emitted substances listed in the Air Toxics “Hot Spots” Program including the following information:

- Substance name and CAS number (from Inventory Guidelines)
- Annual average emissions for each substance (lb/yr)
- Hourly maximum emissions for each substance (lb/hr)

4.16.2.6 Emission Estimation Methods

Report the methods used in obtaining the emissions data indicating whether emissions were measured or estimated. Clearly indicate any emission data that are not reflected in the previously submitted emission inventory report and submit a revised emission inventory report to the district. A reader should be able to reproduce the risk assessment without the need for clarification.

4.16.2.7 List of Substances

Include tables listing all "Hot Spots" Program substances which are emitted, plus any other substances required by the District. Indicate substances to be evaluated for cancer risks and noncancer health impacts.

4.16.3 *Exposed Population and Receptor Location*

Report the following information regarding exposed population and receptor locations. See Chapter 9 and specific sections within this chapter for more detailed information.

- Description of zone of impact including map showing the location of the facility, boundaries of zone of impact, census tracts, emission sources, sites of maximum exposure, and the location of all appropriate receptors. This should be a true map (one that shows roads, structures, etc.), drawn to scale, and not just a schematic drawing. USGS 7.5 minute maps or GIS based maps are usually the most appropriate choices. (If significant development has occurred since the user's survey, this should be indicated.)
- Separate maps for the cancer risk zone of impact and the hazard index (noncancer) zone of impact(s). The cancer zone of impact should include isopleths down to at least the 1/1,000,000 risk level. Because some districts use a level below 1/1,000,000 to define the zone of impact, the District should be consulted. Three separate maps (to represent both chronic, 8-hour, and acute HI) should be created to define the zone of impact for the hazard index from both inhalation and noninhalation pathways greater than or equal to 0.5. The point of maximum impact (PMI), maximum exposed individual at a residential receptor (MEIR), the maximum exposed individual worker (MEIW), and any other locations of interest for both cancer and noncancer risks should be located on the maps.
- Tables identifying population units and sensitive receptors (UTM coordinates, receptor IDs, and street addresses of specified receptors).
- Heights or elevations of the receptor points.
- For each receptor type (e.g., PMI, MEIR, MEIW, and any other location(s) of interest) that will utilize spatial averaging, the domain size and grid resolution must be clearly identified. If another domain or grid resolution other than 20 meters by 20 meters with 5-meter grid spacing will be used for a receptor, then care should be taken to determine the proper domain size and grid resolution that should be used. For a worker, the HRA shall support all assumptions used, including, but not limited to, documentation for all workers showing the area where each worker routinely performs their duties. The final domain size should not be greater than the smallest area of worker movement. Other considerations for determining domain size and grid spacing resolution may include an evaluation of the concentration gradients across the worker area. The grid spacing used within the domain should be sufficient in number and detail to obtain a representative concentration across the area of interest. When spatial averaging over the deposition area of a pasture, garden, or water body, care should be taken to determine the proper domain size to make sure it includes all reasonable areas of potential deposition. The size and shape of the pasture, garden, or water body of interest should be identified and used for the modeling domain. The grid spacing or resolution used within the domain should be sufficient in detail to obtain a representative deposition concentration across the area of interest. One way to determine the grid resolution is to include an evaluation of the concentration gradients across the deposition area. The HRA shall support all assumptions used, including, but not limited to, documentation of the deposition area (e.g., size and shape of the pasture or water body, maps,

representative coordinates, grid resolution, concentration gradients, etc.). The use or spatial averaging is subject to approval by the reviewing authority. This includes the size of the domain and grid resolution that is used for spatial averaging of a worksite or multipathway deposition area.

4.16.4 *Meteorological Data*

If meteorological data were not obtained directly from the District, then the report must clearly indicate the data source and time period used. Meteorological data not obtained from the District must be submitted in electronic form along with justification for their use including information regarding representativeness and quality assurance.

The risk assessment should indicate if the District required the use of a specified meteorological data set. All memos indicating the District's approval of meteorological data should be attached in an appendix.

4.16.5 *Model Selection and Modeling Rationale*

The report should include an explanation of the model chosen to perform the analysis and any other decisions made during the modeling process. The report should clearly indicate the name of the models that were used, the level of detail (screening or refined analysis) and the rationale behind the selection.

Also report the following information for each air dispersion model used:

- version number
- selected options and parameters in table form
- Identify the modeling domain(s) and the spacing of receptor grid(s). Grid spacing should be sufficient in number and detail to capture the concentration at all receptors of interest.

4.16.6 *Air Dispersion Modeling Results*

- Maximum hourly and annual average concentrations of chemicals at appropriate receptors such as the residential and worker MEI receptors
- Annual average and maximum one-hour (and 30-day average for lead only) concentrations of chemicals at appropriate receptors listed and referenced to computer printouts of model outputs
- Model printouts (numbered), annual concentrations, maximum hourly concentrations
- Disk with input/output files for air dispersion program (e.g., the AERMOD input file containing the regulatory options and emission parameters, receptor locations, meteorology, etc.)
- Include tables that summarize the annual average concentrations that are calculated for all the substances at each site. The use of tables that present the relative contribution of each emission point to the receptor concentration is recommended. (These tables should have clear reference to the computer

model which generated the data. It should be made clear to any reader how data from the computer output were transferred to these tables.) [As an alternative, the above two tables could contain just the values for sites of maximum impact (i.e., PMI, MEIR and MEIW), and sensitive receptors, if required. All the values would be found in the Appendices.]

5 - Exposure Assessment
Estimation of Concentration and Dose

5.1 Introduction

This chapter provides a summary of how toxicant ground level air concentrations estimated from air dispersion modeling or monitoring results are used to determine dose at receptors of interest. This chapter includes all the algorithms and data (e.g., point estimates, distributions, and transfer factors) that are needed to determine the substance-specific concentration in exposure media and the dose at a receptor of interest. The determination of exposure concentration and dose precedes the calculations of potential health impacts. See Chapter 8 and Appendix I for information on calculating potential health impacts.

At a minimum, three receptors are evaluated in Hot Spots health risk assessments (HRA) (see Section 4.7); these are:

- the Point of Maximum Impact (PMI),
- the Maximally Exposed Individual Resident (MEIR), and
- the Maximally Exposed Individual Worker (MEIW).

The PMI is defined as the receptor point(s) with the highest acute, 8-hour, chronic, or cancer health impact outside the facility boundary. The facility boundary is defined as the property line. Often the fence is on the property line. The MEIR is typically defined as the existing off-site residence(s) (i.e., house, apartment or other dwelling) with the highest acute, chronic, or cancer health impact. Calculating an 8-hour hazard index is not required for the MEIR, but can be performed at the discretion of the District. The MEIW is typically defined as the existing offsite workplace with the highest acute, 8-hour, chronic, or cancer health impact.

In addition, it may be necessary to determine risks at sensitive receptors (e.g., schools, day care centers, elder care centers, and hospitals). The District or reviewing authority should be consulted in order to determine the appropriate sensitive receptors for evaluation. Some situations may require that on-site receptor (worker or residential) locations be evaluated. Some examples where the health impacts of on-site receptors may be appropriate could be military base housing, prisons, universities, or locations where the public may have regular access for the appropriate exposure period (e.g., a lunch time café or museum for acute exposures). The risk assessor should contact the Air Pollution Control or Air Quality Management District (the District) for guidance about any on-site exposure situations at the emitting facility. These on-site locations should be included in the health risk assessment (HRA). If the facility emits multiple substances from two or more stacks, the acute, 8-hour, chronic, and cancer health impacts at the PMI may be located at different physical locations. The MEIR or MEIW cancer, acute, 8-hour, and chronic receptors may also be at different locations.

The process for determining dose at the receptor location, and ultimately potential health impacts, will likely include air dispersion modeling, and, with less frequency, air monitoring data. Air dispersion modeling combines the facility emissions and release parameters and uses default or site-specific meteorological conditions to estimate downwind, ground-level concentrations at various (user-defined) receptor locations. Air dispersion modeling is described in Chapter 4 and is presented in detail in the *Air Toxics Hot Spots Program Risk Assessment Guidelines; Technical Support Document for Exposure Assessment and Stochastic Analysis (OEHHA, 2012a*).

In summary, the process of using air dispersion modeling results as the basis of an HRA follows these four steps:

- Air dispersion modeling is used to estimate annual average and maximum one-hour ground level concentrations (GLC). The air dispersion modeling results are expressed as an air concentration or in terms of (Chi over Q) for each receptor point. (Chi over Q) is the modeled downwind air concentration (Chi) based on an emission rate of one gram per second (Q). (Chi over Q) is expressed in units of micrograms per cubic meter per gram per second, or ($\mu g/m^3$)/(g/s). (Chi over Q) is sometimes written as (χ/Q) and is sometimes referred to as the dilution factor.

- When multiple substances are evaluated, the χ/Q is normally utilized since it is based on an emission rate of one gram per second. The χ/Q at the receptor point of interest is multiplied by the substance-specific emission rate (in g/s) to yield the substance-specific ground-level concentration (GLC) in units of $\mu g/m^3$. The following equations illustrate this point.

$$\mathbf{GLC} = \left(\frac{\chi}{\mathbf{Q}}\right) \mathbf{x} \left(\mathbf{Q}_{\mathbf{substance}}\right)$$

$$\frac{\chi}{\mathbf{Q}} = \mathbf{(Chi\ \ over\ \ Q)\ in} \left(\frac{\frac{\mu \mathbf{g}}{\mathbf{m}^3}}{\frac{\mathbf{g}}{\mathbf{s}}} \right), \mathbf{\ from\ model\ results\ with\ unit\ emission\ rate}$$

$$\mathbf{Q}_{\mathbf{substance}} = \mathbf{\ substance\ specific\ emission\ rate} \left(\frac{\mathbf{g}}{\mathbf{s}}\right)$$

- The applicable exposure pathways (e.g., inhalation, soil contact, fish consumption) are identified for the emitted substances, and the receptor locations are identified. This determines which exposure algorithms in this chapter are ultimately used to estimate dose. After the exposure pathways are identified, the fate and transport algorithms described in this chapter are used to estimate concentrations in the applicable exposure media (e.g., soil or water) and the exposure algorithms are used to determine the substance-specific dose.

- The dose is used with cancer and noncancer health values to calculate the potential health impacts for the receptor (Chapter 8). An example calculation

using the high-end point-estimates for the inhalation (breathing) exposure pathway can be found in Appendix I. Appendix I and Chapters 5 (this Section) and 8 also contain information on how the annual average and maximum one-hour ground level concentrations are used for chronic, 8-hour, and acute health risk calculations.

The algorithms in this chapter are also used to calculate media concentrations and dose in the rare instance, for the Hot Spots program, when monitoring equipment was used rather than air dispersion modeling to obtain a receptor's substance-specific GLC. One situation that is specific to monitored data is the treatment of results below the sampling method level of detection (LOD). In short, it is standard risk assessment practice when monitoring results are reported both above and below the LOD to use one-half of the LOD for those sample concentrations reported below the LOD. If all testing or monitoring results fall below the LOD, then assessors should contact the District for appropriate procedures. For more information about reporting emissions under the Hot Spots Program, see the ARB's *Emission Inventory Criteria and Guidelines Regulations (Title 17, California Code of Regulations, Sections 93300-93300.5),* and the *Emission Inventory Criteria and Guidelines Report* (EICG Report), which is incorporated by reference therein (ARB, 2007*)*.

The recommended model for calculating and presenting HRA results for the Hot Spots Program is the HARP software, available from the Air Resources Board (ARB). More information on HARP and directions for downloading the software can be found on the ARB's web site at http://www.arb.ca.gov/toxics/harp/downloads.htm.

5.2 Criteria for Exposure Pathway Evaluation

In order to determine total dose to the receptor the applicable pathways of exposure need to be identified. The inhalation pathway must be evaluated for all Hot Spots substances emitted by the facility. A small subset of Hot Spots substances is subject to deposition onto soil, plants, and water bodies. These substances need to be evaluated by the appropriate noninhalation pathways, as well as by the inhalation pathway, and the results must be presented in all HRAs. These substances include semi-volatile organic chemicals and heavy metals. Such substances are referred to as multipathway substances. Two steps are necessary to determine if a substance should be evaluated for multipathway impacts:

1. Determine whether the substance or its group (e.g., dioxins, PAHs) is listed in Table 5.1.
2. Determine if the substance has an oral reference exposure level (REL) listed in Table 6.4, or if it has an oral cancer slope factor listed in Table 7.1. Two other references for checking the presence of oral health factors are OEHHA's website (OEHHA, 2012b) and the *Consolidated Table of OEHHA/ARB Approved Risk Assessment Health Values* on the Air Resources Board website (ARB, 2012). Oral or noninhalation exposure pathways include the ingestion of soil, angler-caught fish, drinking water from surface water sources, mother's milk,

homegrown produce, beef, pork, chicken, eggs and cow's milk. The dermal pathway is also evaluated via contact with contaminated soil.

For all multipathway substances, the minimum exposure pathways that must be evaluated at every residential site (in addition to inhalation) are soil ingestion and dermal exposure. If dioxins, furans, PCBs, PAHs or lead are emitted, then the breast-milk consumption pathway also becomes mandatory. The other exposure pathways (e.g., the ingestion of homegrown produce or angler-caught fish) are evaluated on a site-by-site basis. If the resident can be exposed through an impacted exposure pathway, then it must be included in the HRA. However, if there are no vegetable gardens or fruit trees within the zone of impact for a facility, for example, then the produce pathways need not be evaluated. Note that on-site residential receptors are potentially subject to inhalation and noninhalation exposure pathways. Table 8.2 identifies the residential and worker receptor exposure pathways that are mandatory and those that are dependent on the site-specific decisions. While residents can be exposed though several exposure pathways, worker receptors are only evaluated for inhalation, soil ingestion, and dermal exposure using point estimates.

Table 5.1 shows the multipathway substances that, based on available scientific data, can be considered for each noninhalation exposure pathway. The exposure pathways that are evaluated for a substance depend on two factors: 1) whether the substance is considered a multipathway substance for the Hot Spots Program (Table 5.1), and 2) what the site-specific conditions are. A multipathway substance may be excluded from a particular exposure pathway because its physical-chemical properties can preclude significant exposure via the pathway. For example, some water-soluble substances do not appreciably bioaccumulate in fish; therefore, the fish pathway is not appropriate. In addition, if a particular exposure pathway is not impacted by the facility or is not present at the receptor site, then the pathway is not evaluated. For example, if a fishable water body is not impacted by the facility, or the water source is impacted but no receptor uses it for fishing, then the angler-caught fish pathway is not evaluated.

Table 5.1 Specific Pathways to be Analyzed for Each Multipathway Substance

Substance	Soil Ingestion	Dermal	Meat, Milk & Egg Ingestion	Fish Ingestion	Exposed Vegetable Ingestion	Leafy Vegetable Ingestion	Protected Vegetable Ingestion	Root Vegetable Ingestion	Water Ingestion	Breast Milk Ingestion
Inorganic chemicals										
Arsenic & compounds	X	X	X	X	X	X	X	X	X	
Beryllium & compounds	X	X	X	X	X	X	X	X	X	
Cadmium & compounds	X	X	X	X	X	X	X	X	X	
Chromium VI & compounds	X	X	X[a]	X	X	X	X	X	X	
Fluorides (soluble compounds)	X	X	X		X	X	X	X	X	
Lead & compounds	X	X	X	X	X	X	X	X	X	X
Mercury & compounds	X	X	X	X	X	X	X	X	X	
Nickel & compounds	X	X	X	X	X	X	X	X	X	
Selenium & compounds	X	X	X	X	X	X	X	X	X	
Organic chemicals										
Creosotes	X	X	X	X	X	X			X	X
Diethylhexylphthalate	X	X	X	X	X	X			X	
Hexachlorobenzene	X	X	X	X	X	X			X	
Hexachlorocyclohexanes	X	X	X	X	X	X			X	
4,4'-Methylene dianiline	X	X			X	X			X

PCBs	X	X	X	X	X	X			X	X
Polychlorinated dibenzo-p-dioxins and dibenzofurans	X	X	X	X	X	X			X	X
PAHs	X	X	X	X	X	X			X	X

[a] Cow's milk only; no multipathway analysis for meat and egg ingestion

[b] To be evaluated by pathway in future amendments to the Hot Spots Program

5.3 Estimation of Concentrations in Air, Soil, and Water

Once emissions exit the source, the substances emitted will be dispersed in the air. The substances in the exhaust gas with high vapor pressures will remain largely in the vapor phase, and substances with lower vapor pressures will tend to adsorb to fly ash or other particulate matter. The emission plume may contain both vapor phase substances and particulates. A semivolatile organic toxicant can partition into both vapor and particulate phases. Particulates will deposit on vegetation, on soil, and in water at a rate that is dependent on the particle size. Use the 0.02 m/s deposition rate for emission sources that have verifiable particulate matter control devices or for emission sources that may be uncontrolled but only emit particulate matter that is less than 2.5 microns (e.g., internal combustion engines). The following algorithms are used to estimate concentrations in environmental media including air, soil, water, vegetation, and animal products.

5.3.1 *Air*

The ground level concentration (GLC, or C_{air} as shown in EQ 5.3.1) of a substance in air is a function of the facility emission rate and the dilution factor (χ/Q) at the points under evaluation.

A. Equation 5.3.1: $$C_{air} = Q_{substance} \times \chi/Q$$

1. C_{air} = Ground level concentration ($\mu g/m^3$)
2. $Q_{substance}$ = Substance emission rate (g/sec)
3. χ/Q = Dilution factor provided by dispersion modeling ($\mu g/m^3$/g/sec)

a. Recommended values for EQ 5.3.1:

1. $Q_{substance}$ = Facility-specific, substance emission rate
2. χ/Q = For point of interest, site specific, from dispersion modeling

b. Assumptions for EQ 5.3.1:

1. No plume depletion
2. Emission rate is constant, i.e., assumes steady state

5.3.2 *Soil*

The average concentration of the substance in soil (C_s) is a function of the deposition, accumulation period, chemical specific soil half-life, mixing depth, and soil bulk density. For simplicity and health protection, the Tier 1 default assumes 70-year soil deposition for the accumulation period at end of 70-year facility lifetime. The risk assessor may also choose a supplemental Tier 2 approach, subject to District approval or reviewing authority approval, in which the assessor applies a soil accumulation period based on the facility's start date of operation (e.g., historical date when emissions began), or the current exposure conditions, and the expected duration of operation.

A. Equation 5.3.2 A: $$C_s = Dep \times X / (K_s \times SD \times BD \times T_t)$$

1. C_s = Average soil concentration over the evaluation period ($\mu g/kg$)
2. Dep = Deposition on the affected soil area per day ($\mu g/m^2$-d)
3. X = Integral function for soil accumulation (d), see **EQ 5.3.2 C** below
4. K_s = Soil elimination constant (d^{-1})
5. SD = Soil mixing depth (m)
6. BD = Soil bulk density (kg/m^3)
7. T_t = Soil exposure duration or soil accumulation period (d)

a: Recommended default values for EQ 5.3.2 A:

1. Dep = Calculated in EQ 5.3.2 B
2. X = Calculated in EQ 5.3.2 C
3. K_s = Calculated in EQ 5.3.2 D
4. SD = 0.01 (m) for playground setting (soil ingestion and dermal pathways) and 0.15 (m) for agricultural setting (produce and meat pathways)
5. BD = 1,333 (kg/m^3)
6. T_t = 25,550 (d) = 70 years

b: Assumptions for EQ 5.3.2 A:

1. Substances are uniformly mixed in soil.
2. Substances are not leached or washed away, except where evidence exists to the contrary.
3. It is assumed that toxicants accumulate in the soil for 70 years from deposition over the 70 year lifespan of the facility. Use 70-year soil accumulation (T_t) for Tier 1 estimation of 9-, 30- and 70-year residential exposure, and 25-year off-site worker exposure.
4. For a receptor ingesting mother's milk, the mother is exposed from birth to 25 years of age; the infant is then born and receives mother's milk for one year. Default assumes 70-year soil accumulation for mother's milk pathway. See Table 5.1 for information on which substances or groups of substances must be evaluated by the mother's milk pathway.

B. Equation 5.3.2 B: $$\mathbf{Dep = C_{air} \times Dep\text{-}rate \times 86{,}400}$$

1. C_{air} = Ground level concentration ($\mu g/m^3$)
2. Dep-rate = Vertical rate of deposition (m/sec)
3. 86,400 = Seconds per day conversion factor (sec/d)

a: Recommended default values for EQ 5.3.2 B:

1. C_{air} = Calculated above in EQ 5.3.1 A
2. Dep-rate = Use 0.02 meters/second for controlled sources, or 0.05 meters/second for uncontrolled sources.

b: Assumptions for EQ 5.3.2 B:

1. Deposition rate remains constant. A deposition rate must be used when determining potential noninhalation health impacts. In the absence of facility specific information on the size of the emitted particles, the default values for deposition rate should be used. Currently, the default value of 0.02 meters per second is used for emission sources that have verifiable particulate matter control devices or for emission sources that may be uncontrolled but only emit particulate matter that is less than 2.5 microns

(e.g., internal combustion engines). The 0.05 meters per second default value is used for risk assessment if the emissions are uncontrolled. If other deposition rate factors are used, sufficient support documentation must be included with the HRA.

C. Equation 5.3.2 C: $$X = [\{e^{-Ks * Tf} - e^{-Ks * To}\} / K_s] + T_t$$

1. e = 2.718
2. K_s = Soil elimination constant
3. T_f = End of soil accumulation evaluation period (d)
4. T_o = Beginning of soil accumulation evaluation period (d)
5. T_t = Total days of soil exposure (soil accumulation period) T_f-T_o (d)

a: Recommended default values for EQ 5.3.2 C:

1: K_s = Calculated in EQ 5.3.2 D
2: T_f = 25,550 (d) = 70 years. Total soil exposure time at end of facility operation
3: T_o = 0 (d) The initial time (start period) of soil exposure to all receptors that are impacted by the soil pathway.

Note: Under a Tier 2 scenario, the risk assessor may also adjust T_f and T_t, subject to District approval, to replicate current soil accumulation and expected accumulation at the end of facility operation.

D. Equation 5.3.2 D: $$K_s = 0.693 / t_{1/2}$$

1. 0.693 = Natural log of 2
2. $t_{1/2}$ = Chemical specific soil half-life (d)

a: Recommended default values for EQ 5.3.2 D:

1. $t_{1/2}$ = Chemical-specific. See Table 5.2

5.3.3 *Water*

The water pathway is evaluated if a standing water body (e.g., pond or lake) is impacted by facility emissions and is used as a source for drinking water by food-producing animals or humans, or is a source of angler-caught fish. The average concentration of the substance in water (C_w) is a function of direct deposition and material carried in by surface run-off. However, only the contribution from direct deposition will be considered at this time.

A. Equation 5.3.3 A: $$C_w = C_{depw}$$

1. C_w = Average concentration in water (μg/kg)
2. C_{depw} = Contribution due to direct deposition (μg/kg)

B. Equation 5.3.3 B: $C_{depw} = Dep \times SA \times 365 / (WV \times VC)$

1. Dep = Deposition on water body per day ($\mu g/m^2/d$)
2. SA = Water surface area (m^2)
3. 365 = Days per year (d/yr)
4. WV = Water volume (kg)
5. VC = Number of volume changes per year

a: Recommended default values for EQ 5.3.3 B:

1. Dep = Calculated above in EQ 5.3.2 B
2. SA = Site specific water surface area (m^2)
3. WV = Site specific water volume in (kg) (1L = 1 kg)
4. VC = Site specific number of volume changes per year (SA, WV, and VC values can be obtained from the appropriate Department of Water Resources (DWR) Regional office)

b: Assumptions for EQ 5.3.3 B:

1. With the exception of dilution via number of volume changes per year, all material deposited into the water remains suspended or dissolved in the water column and is available for bioaccumulation in fish.

5.3.4 *Estimation of Concentrations in Vegetation, Animal Products, and Mother's Milk*

Estimates of the concentration of the substance in vegetation, animal products and mother's milk require the use of the results of the air, water, and soil environmental fate evaluation. Plants, animals and nursing mothers will be exposed to the substances at the concentrations previously calculated in Section 5.31 to 5.33 above.

5.3.4.1 Vegetation

The average concentration of a substance in and on vegetation (C_v) is a function of direct deposition of the substance onto the vegetation and of root translocation or uptake from soil contaminated by the substance. We currently recommend root translocation only for the inorganic compounds.

A. Equation 5.3.4.1 A: $C_v = C_{depv} + C_{trans}$

1. C_v = Average concentration in and on specific types of vegetation ($\mu g/kg$)
2. C_{depv} = Concentration due to direct deposition ($\mu g/kg$)
3. C_{trans} = Concentration in vegetation due to root translocation or uptake ($\mu g/kg$) – see EQ 5.3.4.1 C below

B. Equation 5.3.4.1 B: $C_{depv} = [Dep \times IF / (k \times Y)] \times (1 - e^{-kT})$

1. Dep = Deposition on affected vegetation per day ($\mu g/m^2/d$)
2. IF = Interception fraction
3. k = Weathering constant (d^{-1})
4. Y = Yield (kg/m^2)
5. e = Base of natural logarithm (2.718)
6. T = Growth period (d)

a: Recommended default values for EQ 5.3.4.1 B:

1. Dep = Calculated above in EQ 5.3.2 B
2. IF = Crop specific:
    - a: Root crops = 0.0
    - b: Leafy crops = 0.2
    - c: Protected crops = 0.0
    - d: Exposed crops = 0.1
    - e: Pasture = 0.7
3. k = 0.1 (d^{-1})
4. Y = 2 (kg/m^2) for root, leafy, protected, exposed and pasture [CA Department of Food and Agriculture dot maps]
5. T = 45 (d) for leafy crops
   T = 90 (d) for exposed crops

b: Crop-type definitions for EQ 5.3.4.1 B:

1. **Leafy** crop category consists of broad-leafed vegetables in which the leaf is the edible part. Examples include spinach, lettuce, cabbage, and kale.
2. **Root** crop category includes vegetables in which the edible portion is underground. Examples are potato, radish, and carrot.
3. **Exposed** produce category consists of crops with a small surface area subject to air deposition. Examples include strawberries, tomato, cucumber, zucchini, green bean and bell pepper.
4. **Protected** produce category consists of crops in which the edible part is not exposed to air deposition (e.g., the exposed skin of the crop is removed and not eaten). Examples are corn, pea, pumpkin and oranges.

Tables H-9 through H-15 in Appendix H provide more examples of various leafy, root, exposed and protected crop types.

c: Assumptions for EQ 5.3.4.1 B:

1. No deposition on root or protected crops
2. No uptake and translocation of deposited chemicals onto crops

C. Equation 5.3.4.1 C: (for inorganic compounds)

$$C_{trans} = C_s \times UF_2$$

1. C_s = Average soil concentration (μg/kg)
2. UF_2 = Uptake factor based on soil concentration

a: Recommended default values for EQ 5.3.4.1 C:

1. C_s = Calculated above in EQ 5.3.2 A
2. UF_2 = See Table 5.2

D. Equation 5.3.4.1 D: (for organic compounds)

$$UF_2 = [(0.03 \times K_{ow}^{0.77}) + 0.82] / [(K_{oc})(F_{oc})]$$

1. 0.03 = Empirical constant
2. K_{ow} = Octanol:water partition factor
3. 0.77 = Empirical constant
4. 0.82 = Empirical constant
5. K_{oc} = Organic carbon partition coefficient
6. F_{oc} = Fraction organic carbon in soil

a: Recommended default values for EQ 5.3.4.1 D:

1. K_{ow} = Chemical specific, see Table 5.2
2. K_{oc} = Chemical specific, see Table 5.2
3. F_{oc} = 0.1

b: Assumptions for EQ 5.3.4.1 D:

1. OEHHA currently has no recommended root uptake factors for organic compounds listed in Table 5.2. Evidence suggests this route is insignificant compared to airborne deposition. Nevertheless, if it becomes necessary in specific cases to assess root uptake for an organic compound, Equation 5.3.4.1 D would be the algorithm OEHHA recommends using to assess root uptake.

5.3.4.2 Animal Products

The average concentration of the substance in animal products (C_{fa}) depends on which routes of exposure exist for the animals. Animal exposure routes include inhalation, soil ingestion, ingestion of contaminated feed and pasture, and ingestion of contaminated water.

A. Equation 5.3.4.2:

$$C_{fa} = (\text{Inhalation} + \text{Water ingestion} + \text{Feed ingestion} + \text{Pasture/Grazing ingestion} + \text{Soil ingestion}) * Tco$$

1. C_{fa} = Average concentration in farm animals and their products (μg/kg)
2. Inhalation, water ingestion, etc. = Dose through inhalation, water ingestion, etc. (μg/d)
3. Tco = Chemical-specific transfer coefficient of contaminant from diet to animal product (d/kg)

a: Recommended default values for EQ 5.3.4.2:

1. Tco = See Tables 5.3a and 5.3b

b: Assumptions for EQ 5.3.4.2:

1. The Tco for a given chemical is the same for all exposure routes

5.3.4.2.1 Inhalation

A. Equation 5.3.4.2.1: $\text{Inhalation} = BR_a \times C_{air}$

1. Inhalation = Dose through inhalation (μg/d)
2. BR_a = Breathing rate for animal (m^3/d)
3. C_{air} = Ground-level concentration (μg/m^3)

a: Recommended default values for EQ 5.3.4.2.1:

1. BR_a = See Table 5.4
2. C_{air} = Calculated above in EQ 5.3.1 A

b: Assumptions for EQ 5.3.4.2.1:

1. All material inhaled is 100% absorbed

5.3.4.2.2 Water Ingestion

The water ingestion pathway is applied if there are surface water sources of drinking water, such as springs, ponds or lakes, which are exposed to airborne deposition of facility emissions. Due to the site-specific nature for this exposure pathway, OEHHA recommends that the risk assessor conduct a survey at the site to estimate the fraction of contaminated drinking water ingested by the animals, if such sources exist.

A. Equation 5.3.4.2.2: **Water ingestion = $WI_a \times FSW \times C_w$**

1. Water ingestion = Dose through water ingestion (μg/d)
2. WI_a = Water ingestion for animal (kg/d)
3. FSW = Fraction of water ingested from a contaminated body of water (site-specific)
4. C_w = Average concentration in water (μg/kg)
   For water 1 kg = 1 L

a: Recommended default values for EQ 5.3.4.2.2:

1. WI_a = See Table 5.4
2. FSW = Site specific fraction, need to survey water ingestion practices in affected area
3. C_w = Calculated above in EQ 5.3.3 A

5.3.4.2.3 Feed Ingestion

The fraction of feed intake by cattle, pigs and poultry that is contaminated by facility emissions can vary considerably depending on the manner in which the animals are raised. Due to the site-specific nature for this exposure pathway, OEHHA recommends that the risk assessor conduct a survey at the site to estimate the fraction of contaminated feed eaten by the animals. For a Tier 1 assessment, default values are provided by OEHHA (see Table 5.4 and Table 5.4 footnotes) for estimation of exposure to the animals.

Agricultural mixing depth should be used for calculating soil concentration for feed and pasture contamination.

5.3.4.2.3.1 Feed Ingestion

A. Equation 5.3.4.2.3.1: **Feed ingestion = $(1.0 - FG) \times FI \times L \times C_v$**

1. Feed ingestion = Dose through the ingestion of feed (μg/d) that is harvested after it is impacted by source emissions
2. FG = Fraction of diet provided by grazing (site-specific)
3. FI = Feed ingestion rate (kg/d)
4. L = Fraction of locally grown (source impacted) feed that is not pasture (site-specific)
5. C_v = Concentration in feed (μg/kg)

a: Recommended default values EQ 5.3.4.2.3.1:

1. FG = Default values in Table 5.4 footnote b, although a site-specific survey for the fraction of diet provided by grazing is recommended
2. FI = See Table 5.4
3. L = Default values in Table 5.4 footnote b, although a site-specific survey for fraction of locally grown (source impacted) feed that is not pasture is recommended
4. C_v = As calculated above in EQ 5.3.4.1 A

b: Assumptions for EQ 5.3.4.2.3.1:

1. Feed (FI) transported from an off-site location (i.e., not grown locally) is not contaminated by facility emissions.

5.3.4.2.3.2 Pasture/Grazing ingestion

A. Equation 5.3.4.2.3.2: **Pasture/Grazing ingestion = FG × C_v × FI**

1. Pasture/Grazing ingestion = Dose through pasture/grazing (μg/d)
2. FG = Fraction of diet provided by grazing (site-specific)
3. C_v = Concentration in pasture/grazing material (μg/kg)
4. FI = Feed ingestion rate (kg/d)

a: Recommended default values EQ 5.3.4.2.3.2:

1. FG = Default values in Table 5.4 for fraction of diet provided by grazing, although a site-specific survey is recommended
2. C_v = As calculated above in EQ 5.3.4.1 A
3. FI = See Table 5.4

5.3.4.2.4 Soil ingestion

The feeds provided to dairy and beef cattle may contain small quantities of soil. A larger fraction of soil by weight of food is taken up during grazing. Rooting behavior by pigs with access to soil will result in soil ingestion. Likewise, poultry with free access to soil or pasture will also ingest soil. Defaults for soil ingestion are shown in Table 5.4.

A. Equation 5.3.4.2.4 A: **Soil ingestion = SI_a × C_s**

1. Soil ingestion = Dose through soil ingestion (μg/d)
2. SI_a = Soil ingestion rate for animal (kg/d)
3. C_s = Average soil concentration (μg/kg)

a: Recommended default values for EQ 5.3.4.2.4 A:

1. SI_a = Calculated below
2. C_s = Calculated above in EQ 5.3.2 A

B. Equation 5.3.4.2.4 B: $SI_a = [(1 - FG) \times FS_f \times FI] + [FG \times FS_p \times FI]$

1. FG = Fraction of diet provided by grazing
2. FS_f = Soil ingested as a fraction of feed ingested
3. FI = Feed ingestion rate (kg/d)
4. FS_p = Soil ingested as a fraction of pasture ingested

a: Recommended default values for EQ 5.3.4.2.4 B:

1. FG = Site specific fraction of diet provided by grazing
2. FS_f = See Table 5.4
3. FI = See Table 5.4
4. FS_p = See Table 5.4

b: Assumptions for EQ 5.3.4.2.4 B:

1. The transfer coefficient is the same for all exposure routes.
2. Soil ingested in feed (FS_f) transported from an off-site location (i.e., not grown locally) is assumed not to be contaminated by facility emissions.

5.3.4.3 Bioaccumulation in Angler-Caught Fish

The average concentration in fish (C_f) is based on the concentration in water and a chemical-specific bioaccumulation factor.

A. Equation 5.3.4.3: $Ct = Cw \times BAF$

1. Ct = Concentration in wet weight tissue (muscle) of fish (µg/kg)
2. Cw = Concentration in water (µg/kg)
3. BAF = Fish bioaccumulation factor (unitless)

a: Recommended default values for Equation 5.3.4.3:

1. Cw = As calculated above in Equation 5.3.3 A
2. BAF = Chemical-specific; see Table 5.2

b: Assumptions for Equation 5.3.4.3:

1. For conversion of a chemical concentration in a volume of water shown as µg/L, 1 L water = 1 kg water; thus, for concentration of chemical in water, µg/L = µg/kg.
2. For organic chemicals, BAFs lipid-normalized to adult rainbow trout with 4% lipid content in muscle tissue
3. For organic chemicals, BAFs based on the freely dissolved fraction in water under conditions of average particulate organic carbon and dissolved organic carbon in U.S. lakes and other water bodies
4. For inorganic compounds, BAFs based on wet weight muscle tissue concentration and on the total water concentration of the inorganic compound in water.
5. Contaminant concentrations are uniform in water based on dispersion

5.3.4.4 Bioaccumulation in Mother's Milk

The average concentration of a chemical in mother's milk (C_m) is a function of the mother's exposure through all exposure routes (i.e., inhalation, ingestion via food, drinking water, and soil, and dermal absorption via skin contact with soil contaminated with the chemical), the contaminant half-life in the mother's body, and transfer of absorbed chemical to mother's milk. The contaminant half-life in the body and transfer to mother's milk is incorporated in biotransfer coefficients (Tco) in Equation 5.3.4.4. See the TSD (OEHHA, 2012a), Appendix J for details on development of biotransfer factors. The substances assessed by the mother's milk pathway are shown in Table 5.1.

A. Equation 5.3.4.4: $$C_m = [(D_{inder} \times Tco_{m\_inder}) + (D_{ing} \times Tco_{m\_ing})] \times BW$$

1. C_m = Concentration in mother's milk (mg/kg-milk)
2. D_{inder} = The sum of DOSEair + DOSEdermal through inhalation and dermal absorption (mg/kg-BW-day)
3. D_{ing} = The sum of DOSEfood + DOSEsoil + DOSEwater through ingestion (mg/kg-BW-day)
4. Tco_{m_inder} = Biotransfer coefficient from inhalation and dermal absorption to mother's milk (d/kg-milk)
5. Tco_{m_ing} = Biotransfer coefficient from ingestion to mother's milk (d/kg-milk)
6. BW = Body weight of mother (Kg)

a: Recommended cancer risk default values for EQ 5.3.4.4:

1. D_{ing} = As calculated through ingestion of soil in EQ 5.4.3.1.1 + home-grown produce in EQ 5.4.3.2.1 + home-raised animal products in EQ 5.4.3.2.2 + drinking water in EQ 5.4.3.3.1 + angler-caught fish in EQ 5.4.3.4.1
2. D_{inder} = As calculated through inhalation in EQ 5.4.1.1 + dermal exposure in EQ 5.4.2.1
3. Tco_{m_inder} = See Table 5.5
4. Tco_{m_ing} = See Table 5.5

b: Recommended noncancer risk default values for EQ 5.3.4.4:

1. D_{ing} = As calculated through ingestion of soil in EQ 5.4.3.1.2 + home-grown produce and home-raised animal products in EQ 5.4.3.2.3 + drinking water in EQ 5.4.3.3.2 + angler-caught fish in EQ 5.4.3.4.2
2. D_{inder} = As calculated through inhalation in EQ 5.4.1.1 + dermal exposure in EQ 5.4.2.2
3. Tco_{m_inder} = See Table 5.5
4. Tco_{m_ing} = See Table 5.5

c: Assumptions for EQ 5.3.4.4:

1. Default age of mother at birth is 25 years of age, then nurses the infant for 1 year; Use 16<30 year old high-end (95^{th} percentile) daily breathing rate and intake rates for D_{ing} and D_{inder} for estimating dose to mother.
2. For inhalation dose to mother's milk, it is recommended that the EF variate in EQ 5.4.1.1 is left out for calculation of inhalation dose in the mother's milk pathway.
3. Biotransfer coefficient, Tco_{m_inder}, the same for both inhalation and dermal pathways based on lack of first-pass metabolism through the liver for both of these pathways.
4. Biotransfer coefficient, Tco_{m_ing}, the same for all ingestion pathways based on first-pass metabolism through the liver.
5. For chemicals in Table 5.5 lacking either an oral or inhalation Tco, use the oral Tco for the absent inhalation Tco (i.e., for PCDDs and PCDFs and dioxin-like PCBs), or the inhalation Tco for the absent oral Tco (i.e., for lead) in Equation 5.3.4.4.
6. The concentration in the mother's milk is determined using the derived approach to risk assessment. This method allows use of the high-end dose point estimate for driving exposure pathways and the average dose point estimates for other exposure pathways. See Sections 8.2.6 (cancer) and 8.3.3 (noncancer) for the description of the methodology on how to implement the derived methodology.

Table 5.2a Substance-Specific Default Values for Organic Multipathway Substances

				Root Uptake Factors					
Multipathway Substance	**Log K_{oc}**	**Log K_{ow}**	**Fish BAF**	**Root**	**Leafy**	**Exposed**	**Protected**	**GRAF[2]**	**Soil HalfLife (days)**
Creosotes	NA	NA	$8 \times 10^{+2}$	NA	NA	NA	NA	1.0	$4.3 \times 10^{+2}$
Diethylhexyl-phthalate	5.34[1]	7.63[1]	$4 \times 10^{+1}$	NA	NA	NA	NA	1.0	$1.5 \times 10^{+1}$

Polychlorinated Biphenyls	NA	NA	$2 \times 10^{+6}$	NA	NA	NA	NA	1.0	$3.2 \times 10^{+3}$

(1) Averaged log Kow and Koc values determined by most reliable methods (Staples et al., 1997)

(2) GRAF (Gastrointestinal Relative Absorption Factor). The guidelines allow for adjusting for bioavailability where the evidence warrants. For example, there are good data which indicate that dioxin is not as available to an organism when bound to soil or fly ash matrices relative to when it is in solution or in food. Therefore, a bioavailability factor is incorporated into the model to account for this difference. When information becomes available for other chemicals of concern, this type of bioavailability will be incorporated into the model.

(3) Measured by Hansch et al. (1985)

(4) Estimated according to methodology of Lyman et al. (1990)

(5) To be evaluated for specific default values in future amendments to the Hot Spots Program.

(1) GRAF (Gastrointestinal Relative Absorption Factor). The guidelines allow for adjusting for bioavailability where the evidence warrants. For example, there are good data which indicate that dioxin is not as available to an organism when bound to soil or fly ash matrices relative to when it is in solution or in food. Therefore, a bioavailability factor is incorporated into the model to account for this difference. When information becomes available for other chemicals of concern, this type of bioavailability will be incorporated into the model.

(2) Methyl mercury (MeHg) is not represented in the category “mercury & inorganic compounds”. The BAF for methyl mercury is orders of magnitude higher than for inorganic mercury. Assessment of MeHg for the fish pathway is not directly applicable to the Hot Spots program, as no facilities are known to emit MeHg directly into the air (OEHHA, 2012; OEHHA, 2006), but it may be formed by action of microbes in sediment. Assessing the methylation of mercury deposited into a water body is difficult, and is also very water body-specific. At this time OEHHA cannot address this issue in the Hot Spots program, but will consider addressing this problem in future amendments of the Guidance.

NA - Data Not Available or Not Applicable.

Table 5.3a Animal Transfer Coefficients for Persistent Organic Chemicals

Organic Chemical	Tco (d/kg)[a]				
	Cow's Milk	Chicken Egg	Chicken Meat	Cattle Meat	Pig Meat

Mercury	7×10^{-5}	0.8	0.1	4×10^{-4}	0.002[b]
Nickel	3×10^{-5}	0.02	0.02	3×10^{-4}	0.001
Selenium	0.009	3	0.9	0.04	0.5

[a] All Tco values were rounded to the nearest whole number.

[b] The meat Tco was estimated using the metabolic weight adjustment ratio of 4.8 from cattle to pig

[c] NA – no data available or was not applicable

Table 5.4 Point Estimates for Animal Pathway

Parameter	Beef Cattle	Lactating Dairy Cattle	Pigs	Meat Poultry	Egg-laying Poultry
BW (body weight in kg)	533	575	55	1.7	1.6
BR_a (inhalation rate in m^3/d)	107	115	7	0.4	0.4
WI_a (water consumption in kg/d)	45	110	6.6	0.16	0.23
FI (Food Intake in kg/d) DMI[a] and/or pasture grazing[b]	9	22	2.4	0.13	0.12
FS_f (soil fraction of feed)	0.01	0.01	NA	NA	NA
FS_p (soil fraction of pasture)	0.05	0.05	0.04	0.02	0.02

[a] Dry matter intake

[b] For beef and dairy cattle, pasture grazing is assumed to be leafy vegetation (grasses, including greenchop) and accounts for half of the cattle's diet (FG=0.5 in Section 5.3.4.2.3). The default assumes on-site pasture grazing contaminated by facility emissions. Fraction of feed or dry matter intake (e.g., hay, grain) grown on-site is assumed to be contaminated by facility emissions and fraction of feed that is grown off-site is not assumed to be contaminated. A default may be used that assumes all feed is grown off-site (L=0 in Section 5.3.4.2.3), but a survey is recommended to verify the fractions of feed grown on-site and off-site.

For pigs with access to soil, but usually confined to a pen, default assumes no pasture grazing (FG=0 in Section 5.3.4.2.3). For feed, estimated intake consists of equal portions of all plant types including exposed, leafy, protected and root in which 10% (L=0.1 in Section 5.3.4.2.3) of the diet is homegrown and contaminated by facility emissions. The fraction of feed that was transported from an off-site location is assumed not to be contaminated by facility emissions.

For poultry including egg-laying and broiler chickens that have access to soil, default assumes no pasture grazing (FG=0 in Section 5.3.4.2.3). Estimated feed intake is composed of equal proportions of all plant types with 5% (L=0.05 in Section 5.3.4.2.3) homegrown and contaminated by facility emissions. The fraction of feed grown off-site and transported to the receptor was not contaminated by facility emissions.

NA - Not applicable. Assume FS_f is equal to zero.

Table 5.5 Mother's Milk Transfer Coefficients (Tco_m)[a]

Chemical/chem. group	Tco_m (day/kg-milk)
PCDDs - oral[b]	3.7
PCDFs - oral[b]	1.8
Dioxin-like PCBs - oral[b]	1.7
PAHs – inhalation[c]	1.55
PAHs – oral	0.401
Lead - inhalation[d]	0.064

[a] These compound classes represent the chemicals of greatest concern for the mother's milk pathway under the Hot Spots program. It is expected that additional transfer coefficients will be developed for other multipathway chemicals in the Hot Spots Program as data becomes available and is reviewed.

[b] Use the oral Tco_m for the inhalation and dermal pathways. The PCDD, PCDF and dioxin-like PCB Tcos were derived using a Random-effects model from individual Tco_m estimates for 7 PCDDs, 9 PCDFs and 12 dioxin-like PCBs (See OEHHA, 2012, Appendix J).

[c] Use the inhalation Tco_m for the dermal pathway

[d] Use the inhalation Tco_m for the ingestion and dermal pathways

5.4 Estimation of Dose

Once the concentrations of substances are estimated in air, soil, water, plants, and animal products, they are used to evaluate estimated exposure to people. Exposure is evaluated by calculating the daily dose in milligrams per kilogram body weight per day (mg/kg/d). The following algorithms calculate this dose for exposure through inhalation, dermal absorption, and ingestion pathways. All chemicals must be assessed for exposure through inhalation. If there are emissions of one or more of the subset of semi- or non-volatile multipathway substances, the soil ingestion pathway and the dermal soil exposure pathway are also assessed. The mother's milk pathway may also be a mandatory pathway depending on the multipathway substance released (See Table 5.1). The other exposure pathways may also need to be assessed if a survey of the exposure site shows they are present (e.g., ingestion of water, home-grown crops, home-raised animal products, and angler-caught fish).

This section contains average and high-end point estimates and data distributions for adults and children for many exposure pathways. The point-estimates and data distributions for children fall within the 3rd trimester, 0<2, 2<9, and 2<16 year age groupings. The point-estimates and data distributions for adults fall within the 16<30 and 16-70 year age groupings. When evaluating 9-, 30-, and 70-year exposure durations for cancer risk assessment, assessors will use distributions starting at the third trimester.

Workers are assessed for cancer risk as adults using 8-hour breathing rate point estimates (See Table 5.8). Point estimates for workers are listed under "offsite worker." OEHHA has not developed stochastic distributions for worker exposure. Therefore, there is no Tier 3 stochastic approach for offsite worker cancer risk assessment.

5.4.1 *Estimation of Exposure through Inhalation*

The dose through the inhalation route is estimated for cancer risk assessment and noncancer hazard assessment. Both residential and offsite worker exposures are considered. Since residential exposure includes near-continuous long-term exposure at a residence and workers are exposed only during working hours (i.e., 8 hours/day), different breathing rate distributions are used.

5.4.1.1 Residential Inhalation Dose for Cancer Risk Assessment

Exposure through inhalation is a function of the breathing rate, the exposure frequency, and the concentration of a substance in the air. For residential exposure, the breathing rates are determined for specific age groups, so inhalation dose (Dose-air) is calculated for each of these age groups, 3rd trimester, 0<2, 2<9, 2<16, 16<30 and 16-70 years. OEHHA used the mother's breathing rates to estimate dose for the 3rd trimester fetus assuming the dose to the fetus during the 3rd trimester is the same as the mother's dose. These age-specific groupings are needed in order to properly use the age sensitivity factors for cancer risk assessment (see Chapter 8). A Tier 1 evaluation uses the high-end point estimate (i.e., the 95th percentiles) breathing rates for the inhalation

pathway in order to avoid underestimating cancer risk to the public, including children. A possible exception for using high-end breathing rates are when there is exposure to multipathway substances and two of the non-inhalation pathways drive the risk, rather than the inhalation pathway (see Chapter 8).

A. Equation 5.4.1.1: $$\text{Dose-air} = C_{air} \times \{BR/BW\} \times A \times EF \times 10^{-6}$$

1. Dose-air = Dose through inhalation (mg/kg/d)
2. C_{air} = Concentration in air ($\mu g/m^3$)
3. {BR/BW} = Daily Breathing rate normalized to body weight (L/kg body weight - day)
4. A = Inhalation absorption factor (unitless)
5. EF = Exposure frequency (unitless), days/365 days
6. 10^{-6} = Micrograms to milligrams conversion, liters to cubic meters conversion

a: Recommended default values for EQ 5.4.1.1:

1. {BR/BW} = Daily breathing rates by age groupings, see As supplemental information, the assessor may wish to evaluate the inhalation dose by using the mean point estimates in Table 5.6 to provide a range of breathing rates for cancer risk assessment to the risk manager.
2. Table (point estimates) and Table 5.7 (parametric model distributions for Tier III stochastic risk assessment). For Tier 1 residential estimates, use 95th percentile breathing rates in Table 5.6.
3. A = 1
4. EF = 0.96 (350 days/365 days in a year for a resident)

b: Assumption for EQ 5.4.1.1:

1. The fraction of chemical absorbed (A) is the same fraction absorbed in the study on which the cancer potency or Reference Exposure Level is based.

As supplemental information, the assessor may wish to evaluate the inhalation dose by using the mean point estimates in Table 5.6 to provide a range of breathing rates for cancer risk assessment to the risk manager.

Table 5.6 Point Estimates of Residential Daily Breathing Rates for 3rd trimester, 0<2, 2<9, 2<16, 16<30 and 16-70 years (L/kg BW-day)

5.4.1.2 Offsite Worker (MEIW) Inhalation Dose for Cancer Risk Assessment

For worker exposure, the default assumes working age begins at 16 years, and that exposures to facility emissions occur during the work shift, typically up to 8 hours per day during work days. Breathing rates that occur over an 8-hour period vary depending on the intensity of the activity (See Table 5.8), and are used to estimate the inhalation dose. The 8-hour breathing rates may also be useful for cancer risk assessment of children and teachers exposed at schools during school hours.

Another risk management consideration for the offsite worker scenario for cancer assessment of a Hot Spots facility is whether there are women of child-bearing age at the MEIW location and whether the MEIW has a daycare center. Since the third trimester is only a short segment of the 25 year exposure duration used for the MEIW, the resulting risk estimate would not differ significantly. An exception to this assumption is high exposure to carcinogens over a short period, as might occur during short-term projects (see Section 8.2.10). In this case, risk assessment during the third trimester may be warranted. However, if there is onsite daycare at the MEIW, then the risks to the children will be underestimated using the offsite adult worker scenario due to increased exposure (per kg body weight) and increased sensitivity to carcinogen exposure (see Section 8.2.1). In this case, the Districts may wish to include a calculation of inhalation dose for the children in the onsite daycare, assuming they could be there from 0 to age 6 years.

Exposed workers may be engaged in activities ranging from desk work, which would reflect breathing rates of sedentary/passive or light activities, to farm worker activities, which would reflect breathing rates of moderate intensity (See Table 5.9). OEHHA recommends default (Tier 1) point estimate 8-hour breathing rates in L/kg-8-hrs based on the mean and 95th percentile of moderate intensity activities, 170 and 230 L/kg-8-hrs, respectively, for adults 16-70 years old.

Many facilities operate non-continuously, as in only 8-10 hours per day, but the air dispersion modeling is performed as if the emissions were uniformly emitted over 24 hours a day, 7 days per week. The air dispersion computer model used, including AERMOD and other models, typically calculate an annual average air concentration based on actual operating conditions but also include the hours of nonoperation in the average concentration.

Therefore, there are two components that determine the worker exposure to facility emissions:

1) What is the estimated concentration the worker is exposed to (i.e., breathes), during the work shift, and

2) What is the amount of time the offsite worker's schedule overlaps with the facility's emission schedule?

There are two approaches to estimating the modeled concentration the worker is breathing during the work shift. The first approach uses a worker adjustment factor (i.e.,

the WAF) to approximate what the worker is breathing based on the modeling run used for residential receptors. The second approach uses a special modeling run with the hourly raw results from an air dispersion analysis and is described in Appendix M.

The first and more basic approach is to obtain the long term average concentration as you would for modeling a residential receptor, then adjusting this exposure concentration using the calculated WAF (EQ 5.4.1.2 B) to estimate the concentration the offsite worker is exposed to during the work shift (shown as (C_{air} × WAF) in EQ 5.4.1.2 A). This method is characteristic of a default approach used in a Tier 1 assessment. Once the exposure concentration is determined, the worker's inhalation dose (Dose-air) can be calculated as shown in EQ 5.4.1.2 A.

The second approach for determining the air concentration the worker is exposed to uses a refined modeling run where the hourly raw dispersion model output are post processed to examine the hourly concentrations that fall within the offsite worker's shift. This method provides a more representative estimate of the air concentration, but is more complex, and time consuming than the first method. See Appendix M for information on how to simulate the long term concentration for the offsite worker that can be used to estimate inhalation cancer risk.

The HARP software has the ability to calculate worker impacts using an approximation factor and, in the future, it will have the ability to post process refined worker concentrations using the hourly raw results from an air dispersion analysis.

If the off-site worker's shift does not completely overlap the emission schedule of the facility, then a Discount Factor (DF) may be applied to the WAF. Calculation of the DF is shown in EQ 5.4.1.2 C. The default assumption is that the offsite worker's shift falls completely within the emission schedule of the facility, in which case DF=1. Use of a DF less than 1 requires a survey at the MIEW to verify that some portion of the off-site worker shift is not subject to the facility emissions.

A. Equation 5.4.1.2 A: $\textbf{Dose-air} = (C_{air} \times WAF) \times \{BR/BW\} \times A \times EF \times 10^{-6}$

1. Dose-air = Dose through inhalation (mg/kg/d)
2. C_{air} = Annual average concentration in air ($\mu g/m^3$)
3. WAF = Worker air concentration adjustment factor (unitless)
4. {BR/BW} = Eight-hour breathing rate normalized to body weight (L/kg body weight - day)
5. A = Inhalation absorption factor (unitless)
6. EF = Exposure frequency (unitless), days/365 days)
7. 10^{-6} = Micrograms to milligrams conversion, Liters to cubic meters conversion

a: Recommended default values for EQ 5.4.1.2 A:

1. WAF = See EQ. 5.4.1.2 B for formula to calculate WAF, or App. M for refined post-processing modeling to calculate WAF.
2. {BR/BW} = For workers, use age16-70 year, 95th percentile, moderate intensity 8-hour point estimate breathing rates (see Table 5.8). No worker breathing rate distributions exist for stochastic risk assessment.
3. A = 1
4. EF = 0.68 (250 days / 365 days). Equivalent to working 5 days/week, 50 weeks/year.

b: Assumption for EQ 5.4.1.2 A:

1. The fraction of chemical absorbed (A) through the lungs is the same fraction absorbed in the study on which the cancer potency factor is based.
2. The source emits during the daylight hours. Calculate WAF (EQ 5.4.1.2 B) if a special post-processing modeling run described in App. M was not completed. For nighttime emissions and exposure scenarios, see Appendix N.

B. Equation 5.4.1.2 B: $$WAF = (H_{res} / H_{source}) \times (D_{res} / D_{source}) \times DF$$

1. WAF = Worker adjustment factor (unitless)
2. H_{res} = Number of hours per day the annual average residential air concentration is based on (always 24 hours)
3. H_{source} = Number of hours the source operates per day
4. D_{res} = Number of days per week the annual average residential air concentration is based on (always 7 days)
5. D_{source} = Number of days the emitting source operates per week
6. DF = Discount factor, for when the offsite worker's schedule partially overlaps the source's emission schedule

b: Recommended default values for EQ 5.4.1.2 B:

1. DF = 1 for offsite worker's schedule occurring within the source's emission schedule. A site-specific survey may be used to adjust the DF using EQ 5.4.1.2 C.

C. Equation 5.4.1.2 C: $$DF = (H_{coincident} / H_{worker}) \times (D_{coincident} / D_{worker})$$

1. $H_{coincident}$ = Number of hours per day the offsite worker's schedule and the source's emission schedule coincide
2. H_{worker} = Number of hours the offsite worker works per day
3. $D_{coincident}$ = Number of days per week the offsite worker's schedule and the source's emission schedule coincide
4. D_{worker} = Number of days the offsite worker works per week

Tier 2 adjustments for EQ 5.4.1.2 A-C may be used for:

1. Eight-hour breathing rate. Point estimates in Table 5.8 for lower breathing rates of sedentary/passive and light intensity work activities may be substituted in site-specific Tier 2 scenarios. Table 5.9 can be used to estimate breathing rate intensities for various job activities. Use of different breathing rates requires a survey of the exposed workplace and approval by Air District, ARB and OEHHA.
2. Discount Factor (DF) in EQ 5.4.1.2 C. If a site-specific survey of the offsite worker schedule only partially overlaps with the source's emission schedule, then a DF less than 1 may be calculated. Use of a DF less than 1 requires a survey of the exposed workplace and approval by the Air District or ARB.

The 8-hour breathing rates are based on minute ventilation rates derived by U.S. EPA (2009). U.S. EPA employed a metabolic equivalent (METS) approach for estimating breathing rates. This method determines daily time-weighted averages of energy expenditure (expressed as multipliers of the basal metabolic rate) across different levels of physical activity. The 8-hour breathing rates shown in Table 5.8 are divided into three categories:

Sedentary & Passive Activities (METS $\leq$ 1.5)

Light Intensity Activities (1.5 < METs $\leq$ 3.0)

Moderate Intensity Activities (3.0 < METs $\leq$ 6.0)

For example, a METS = 1 is roughly equivalent to energy expenditure during sleep and is close to the basal metabolic rate. A METS activity that is two to three times greater (METS = 2 to 3) is characteristic of light intensity activities, such as administrative office work or sales work as shown in Table 5.9.

Under a Tier 1 scenario, the risk assessor may simply use the 95th percentile breathing rate for moderate intensity activities of 230 L/kg-8 hrs in Eq. 5.4.1.2 A to calculate the daily dose via the inhalation route to the worker. In an example of a Tier 2 scenario, the risk assessor surveys the workplace and determines that the worker(s) at the MEIW receptor are primarily sitting at a desk performing administrative-type work on a computer. Referring to Table 5.9, this activity corresponds most closely to "administrative office work" with a mean activity level of 1.7 and a SD = 0.3. This level of activity is considered "light intensity activity" (i.e., 1.5 < METs $\leq$ 3.0). With the prior approval of the Air District or ARB, the risk assessor may then use the 95th percentile breathing rate of 100 L/kg-8 hr for light intensity activities in Equation 5.4.1.2 A.

Table 5.8. Eight-Hour Breathing Rate (L/kg per 8 Hrs) Point Estimates for Males and Females Combined[a,b]

	0<2 years	2<9 years	2<16 years	16<30 years	16-70 years
	Sedentary & Passive Activities (METS $\leq$ 1.5)				
Mean	200	100	80	30	30
95th Percentile	250	140	120	40	40
	Light Intensity Activities (1.5 < METs $\leq$ 3.0)				
Mean	490	250	200	80	80
95th Percentile	600	340	270	100	100
	Moderate Intensity Activities (3.0 < METs $\leq$ 6.0)				
Mean	890	470	380	170	170
95th Percentile	1200	640	520	240	230

[a] For pregnant women, OEHHA recommends using the mean and 95th percentile 8-hour breathing rates based on moderate intensity activity of 16<30 year-olds for 3rd trimester.
[b.] Breathing rates in the table may be used for worker, school, or residential exposures

Table 5.9. METS Distributions for Workplace and Home Activities

Activity Description	Mean	Median	SD	Min	Max
Workplace Activities					
Administrative office work	1.7	1.7	0.3	1.4	2.7
Sales work	2.9	2.7	1.0	1.2	5.6

Walk/bike/jog (not in transit) age 20	5.8	5.5	1.8	1.8	11.3
Walk/bike/jog (not in transit) age 30	5.7	5.7	1.2	2.1	9.3
Walk/bike/jog (not in transit) age 40	4.7	4.7	1.8	2.3	7.1

Table 5.10 lists some WAFs for a few typical scenarios. For example, if the source is continuously emitting, then the offsite worker is assumed to breathe the long-term annual average concentration during their work shift. The WAF then becomes one and no concentration adjustments are necessary in this situation when estimating the inhalation cancer risk. If the source is non-continuously emitting for 8 hours/day, 5 days/week and the offsite worker's shift completely overlaps the emitting facility's operating schedule, then the WAF would be 4.2:

$$(24 \text{ hrs/day} / 8 \text{ hrs/day}) \times (7 \text{ days/week} / 5 \text{ days/week}) = 4.2$$

If the offsite worker's 8 hour/day shift only overlaps the emitting facility's operation schedule for 4 hrs/day, then the WAF is 2.1 because the DF = 0.5 will reduce the WAF by half: DF = (4 hrs/day / 8 hrs/day) x (5 days/week / 5 days/week) = 0.5

Table 5.10: Example Worker Adjustment Factors (WAF) to Convert a Long-Term Daily Average Emission Concentration to an Off-Site Worker Receptor Exposure

Off-Site Workers' Shift Overlap with Facility's Emission Schedule[a]	Facility Operating Schedule	Adjustment Factor
8 hrs/day, 5 days/week	Continuous (24 hrs/7 days/week)	1.0
8 hrs/day, 5 days/week[b]	Non-continuous (8 hrs/5 days/week)	4.2
4 hrs/day, 5 days/week	Non-continuous (8 hrs/5 days/week)	2.1

[a] Worker works 8 hours per day, 5 days per week
[b] Workers' work hours completely overlap the facilities operating hours

5.4.1.3 Inhalation Dose for Children at Schools and Daycare Facilities for Cancer Risk Assessment

The 8-hour breathing rates and inhalation dose equations (EQ 5.4.1.2 A-C) may also be used to estimate risk to children when exposures occur while at school or at day care facilities. Breathing rate point estimates to use in Table 5.8 depend on the ages of the children at the exposed schools and day cares. As a Tier 1 default, moderate intensity breathing rates are recommended. Equations 5.4.1.2 A-C is used in the same way to estimate dose in children as it is for workers.

5.4.1.4 Non-Cancer Inhalation Exposure for Workers and Residents

For typical daily work shifts of 8-9 hours, acute, 8-hour and chronic Reference Exposure Levels (RELs) described in Chapter 8 are used in health risk assessments to characterize the noncancer risks using the Hazard Index approach described in Chapter 8 and in OEHHA (2008). Uncertainty factors are already incorporated into the RELs used to assess noncancer risk, as explained in Chapter 8, so all that is needed to evaluate the noncancer hazard is the air concentration that the worker is exposed to. The modeled maximum 1-hour air concentration is determined for acute hazard assessment and the annual average air concentration is determined for chronic hazard assessment. The modeled average air concentration during a work shift is determined for 8-hour hazard assessment using the adjusted annual average air concentration described below.

The 8-hour RELs are primarily designed to address offsite worker inhalation exposure at the MEIW because they better characterize the daily intermittent exposures of workers than the chronic RELs do. They are used in estimating the 8 hour Hazard Index for offsite workers. The 8-hour RELs should be used for typical daily work shifts of 8-9 hours. For further questions, assessors should contact OEHHA, the District, or reviewing authority to determine if the 8-hour RELs should be used in your HRA. Any discussions or directions to exclude the 8-hour REL evaluation should be documented in the HRA.

Note, however, there are only a handful of 8-hour RELs currently adopted for use in the Hot Spots program. Therefore, we also recommend performing chronic noncancer exposure assessment for the offsite worker (MEIW) based on the annual average air concentration at the MEIW. Evaluation of the chronic Hazard Index should help protect workers who routinely work longer than 8 hour shifts. Exposure to multipathway substances also requires noncancer hazard assessment for the dermal and oral soil exposure pathways for offsite workers. Because there are few 8-hour RELs currently available, hazard assessment for the noninhalation pathways for multipathway substances is only applied when estimating the chronic Hazard Index.

In addition, the Districts may wish to determine if there is an onsite daycare at the MEIW and include a calculation of the chronic and 8-hour inhalation dose for children, although onsite hazard assessment is not a requirement for a Hot Spots risk assessment.

As explained in Section 5.4.1.2 for cancer risk, the modeled annual average air concentration is adjusted to the air concentration that the worker is actually exposed to if the facility operates non-continuously. The typical method for this adjustment is by calculating the Worker Adjustment Factor (WAF) shown in EQ 5.4.1.4 B and multiplying this value by the annual average air concentration (C_{air}, in $\mu g/m^3$) in EQ 5.4.1.4 A.

Unlike cancer risk assessment, no discount factor (DF) is applied in noncancer assessment for partial overlap between the worker's schedule and the source's emission schedule. Adjustments for worker vacations, work shifts for shortened weeks (e.g., 1 - 4 days), and worker time away on weekends are also not appropriate.

An alternative refined post-processing method, described in Appendix M, may be used to estimate the air concentration the worker is exposed to during their work schedule. OEHHA may be consulted about the particular chemical involved if it is important to make a more refined analysis.

The equation to adjust the annual average air concentration to a worker 8-hour exposure concentration (i.e., the adjusted annual average ground level concentration) is expressed as:

A. Equation 5.4.1.4 A: $$\text{Adjusted } C_{air} \ (\mu g/m^3) = C_{air} \times WAF$$

Where WAF is determined as:

B. Equation 5.4.1.4 B: $$WAF = (H_{res} / H_{source}) \times (D_{res} / D_{source})$$

a: Assumptions for EQ 5.4.1.4 B:

1. No adjustment of the WAF allowed for partial overlap of the worker's schedule and the source's emission schedule.

Alternatives for calculating off-site worker Adjusted C_{air} in EQ 5.4.1.4 A-B:

1. Rather than calculate the WAF for a non-continuous emitting facility, a post-processing of the hourly raw dispersion model output and examination of the hourly concentrations that fall within the offsite worker's shift can be conducted to estimate the air concentration the worker is exposed to. This method is a more refined, complex, and time consuming approach, but should result in a more representative exposure concentration. See Appendix M for information on how to simulate the exposure concentration for the off-site worker.
2. For continuously-emitting facilities (i.e., 24 hrs/day, 7 days/week), if an assessor does not wish to assume the worker breathes the long-term annual average concentration during the work shift, then a refined concentration can also be post-processed as described in Appendix M. All alternative assumptions should be approved by the reviewing authority and supported in the presentation of results.

For residential exposure to non-continuously operating facilities, the modeled maximum 1-hour and chronic air concentrations at the MEIR are determined for noncancer hazard assessment. Hazard assessment for repeated 8-hour exposure at the MEIR is not required. Chronic exposure assessment based on the annual average air concentration should adequately protect individuals, in part because residents are considered to be present at the MEIR at or near 24 hrs per day. Many facilities operate for periods longer than 8 hours per day and the hazards are better characterized based on chronic exposure. Nevertheless, differences between 8-hour and chronic exposures (i.e., higher daily 8-hour exposures vs. lower longer daily exposure 24 hrs/day) may result in different toxicological responses including potentially greater toxicological responses with either 8-hour or chronic exposure. There may also be cases such as special meteorological situations (e.g., significant diurnal-nocturnal meteorological differences) where the 8-hour REL will be more protective than the chronic REL. Thus, the air districts may also elect to have an 8-hour hazard assessment performed at the MEIR, using daily 8 hour exposures and the 8 hr RELs.

Eight-hour exposure assessment is not recommended for continuously emitting sources for residential receptors. In this situation it is only necessary to estimate chronic exposure based on the annual average concentration. However, there may be situations where the air district may wish to assess an 8-hour residential exposure to continuously operating facilities, for example, where there are significant differences in modeled concentration of emissions during the day due to diurnal wind patterns.

For estimating the air concentration from non-continuously operating facilities, EQ 5.4.1.4.A is also used to adjust the annual average concentration to what the residents are exposed to. This is the air concentration that the 8-hour REL will be compared to as discussed in Chapter 8. The alternative refined post-processing method described in Appendix M may also be used to estimate residential exposure.

In summary, the requirements for noncancer hazard assessment using the Hazard Index approach at the MEIW and MEIR are as follows.

For offsite worker exposure:

- Acute hazard assessment based on the maximum 1-hour air concentrations and 1-hour RELs
- Eight-hour hazard assessment based on daily average 8-hour exposure (estimated using adjusted annual average air concentration in EQ 5.4.1.4 A and B or by post-processing method in App. M) for those substances with 8-hour RELs
- Chronic hazard assessment based on annual average exposure and chronic RELs, and oral chronic RELs for noninhalation routes of multipathway substances

For residential exposure:

- Acute hazard assessment based on the maximum 1-hour air concentration and 1-hour RELs
- Eight-hour hazard assessment based on daily average 8-hour exposure not required, but can be performed at the discretion of the air districts for exposure to non-continuously operating facilities based on the adjusted annual average air concentration (EQ 5.4.1.4 A and B or method in App. M). Eight-hour assessments not recommended for exposure to continuously operating facilities
- Chronic hazard assessment based on annual average exposure and chronic RELs, and oral chronic RELs for noninhalation routes of multipathway substances

5.4.1.5 Exposure Frequency and Age Groupings for Noncancer Hazard Assessment

For cancer risk, the basic assumption is that risk is associated with cumulative dose of carcinogen. Thus, the dose used to estimate cancer risk can be adjusted for exposure frequency, as well as time spent within the MEIR or MEIW location. Chronic RELs are not necessarily related to cumulative dose. Thus, adjusting the estimated dose used to calculate hazard index for exposure frequency or time away from the MEIR or MEIW is not appropriate.

The average daily dose for chronic noncancer assessment is based on exposure beginning at birth to 70 years of age, necessitating calculation of a time-weighted average for age 0-2, 2-16 and 16-70 years. Since we are not applying Age Sensitivity Factors for assessing non-cancer hazard, the 3rd trimester is not explicitly called out for determining dose, as it is for cancer risk assessment. Rather adult exposure is considered, which would include pregnant women in any trimester. Both inhalation and oral RELs incorporate safety factors to protect sensitive human populations.

5.4.2 *Estimation of Exposure through Dermal Absorption*

Exposure through dermal absorption (dose-dermal) is a function of the soil or dust loading of the exposed skin surface, the amount of skin surface area exposed, and the concentration and availability of the substance. In the previous edition of OEHHA's

exposure guidelines document (OEHHA, 2000), we recommended using specified average and high-end point estimate values for four of the variates (body weight, exposed surface area of skin, soil load on skin and frequency of exposure) in the stochastic analysis for dermal dose. This equation required multiplying values together, which could lead to overly conservative exposure estimates when high-end values were used. By combining information from the four variates into one composite distribution, over-conservatism may be avoided.

To this end, OEHHA created a new variate, "annual dermal load", or ADL, which is a composite of the body surface area (BSA) per kg body weight, exposure frequency, and soil adherence variates. Point estimates from the composite "annual dermal load" can be used for point estimate assessments while parameters and information on the type of distribution (e.g., lognormal) can be used for Tier III stochastic risk assessments. For details on the development of the ADL, refer to the Technical Support Document for Exposure and Stochastic Analysis (OEHHA, 2012).

5.4.2.1 Dermal Dose for Cancer Risk Assessment

The dose through residential dermal exposure to contaminated soil varies by age and is calculated for each age group (e.g., 3rd trimester, 0<2 yrs, 2<9 yrs, 2<16 yrs, 16<30 and 16-70 yrs). These age-specific groupings are needed in order to properly use the age sensitivity factors for cancer risk assessment (see Chapter 8). This pathway is also assessed for exposure to offsite workers; a separate ADL for offsite workers is presented in Table 5.11. Children at a MEIW daycare, if present, may also be assessed for exposure if the District deems it advisable.

A. Equation 5.4.2.1: $$\mathbf{Dose_{dermal} = ADL \times Cs \times ABS \times 10^{-9} / 365}$$

1. $Dose_{dermal}$ = Exposure dose through dermal absorption (mg/kg-d)
2. ADL = Annual dermal load (mg soil/kg BW-yr)
3. C_s = Average soil concentration (μg/kg)
4. ABS = Fraction absorbed across skin (unitless)
5. 10^{-9} = Conversion factor for chemical & soil (μg to mg, mg to kg)
6. 1/365 = Conversion factor for ADL from yrs to days

a: Recommended default values for EQ 5.4.2.1:

1. ADL = See Table 5.11 (point estimates) & Table 5.12 a-d (distributions)
2. C_s = Calculated above in EQ 5.3.2 A
3. ABS = See Table 5.13

b: Assumption for EQ 5.4.2.1:

1. The ADL for the third trimester of the fetus is based on the ADL of the mother; when normalized to body weight, we assume that exposure to the

mother and the fetus will be the same. The mother's exposure is based on that of adults 16-30 years of age in Table 5.11 and 5.12d.

2. Exposure frequency (EF) for vacation time spent away from exposure does not appear as a variate in EQ 5.4.2.1, as it is incorporated in the ADL and includes a 2-week vacation per year away from dermal soil exposure for both residents and offsite workers.

Climate will strongly influence people's choice of clothing. Due to California's varied climatic regions and existing data on clothing choices at different temperatures, three levels of climatic conditions, warm, mixed, and cold, are used to describe California's climate regions:

1. A warm climate is characteristic of Southern California areas such as Los Angeles, which can have warm to hot temperatures throughout the year.
2. A "mixed" climate is one that has warm-to-hot temperatures during much of the year (daily highs over 80 degrees are common), roughly from April to October, and cold temperatures (lows near or below freezing) during the remainder of the year. The mountains and central valley are examples of a mixed climate.
3. A cold climate is representative of San Francisco, Eureka, and other northern coastal communities, which have cool temperatures (daily highs of less than 65 degrees) for the majority of the year and can receive a considerable amount of fog and rainfall.

OEHHA recommends consulting the local air district for assistance on selecting the most appropriate climate.

Table 5.11 Recommended Annual Dermal Load Point Estimates (in mg/kg-yr) for Dermal Exposure

	3rd Trimester[a]	Children 0<2 yrs	Children 2<9 yrs	Children 2<16 yrs	Adults[b]	Offsite Worker[c]
Warm climate						
Mean	1.2×10^3	3.6×10^3	7.5×10^3	6.4×10^3	1.2×10^3	2.6×10^3
95th percentile	2.6×10^3	4.3×10^3	9.1×10^3	8.5×10^3	2.6×10^3	5.0×10^3
Mixed climate						
Mean	1.1×10^3	2.2×10^3	6.6×10^3	5.7×10^3	1.1×10^3	2.6×10^3
95th percentile	2.4×10^3	2.9×10^3	8.7×10^3	8.1×10^3	2.4×10^3	5.0×10^3
Cold climate						
Mean	0.7×10^3	1.2×10^3	3.1×10^3	2.8×10^3	0.7×10^3	2.6×10^3
95th percentile	2.1×10^3	1.9×10^3	5.2×10^3	5.1×10^3	2.1×10^3	5.0×10^3

[a] The ADL for the 3rd trimester of the fetus is based on the ADL of the mother; when normalized to body weight, we assume that exposure to the mother and the fetus will be the same

[b] Residential adult ADLs are for both 16<30 and 16-70 year age groups

[c] Assumes exposure only to face, hands and forearms regardless of climate region

4,4'methylene dianiline	10
Pentachlorophenol	[a]
Polychlorinated biphenyls	14
Polychlorinated dibenzo-p-dioxins and dibenzofurans	3
Polycyclic aromatic hydrocarbons	13

[a] To be determined in future amendments to the Hot Spots Program

Skin permeability is related to the solubility or strength of binding of the chemical in the delivery matrix (soil or other particles) versus the receptor matrix, the skin's stratum corneum. Fractional dermal absorption point estimate values were derived by OEHHA from available literature sources for the semi-volatile and nonvolatile chemicals in the "Hot Spots" program. The rationale for the chemical-specific dermal absorption fraction values, and the use of default values in cases where sufficient data are lacking, can be found in Appendix F of the Technical Support Document for Exposure and Stochastic Analysis (OEHHA, 2012).

5.4.2.2 Chronic Noncancer Dermal Dose

Dermal exposure, and thus annual dermal load (ADL), varies by age group. Therefore, a time-weighted average ADL for age 0-70 years (0-2, 2-16, and 16-70 years) is estimated for chronic residential exposure using ADL values in Table 5.12. This exposure pathway is also assessed for offsite workers using the offsite worker ADL values in Table 5.12d. Children at a MEIW daycare, if present, may also be assessed for exposure if the District deems it advisable. The contribution to the dermal dose is determined for each age group in EQ 5.4.2.2:

A. Equation 5.4.2.2: $\mathbf{Dose_{dermal} = ADL \times Cs \times ABS \times 10^{-9} \times ED/AT \times (1/350)}$

1. $Dose_{dermal}$ = Exposure dose through dermal absorption (mg/kg/d)
2. ADL = Annual dermal load (mg/kg-yr), age-specific
3. Cs = Average soil concentration (μg/kg)
4. ABS = Fraction absorbed across skin (unitless)
5. 10^{-9} = Conversion factor for chemical & soil (μg to mg, mg to kg)
6. 1/350 = Conversion factor for ADL from yrs to days (Note: this conversion is needed to remove EF, expressed as 350 days/365 days, from the ADLs in Table 5.12a-d)
7. ED = Exposure duration for specified age groups: 2 yrs for 0<2, 14 yrs for 2<16, 54 yrs for 16-70 for residential exposure,
8. AT = Averaging time for residential exposure – 70 yrs

a: Recommended default values for EQ 5.4.2.2:

1. ADL = See Table 5.11 for point estimates by age group, climate region and receptor type (resident or worker)
2. Cs = Calculated above in EQ 5.3.2 A
3. ABS = See Table 5.13

b: Recommended off-site worker default modifications to EQ 5.4.2.2:

1. Chronic dermal dose to the off-site worker assumes only adult exposure and is incorporated into the off-site worker ADL in Table 5.12d.
2. A time-weighted average estimate of dose is not necessary and the ED and AT variates are left out of EQ 5.4.2.2 for dermal dose to the worker.

c: Recommended nursing mother default modifications to EQ 5.4.2.2:

1. For dermal dose to mother's milk, use the ADL for age 16-30 years in Table 5.12d.
2. The ED and AT variates in EQ 5.4.2.2 are left out for dermal dose in the mother's milk pathway.

d: Assumptions for EQ 5.4.2.2:

1. For cancer risk assessment, Exposure Frequency (EF) for vacation time away from exposure is incorporated into the ADLs shown in Tables 5.11 and 5.12 using the basic assumption that cancer risk is associated with cumulative dose of carcinogen. The dose used to estimate cancer risk can be adjusted for EF, and for time spent within the MEIR or MEIW location. Chronic RELs are not necessarily related to cumulative dose. Thus, adjusting the estimated dose for EF at the MEIR or MEIW is not appropriate, and the unadjusted daily rate is used in EQ 5.4.2.2.
2. For worker exposure, the annual average concentration should not be adjusted to account for worker and facility emission schedules, as done for

inhalation cancer risk assessment. The pollutant will be deposited and accumulate in the soil in the absence or presence of the worker; therefore, the total deposition and soil concentration will be dependent on the annual average air concentration.

For residential chronic exposure, the dermal dose contribution for each age group is summed together to obtain the time-weighted average daily dermal dose for chronic hazard assessment:

(ADL age 0<2 × Cs × ABS × 10^{-9} × 2 / 70 × (1/350)) +

(ADL age 2<16 × Cs × ABS × 10^{-9} × 14 / 70 × (1/350)) +

(ADL age 16-70 × Cs × ABS × 10^{-9} × 54 / 70 × (1/350)) = Chronic $Dose_{dermal}$

5.4.3 *Estimation of Exposure through Ingestion*

Exposure through ingestion is a function of the concentration of the substance in the ingested soil, water, and food, the gastrointestinal absorption of the substance, and the amount ingested.

5.4.3.1 Exposure through Ingestion of Soil

There are no distributions for soil ingestion currently recommended. Tier III stochastic risk assessments should include a high-end point estimate of soil ingestion, soil loading, exposure frequency and soil area.

5.4.3.1.1 Soil Ingestion Dose for Cancer Risk

The exposure dose through residential soil ingestion varies by age and is calculated for each age group ((e.g., 3rd trimester, 0<2 yrs, 2<9 yrs, 2<16 yrs, 16<30 and 16-70 yrs). These age-specific groupings are needed in order to properly use the age sensitivity factors for cancer risk assessment (see Chapter 8). This pathway is also assessed for exposure to off-site workers. Children at a MEIW daycare, if present, may also be assessed for exposure if the District deems it advisable. The dose from inadvertent soil ingestion can be estimated by the point estimate approach using the following general equation:

A. Equation 5.4.3.1.1: $DOSE_{soil} = C_{soil} \times GRAF \times SIR \times 10^{-9} \times EF$

1. $DOSE_{soil}$ = Dose from soil ingestion (mg/kg BW-day)
2. 10^{-9} = Conversion factor (μg to mg, mg to kg)
3. C_{soil} = Concentration of contaminant in soil (μg/kg)
4. GRAF = Gastrointestinal relative absorption fraction, chemical-specific (unitless)
5. SIR = Soil ingestion rate (mg/kg BW-day)
6. EF = Exposure frequency (unitless), (days/365 days)

a: Recommended default values for EQ 5.4.3.1.1:

1. C_{soil} = Calculated above in EQ 5.3.2 A
2. GRAF = See Table 5.2
3. SIR = See Table 5.14
4. EF = 350 d/year resident, 250 d/year worker

In this approach, it is assumed that the soil ingested contains a representative concentration of the contaminant(s) and the concentration is constant over the exposure period.

The term **GRAF**, or gastrointestinal relative absorption factor, is defined as the fraction of contaminant absorbed by the GI tract relative to the fraction of contaminant absorbed from the matrix (feed, water, other) used in the study(ies) that is the basis of either the cancer potency factor (CPF) or the Reference Exposure Level (REL). If no data are available to distinguish absorption in the toxicity study from absorption from the environmental matrix in question (i.e., soil), then GRAF = 1. The GRAF allows for adjustment for absorption from a soil matrix if it is known to be different from absorption across the GI tract in the study used to calculate the CPF or REL. In most instances, the GRAF will be 1.

Table 5.14 Recommended Soil Ingestion Rate (SIR) Estimates for Adults and Children (mg/kg-day)*

Age Groups (years)	Mean (mg/kg-day)	95th % (mg/kg-day)
3rd Trimester[a]	0.7	3
0<2	20	40
2<9	5	20
2<16	3	10
16<30	0.7	3
16 to 70	0.6	3
PICA adult	NR	-

[a] Assumed to be the mother's soil ingestion rate (adult age 16 <30)
* Soil includes outdoor settled dust
NR = No recommendation

5.4.3.1.2 Chronic Noncancer Dose for Soil Ingestion

The soil ingestion rate varies by age. A time-weighted average approach is used to combine soil intake rates of the age groupings (i.e., 0<2 yrs, 2<16 yrs, and 16-70 yrs) to determine the residential soil ingestion dose for chronic noncancer hazard assessment. This pathway is also assessed for exposure to offsite workers using the adult intake values for age 16-70 years in Table 5.14. Children at a MEIW daycare, if present, may also be assessed for exposure if the District deems it advisable. The contribution to the soil ingestion dose by each age group is determined in EQ 5.4.3.1.2:

A. Equation 5.4.3.1.2: $$DOSE_{soil} = C_{soil} \times GRAF \times SIR \times 10^{-9} \times ED/AT$$

1. $DOSE_{soil}$ = Dose from soil ingestion (mg/kg BW-day)
2. 10^{-9} = Conversion factor (μg to mg, mg to kg)
3. C_{soil} = Concentration of contaminant in soil (μg/kg)
4. GRAF = Gastrointestinal relative absorption fraction, unitless; chemical-specific
5. SIR = Soil ingestion rate (mg/kg BW-day)
6. ED = Exposure duration for a specified age group: 2 yrs for 0<2, 14 yrs for 2<16, 54 yrs for 16-70
7. AT = Averaging time for lifetime exposure – 70 yrs

a: Recommended default values for EQ 5.4.3.1.2:

1. C_{soil} = Calculated above in EQ 5.3.2 A
2. GRAF = See Table 5.2
3. SIR = See Table 5.14; use 16-70 age group SIR for workers

b: Recommended off-site worker default modifications to EQ 5.4.3.1.2:

1. A time-weighted average estimate of dose is not necessary and the ED and AT variates are left out of EQ 5.4.3.1.2 for oral soil dose to the worker.

c: Recommended nursing mother default modifications to EQ 5.4.3.1.2:

1. For mother's ingested soil dose to milk, use the SIR for age 16-30 years in Table 5.14.
2. The ED and AT variates in EQ 5.4.3.1.2 are left out for soil ingestion dose in the mother's milk pathway.

d: Assumptions for EQ 5.4.3.1.2:

1. For worker exposure, the annual average concentration should not be adjusted to account for overlap of worker and facility emission schedules. The pollutant will be deposited and accumulate in the soil in the absence or presence of the worker; therefore, the total deposition and soil concentration will be dependent on the annual average air concentration.

For residential exposure, the soil ingestion dose contribution for each age group is summed together to obtain the time-weighted average daily soil intake dose for chronic hazard assessment:

(SIR for age 0<2 yrs × C_{soil} × GRAF × 10^{-9} × 2 / 70) +

(SIR for age 2<16 yrs × C_{soil} × GRAF × 10^{-9} × 14 / 70) +

(SIR for age 16-70 yrs × C_{soil} × GRAF × 10^{-9} × 54 / 70) = Chronic $Dose_{soil}$

5.4.3.2 Exposure through Ingestion of Food

The exposure through food ingestion can be through ingestion of home-grown plant products (categorized as leafy, protected, exposed and root produce), home-raised animals (categorized as meat, cow's milk and eggs), angler-caught fish and mother's milk. When a specific food pathway is a dominant pathway (e.g., homegrown produce), and multiple pathways such as home raised meat, milk, and eggs categories all need to be assessed, the 95th percentile default consumption rate for the driving exposure pathway is used, while the mean consumption values for the remaining exposure pathways (i.e., food categories) are used. See Section 8.2.6 for a complete discussion of the methodology on how to implement the derived methodology.

5.4.3.2.1 Dose for Cancer Risk from Home-Grown Produce

Exposure through ingesting home-grown produce (DOSEp) is a function of the type of crop (i.e., exposed, leafy, protected, root), gastrointestinal relative absorption factor, bioavailability and the fraction of plant ingested that is homegrown. The calculation is done for each type of crop, then summed to get total dose for this pathway. The

exposure dose through ingestion of home-grown produce varies by age and is calculated for each age group (e.g., 3rd trimester, 0<2 yrs, 2<9 yrs, 2<16 yrs, 16<30 and 16-70 yrs). These age-specific groupings are needed in order to properly use the age sensitivity factors for cancer risk assessment (see Chapter 8).

A. Equation 5.4.3.2.1: $$DOSEp = C_v \times IP \times GRAF \times L \times EF \times 10^{-6}$$

1. DOSEp = Exposure dose through ingestion of home-grown produce (mg/kg/d)
2. C_v = Concentration in specific type of crop, i.e., exposed, leafy, protected, root (μg/kg)
3. IP = Consumption of specific type of crop (g/kg BW*day)
4. GRAF = Gastrointestinal relative absorption factor (unitless)
5. L = Fraction of plant type consumed that is home-grown or locally grown (unitless)
6. EF = Exposure frequency (unitless, days/365 days)
7. 10^{-6} = Conversion factors (μg/kg to mg/g)

a: Recommended default values for Equation 5.4.3.2.1:

1. C_v = Calculated above in EQ 5.3.4.1 A
2. IP = See Table 5.15 (point estimates) and 5.16a-e (distributions)
3. GRAF = See Table 5.2
4. L = Site-specific survey is recommended. Otherwise, see Table 5.17 for Tier I default values
5. EF = 0.96 (350 d/365 d in a yr)

Once the dose for each type of crop that applies is calculated (See Section 5.3.4.1 for definition of crops types), the doses are summed to get the total dose for the home-grown produce pathway:

Total DOSEp = DOSEp (leafy) + DOSEp (root) + DOSEp (exposed) + DOSEp (protected)

The total home-grown produce dose will need to be calculated for each age group that applies.

5.4.3.2.2 Dose for cancer risk from home-raised meat, eggs, and cow's milk

Exposure through ingesting home-raised or farm animal products ($DOSE_{fa}$) is a function of the type of food (meat, eggs and cow's milk), gastrointestinal relative absorption factor, bioavailability and the fraction of food ingested that is home-raised. The only meat sources considered here are beef, pork and poultry. Unlike the home-grown produce pathway, the dose is calculated and presented separately for each type of home-raised food. The age-specific groupings to determine dose (3rd trimester, 0<2 yrs, 2<9 yrs, 2<16 yrs, 16<30 yrs or 16-70 yrs) is needed in order to properly use the age sensitivity factors for cancer risk assessment (see Chapter 8).

A. Equation 5.4.3.2.2: $DOSE_{fa} = C_{fa} \times I_{fa} \times GRAF \times L \times EF \times 10^{-6}$

1. $DOSE_{fa}$ = Exposure dose through ingestion of home-raised animal product (mg/kg/d)
2. C_{fa} = Concentration in animal product, e.g., beef, pork, poultry, dairy, eggs (μg/kg)
3. I_{fa} = Consumption of animal product (g/kg BW-day)
4. GRAF = Gastrointestinal relative absorption factor (unitless)
5. L = Fraction of animal product consumed that is home-raised or locally produced (unitless)
6. EF = Exposure frequency (unitless, days/365 days)
7. 10^{-6} = Conversion factors (μg/kg to mg/g)

a: Recommended default values for EQ 5.4.3.2.2:

1. C_{fa} = Calculated above in EQ 5.3.4.2 A
2. I_{fa} = See Table 5.15 (point estimates) and Table 5.16a-e (distributions)
3. GRAF = See Table 5.2
4. L = Site-specific survey is recommended. Otherwise, see Table 5.17 for Tier I default values
5. EF = 0.96 (350 days / 365 days in a year)

5.4.3.2.3 Chronic Noncancer Dose for Ingestion of Food

For oral noncancer hazard assessment, a time-weighted average approach is used to combine food ingestion rates for the age groups (i.e., 0<2, 2<16 and 16-70 yrs) to estimate the chronic dose for residential exposure. The equation used to estimate dose through home-grown produce and home-raised meat/eggs/cow's milk is similar and is shown below in one equation. Similar to the cancer risk dose calculation, home-grown produce is presented as a total dose for all types of crops (See Section 5.4.3.2.1) and home-raised animal product dose is presented separately for each type of animal product that applies (See Section 5.4.3.2.2).

The contribution to the food intake dose is determined for each age group in EQ 5.4.3.2.3:

A. Equation 5.4.3.2.3: $\mathbf{DOSE_{food} = C_{food} \times I_{food} \times GRAF \times L \times 10^{-6} \times ED/AT}$

1. $DOSE_{food}$ = Exposure dose through ingestion of home-grown produce or home-raised animal product (mg/kg/d)
2. C_{food} = Concentration (μg/kg) in produce (e.g., exposed, leafy, protected, root) or animal product (e.g., beef, pork, poultry, dairy, eggs)
3. I_{food} = Consumption of produce or animal product (g/kg BW-day)
4. GRAF = Gastrointestinal relative absorption factor (unitless)
5. L = Fraction of produce or animal product consumed that is home-grown (unitless)
6. 10^{-6} = Conversion factors (μg/kg to mg/g)
7. ED = Exposure duration for a specified age group (2 yrs for 0<2, 14 yrs for 2<16, 54 yrs for 16-70
8. AT = Averaging time for lifetime exposure: 70 yrs

a: Recommended default values for EQ 5.4.3.2.3:

1. C_{food} = Calculated above in EQ 5.3.4.1 A (for home-grown produce) or EQ 5.3.4.2 A (for home-raised animal products)
2. I_{food} = Age-specific, see Table 5.15 for point estimates
3. GRAF = See Table 5.2
4. L = Site-specific survey is recommended. Otherwise, see Table 5.17 for Tier I default values

b: Recommended nursing mother default modifications to EQ 5.4.3.2.3:

1. For the mother's dose to milk through ingested food, use the food intake rates for age 16-30 years in Table 5.15 and 5.16d.
2. The ED and AT variates in EQ 5.4.3.2.3 are left out for ingested food dose in the mother's milk pathway.

Following calculation of the intake dose contributions for each age group, the intake rates for home-grown produce and the intake rates for home-raised animal products are summed separately to obtain the residential time-weighted average intake dose for chronic residential exposure to home-grown produce and to home-raised animal products:

(I_{food} for age 0<2 yrs × C_{food} × GRAF × L × 10^{-6} × 2 / 70) +

(I_{food} for age 2<16 yrs × C_{food} × GRAF × L × 10^{-6} × 14 / 70) +

(I_{food} for age 16-70 yrs × C_{food} × GRAF × L × 10^{-6} × 54 / 70) = Chronic $Dose_{food}$

Table 5.15 Recommended Average and High End Point Estimate Values for Home Produced Food Consumption (g/kg-day)

Food Category	Third Trimester		Ages 0<2		Ages 2<9	
Produce	Avg.	High End	Avg.	High End	Avg.	High End
Exposed	1.9	5.9	11.7	30.2	7.4	21.7
Leafy	0.9	3.2	3.8	10.8	2.5	7.9
Protected	1.7	5.8	5.9	17.5	4.7	13.3

Table 5.17 Default Values for L in EQs 5.4.3.2.1., 5.4.3.2.2 and 5.4.3.2.3: Fraction of Food Intake that is Home-Produced

Food Type	Households that Garden[a]	Households that Farm[a]
Avg. Total Veg & Fruits	0.137	0.235
	Households that Garden/Hunt[b]	**Households that Farm[b]**
Beef	0.485	0.478
Pork	0.242	0.239
Poultry	0.156	0.151
Eggs	0.146	0.214
Total Dairy (Cow's milk)	0.207	0.254

[a] As a default for home-produced leafy, exposed, protected and root produce, OEHHA recommends 0.137 as the fraction of produce that is home-grown. The households that grow their own vegetables and fruits are the population of concern. In rural situations where the receptor is engaged in farming, OEHHA recommends 0.235 as the default value for fraction of leafy, exposed, protected and root produce that is home-grown.

[b] OEHHA recommends the fraction home-raised under "Households that raise animals/hunt" (for beef, pork, poultry (chicken), eggs and dairy (cow's milk), with the exception of rural household receptors engaged in farming. OEHHA recommends that the fractions listed under "Households that farm" be used for the rural household receptors.

5.4.3.3 Exposure through Ingestion of Water

Intake of drinking water varies by age on a ml per kg body weight per day basis resulting in differences in exposure dose by age. The age-specific groupings to determine dose are needed in order to properly use the age sensitivity factors for

cancer risk assessment (see Chapter 8) and to calculate a time-weighted average dose for chronic noncancer assessment.

5.4.3.3.1 Dose for Cancer Risk through Ingestion of Water

$DOSE_{water}$ is calculated for each age group (i.e., 3rd trimester, 0<2 yrs, 2<9 yrs, 2<16 yrs, 16<30 yrs and 16-70 yrs), then incorporated into EQ 8.2.5 in Chapter 8 to determine cancer risk through exposure in drinking water.

A. Equation 5.4.3.3.1: $$\mathbf{DOSE_{water} = C_w \times WIR \times ABS_{wa} \times Fdw \times EF \times 10^{-6}}$$

1. $DOSE_{water}$ = Exposure dose through ingestion of water (mg/kg BW/d)
2. C_w = Water concentration (μg/L)
3. WIR = Water ingestion rate (ml/kg BW-day)
4. ABS_{wa} = Gastrointestinal relative absorption factor (unitless)
5. Fdw = Fraction of drinking water from contaminated source
6. EF = Exposure frequency (unitless, days/365 days)
7. 10^{-6} = Conversion factors (mg/μg)(L/ml)

a: Recommended default values for EQ 5.4.3.3.1:

1. C_w = Calculated above 5.3.3 A
2. WIR = See 5.18 (point estimates) and Table 5.19 (distributions)
3. ABS_{wa} = Default set to 1
4. Fdw = Default set to 1, although a site-specific survey is recommended for this variate
5. EF = 0.96 (350 days/365 days in a year)

5.4.3.3.2 Chronic Noncancer Dose through Ingestion of Water

Because water intake varies by age group, a time-weighted average intake approach is used to determine the daily water ingestion dose for chronic residential exposure. The contribution to the water ingestion dose is determined for each age group (i.e., 0<2, 2<16 and 16-70 yrs) in EQ 5.4.3.3.2.

A. Equation 5.4.3.3.2:

$$\mathbf{DOSE_{water} = C_w \times WIR \times ABS_{wa} \times Fdw \times 10^{-6} \times ED/AT}$$

1. $DOSE_{water}$ = Exposure dose through ingestion of water (mg/kg BW/d)
2. C_w = Water concentration (μg/L)
3. WIR = Water ingestion rate (ml/kg BW-day)
4. ABS_{wa} = Gastrointestinal absorption factor
5. Fdw = Fraction of drinking water from contaminated source (site-specific)
6. 10^{-6} = Conversion factors (mg/μg)(L/ml)
7. ED = Exposure duration for a specified age group: 2 yrs for 0<2, 14 yrs for 2<16, 54 yrs for 16-70
8. AT = Averaging time for residential exposure: 70 yrs

a: Recommended default values for EQ 5.4.3.3.2:

1. C_w = Calculated above in 5.3.3 A
2. WIR = See 5.18 (point estimates)
3. ABS_{wa} = Default set to 1
4. Fdw = Default set to 1, although a site-specific survey is recommended for this variate

b: Recommended nursing mother default modifications to EQ 5.4.3.3.2:

1. For the dose to mother's milk through water ingestion, use the WIR for age 16-30 years in Table 5.18.
2. The ED and AT variates in EQ 5.4.3.3.2 are left out for ingested water dose in the mother's milk pathway.

The water intake dose contribution for each age group is summed together to obtain the time-weighted average daily residential water ingestion dose:

(WIR for age 0<2 yrs × C_w × ABS_{wa} × Fdw × 10^{-6} × 2 / 70) +

(WIR for age 2<16 yrs × C_w × ABS_{wa} × Fdw × 10^{-6} × 14 / 70) +

(WIR for age 16-70 yrs × C_w × ABS_{wa} × Fdw × 10^{-6} × 54 / 70) = Chronic $Dose_{water}$

5.4.3.4 Exposure through Ingestion of Angler-caught Fish

Exposure through ingestion of angler-caught fish ($DOSE_{fish}$) is a function of the fraction of fish ingested that is caught in the exposed water body, which differs for each age grouping, and the gastrointestinal absorption factor. Ingestion of angler-caught fish on a mg/kg body weight per day basis varies by age resulting in differences in exposure dose by age. The age-specific groupings to determine dose is needed primarily to properly use the age sensitivity factors for cancer risk assessment (see Chapter 8) and to calculate a time-weighted average dose for chronic noncancer assessment.

5.4.3.4.1 Cancer Risk Dose via Ingestion of Angler-Caught Fish

$DOSE_{fish}$ is calculated for each age group separately (i.e., 3rd trimester, 0<2 yrs, 2<9 yrs, 2<16 yrs, 16<30 yrs and 16-70 yrs), then incorporated into EQ 8.2.5 in Chapter 8 to determine cancer risk through exposure to angler-caught fish.

A. Equation 5.4.3.4.1: $$DOSE_{fish} = C_t \times I_{fish} \times Gf \times L \times EF \times 10^{-6}$$

1. $DOSE_{fish}$ = Dose via ingestion of angler-caught fish (mg/kg BW-day)
2. C_t = Concentration in fish muscle tissue (μg/kg)
3. I_{fish} = Angler-caught fish ingestion rate (g/kg BW per day)
4. Gf = Gastrointestinal absorption factor (unitless)
5. L = Fraction of fish caught at exposed site (unitless)
6. EF = Exposure frequency (days/365 days)
7. 10^{-6} = Conversion factor (mg/μg, kg/g)

a: Recommended default values for Equation 5.4.3.4.1:

1. C_t = Calculated above in Equation 5.3.4.7
2. I_{fish} = See Table 5.20 (point estimates) and Table 5.21 (distributions)
3. Gf = Default set to 1
4. L = Default set to 1 for fraction of fish caught locally, although a site-specific survey is recommended for this variate
5. EF = 0.96 (350 days/365 days in a yr)

5.4.3.4.2 Chronic Noncancer Dose via Ingestion of Angler-Caught Fish

Angler-caught fish consumption varies by age group. A time-weighted average intake for residential consumption over 70 years is used to determine dose for average and high-end exposure. The contribution to the angler-caught fish consumption dose is determined for each age group in EQ 5.4.3.4.2:

A. Equation 5.4.3.4.2: $\mathbf{DOSE_{fish} = C_t \times I_{fish} \times Gf \times L \times 10^{-6} \times ED/AT}$

1. $DOSE_{fish}$ = Dose via ingestion of angler-caught fish (mg/kg BW-day)
2. C_t = Concentration in fish muscle tissue (μg/kg)
3. I_{fish} = Angler-caught fish ingestion rate (g/kg BW per day)
4. Gf = Gastrointestinal absorption factor (unitless)
5. L = Fraction of fish caught at exposed site (unitless)
6. 10^{-6} = Conversion factor (mg/μg, kg/g)
7. ED = Exposure duration for a specified age group: 2 yrs for 0<2, 14 yrs for 2<16 and 54 yrs for 16-70
8. AT = Averaging time for chronic exposure – 70 yrs

a: Recommended default values for Equation 5.4.3.4.2:

1. C_t = Calculated above in Equation 5.3.4.7
2. I_{fish} = See Table 5.20 (point estimates)
3. Gf = Default set to 1
4. L = Default set to 1 for fraction of fish caught locally, although a site-specific survey is recommended for this variate

b: Recommended nursing mother default modifications to EQ 5.4.3.4.2:

1. For the dose to mother's milk through fish consumption, use the I_{fish} for age 16-30 years in Table 5.20.
2. The ED and AT variates in EQ 5.4.3.4.2 are left out for the dose via fish consumption in the mother's milk pathway.

Following calculation of the angler-caught fish consumption dose contribution for each age group, 0<2 yr, 2<16 yr and 16-70 yr fish consumption doses are summed together to obtain the residential chronic dose:

(I_{fish} for age 0<2 yrs × C_t × Gf × L × 10^{-6} × 2 / 70) +

(I_{fish} for age 2<16 yrs × C_t × Gf × L × 10^{-6} × 14 / 70) +

(I_{fish} for age 16-70 yrs × C_t × Gf × L × 10^{-6} × 54 / 70) = Chronic $Dose_{fish}$

Table 5.20 Point Estimate Values for Angler-Caught Fish Consumption (g/kg-day) by Age Group

5.4.3.5 Mother's Milk

Exposure through mother's milk ingestion (Dose-Im) is a function of the average concentration of the substance in mother's milk and the amount of mother's milk ingested. The minimum pathways that the nursing mother is exposed to include inhalation, soil ingestion, and dermal, since the chemicals evaluated by the mother's milk pathway are multipathway chemicals. Other pathways may be appropriate depending on site conditions (e.g., the presence of vegetable gardens or home grown chickens). The compounds currently considered for the mother's milk pathway are:

1. Dioxins and Furans (PCDDS and PCDFs)
2. Polychlorinated biphenyls (PCBs)
3. Polycyclic Aromatic Hydrocarbons (PAHs), including creosotes
4. Lead

These compound classes represent the chemicals of greatest concern for the mother's milk pathway under the Hot Spots program, and for which data are available to estimate transfer coefficients. It is expected that additional transfer coefficients will be developed for other multipathway chemicals in the Hot Spots Program as data becomes available and is reviewed. The nursing mother in the mother's milk pathway is not herself subject to the mother's milk pathway. The summed average daily dose (mg/kg BW-day) from all pathways is calculated for the nursing mother using the equations that follow.

5.4.3.5.1 Cancer Risk Dose to Infant via Mother's Milk

A. Equation 5.4.3.5.1: $$\textbf{Dose-Im} = C_m \times BMI_{bw} \times EF \times 10^{-3}$$

1. Dose-Im = Dose to infant through ingestion of mother's milk (mg/kg BW per day)
2. C_m = Concentration of contaminant in mother's milk (mg/kg milk)
3. BMI_{bw} = Daily breast-milk ingestion rate (g/kg BW-day)
4. EF = Frequency of exposure (days / 365 days)
5. 10^{-3} = Conversion factor (kg to g)

a: Recommended default values for EQ 5.4.3.5.1:

1. C_m = See EQ 5.3.4.8
2. BMI_{bw} = See Table 5.22 for point estimates. For distribution (parametric model) for Tier 3 stochastic risk assessments see Table 5.23.
3. EF = 1 (all 365 days of the first year of birth)

b: Assumptions for EQ 5.4.3.5.1:

1. For the MEIR, mother is exposed from birth up to 25 years of age when the infant is born. The exposed infant is then fully breastfed only during the first year of life.
2. For cancer risk assessment, exposure of breast-feeding infants to contaminants in breast milk applies only to the first year of the 0<2 yr age group for calculation of risk to this group, which then can be summed with the risk calculated for the other age groups (See Chapter 8).

5.4.3.5.2 Chronic Noncancer Dose to Infant via Mother's Milk

For oral noncancer hazard assessment, exposure of the infant through mother's milk ingestion occurs during the first year of life. After one year of age, the mother's milk pathway is not a factor for noncancer assessment.

A. Equation 5.4.3.5.2: $\text{Dose-Im} = C_m \times BMI_{bw} \times 10^{-3}$

1. Dose-Im = Dose to infant through ingestion of mother's milk (mg/kg BW/d)
2. C_m = Concentration of contaminant in mother's milk (mg/kg milk)
3. BMI_{bw} = Daily breast-milk ingestion rate (g/kg BW-day)
4. 10^{-3} = Conversion factor (kg to g)

a: Recommended default values for EQ 5.4.3.5.2:

1. C_m = See EQ 5.3.4.8
2. BMI_{bw} = See Table 5.22 for point estimates

Table 5.22 Default Point Estimates for Breast Milk Intake (BMI_{bw}) for Breastfed Infants

Infant Group	Intake (g/kg-day)
Fully breastfed over the first year (i.e., fed in accordance with AAP recommendations)	
Mean	101
95th percentile	139

Table 5.23 Recommended Distribution of Breast Milk Intake Rates Among Breastfed Infants for Stochastic Assessment* (Averaged Over an Individual's First Year of Life)

	Mean (SD)	Percentile							
		5	10	25	50	75	90	95	99
Intake (g/kg-day)	101 (23)	62	71	85	101	116	130	139	154

* For stochastic analysis, the mother's milk data are normally distributed.

6 - Dose-Response Assessment for Noncarcinogenic Endpoints

6.1 Derivation of Toxicity Criteria for Noncancer Health Effects

Dose-response assessment describes the quantitative relationship between the amount of exposure to a substance (the dose) and the incidence or occurrence of an adverse health impact (the response). Dose-response information for noncancer health effects is used to determine Reference Exposure Levels (RELs). Inhalation RELs are air concentrations or doses at or below which adverse noncancer health effects are not expected even in sensitive members of the general population under specified exposure scenarios. The acute RELs are for infrequent 1 hour exposures that occur no more than once every two weeks in a given year, although this time frame of exposure does not necessarily apply to chemicals that can bioaccumulate (e.g., dioxins and furans, PCBs, and various metals). The chronic RELs are for 24 hour per day exposures for at least a significant fraction of a lifetime, defined as about 8 years (≥12 percent of a 70-year lifespan). The 8-hour RELs are for repeated 8-hour exposures for a significant fraction of a lifetime such as the exposures that offsite workers might typically receive. Eight-hour RELs are only available for 10 chemicals at present, but OEHHA will develop 8-hour RELs as we re-evaluate our existing RELs to ensure they are protective of children's health, and as we develop RELs for new chemicals. There are oral chronic RELs for some chemicals in the Hot Spots program that are semivolatile or nonvolatile and thus subject to deposition and oral ingestion or dermal exposure. The methodology for developing RELs is similar to that used by U.S. EPA in developing the inhalation Reference Concentrations (RfCs) and oral Reference Doses (RfDs).

Review and revision of RELs to take into account new information and sensitive subpopulations including infants and children is an ongoing process. All draft RELs for individual chemicals revised under the current noncancer methodology will undergo public comment and peer review, as mandated by the Hot Spots Act. .

The first step in determining an acute, 8-hour, or chronic REL is to determine a point of departure. The point of departure is preferably determined by the benchmark concentration procedure applied to human or animal studies, but if this method of calculation cannot be used with a particular data set, a no observed adverse effect level (NOAEL) or lowest observed adverse effect level (LOAEL) may be used as the point of departure. The benchmark concentration method (also referred to as the benchmark dose method for oral exposures) is a preferred method to estimate a point of departure because it takes all of the available dose-response data into account to statistically estimate, typically, a 5 percent response rate.

Dosimetric or toxicokinetic adjustments are often made to the point of departure to adjust for differences in dosimetry or kinetics across species or among humans. Time adjustments are generally applied to adjust experimental exposure to the exposure of

interest for the REL (e.g., 1 hour for acute, continuous for chronic). A modified Haber's equation is used where needed to adjust studies with different exposure times to the one-hour period needed for acute RELs. A simple Haber's law (C x T) adjustment for exposure period duration is used for most 8-hour and chronic RELs.

The time and dosimetry adjusted point of departure is divided by uncertainty factors that reflect the limitations in the current toxicology of the chemical. For example, an interspecies uncertainty factor is applied to account for the differences between humans and animals when an animal study is used. An intraspecies uncertainty factor is usually included to account for differences in susceptibility among the human population. In addition, where benchmark dose modeling is not suitable and a NOAEL is not available, a LOAEL to NOAEL uncertainty factor may be applied when the LOAEL serves as the point of departure. If a chronic study is not available to serve as a basis for a chronic REL, then a subchronic uncertainty factor (for chronic and 8-hour RELs only) may also be applied. Finally, if there are data deficiencies, for example, lack of a developmental toxicity study for a chemical, then a database deficiency factor may be applied. The individual uncertainty factors, which range from 2 to 10 depending on the limitations in the data, are multiplied together for a total uncertainty factor. The point of departure is then divided by the total UF to obtain the REL.

The most sensitive toxicological end point is selected as the basis for the REL when there are multiple adverse health effects. The selection of the most sensitive endpoint as the basis for a REL helps ensure that the REL is protective for all health effects. The use of uncertainty factors helps ensure that the REL is protective for nearly all individuals, including sensitive subpopulations, within the limitations of current scientific knowledge. For detailed information on the methodology and derivations for RELs, including guidance on selection of uncertainty factors, see the Air Toxics Hot Spots Risk Assessment Guidelines Technical Support Document for the Derivation of Noncancer Reference Exposure Levels (OEHHA, 2008).

It should be emphasized that exceeding the acute or chronic REL does not necessarily indicate that an adverse health impact will occur. The REL is not the threshold where population health effects would first be seen. However, levels of exposure above the REL have an increasing but undefined probability of resulting in an adverse health impact, particularly in sensitive individuals (e.g., depending on the toxicant, the very young, the elderly, pregnant women, and those with acute or chronic illnesses). The significance of exceeding the REL is dependent on the seriousness of the health endpoint, the strength and interpretation of the health studies, the magnitude of combined safety factors, and other considerations. In addition, there is a possibility that a REL may not be protective of certain small, unusually sensitive human subpopulations. Such subpopulations can be difficult to identify and study because of their small numbers, lack of knowledge about toxic mechanisms, and other factors. It may be useful to consult OEHHA staff when a REL is exceeded (hazard quotient or hazard index is greater than 1.0). Chapter 8 discusses the methods used for determining potential noncancer health impacts and Appendix I presents example calculations used to determine a hazard quotient (HQ) and hazard indices (HI).

Tables 6.1 through 6.3 list the currently adopted acute, 8-hour, and chronic inhalation RELs. Some substances that pose a long-term inhalation hazard may also present a chronic hazard via non-inhalation (oral, dermal) routes of exposure. The oral RELs for these substances are presented in Table 6.3. Appendix L provides a consolidated listing of all the acute, 8-hour, and chronic RELs with the respective target organs that are approved for use by OEHHA and ARB for the Hot Spots Program. Periodically, new or updated RELs are adopted by OEHHA and these guidelines will be updated to reflect those changes. See OEHHA's web site at *www.oehha.ca.gov* (look under "Air", then select "Hot Spots Guidelines") to determine if any new or updated RELs have been adopted since the last guideline update.

6.2 Acute Reference Exposure Levels

OEHHA developed acute RELs for assessing potential noncancer health impacts for short-term, one-hour peak exposures to facility emissions (OEHHA, 2008; http://www.oehha.ca.gov/air/allrels.html). By definition, an acute REL is an exposure that is not likely to cause adverse health effects in a human population, including sensitive subgroups, exposed to that concentration (in units of micrograms per cubic meter or $\mu g/m^3$) for the specified exposure duration on an intermittent basis.

The target organ systems and the acute RELs for each substance are presented in Table 6.1. Many acute RELs are based on mild adverse effects, such as mild irritation of the eyes, nose, or throat, or may result in other mild adverse physiological changes. For most individuals, it is expected that the mild irritation and other adverse physiological changes will not persist after exposure ceases. For RELs that have been recently developed or revised, the notation "sensory irritation" has been added in parenthesis in Table 6.1 for those chemicals that have an acute REL based on sensory irritation of the respiratory system (i.e., nose , throat) and/or eyes.

Other acute RELs are based on reproductive/developmental endpoints, such as teratogenicity or fetotoxicity, which are considered severe adverse effects. The inhalation pathway is the only pathway to assess for acute exposure. Other non-inhalation pathways of exposure are evaluated for worker and residential scenarios where the exposures are chronic or repeated daily in nature. The oral RELs are used to evaluate the non-inhalation pathways of exposure. Noninhalation (oral) RELs are discussed in Section 6.5. Chapter 8 discusses the methods used for determining noncancer acute health impacts. Appendix I presents an example calculation used to determine an HQ and HI.

Table 6.1 Acute Inhalation Reference Exposure Levels (RELs) and Acute Hazard Index Target Organ System(s)

Substance	Chemical Abstract Service Number (CAS)	Acute Inhalation REL ($\mu g/m^3$)	Acute Hazard Index Target Organ Systems(s)
Acetaldehyde	75-07-0	$4.7 \times 10^{+2}$	Eyes; Respiratory System (sensory irritation)
Acrolein	107-02-8	$2.5 \times 10^{+0}$	Eyes; Respiratory System (sensory irritation)
Acrylic Acid	79-10-7	$6.0 \times 10^{+3}$	Eyes; Respiratory System
Ammonia	7664-41-7	$3.2 \times 10^{+3}$	Eyes; Respiratory System
Arsenic and Inorganic Arsenic Compounds (including arsine)	7440-38-2	2.0×10^{-1}	Development; Cardiovascular System; Nervous System
Benzene	71-43-2	$2.7 \times 10^{+1}$	Reproductive/Developmental; Immune System; Hematologic System
Benzyl Chloride	100-44-7	$2.4 \times 10^{+2}$	Eyes; Respiratory System
1,3-Butadiene	106-99-0	$6.6 \times 10^{+2}$	Development
Caprolactam	105-60-2	$5.0 \times 10^{+1}$	Eyes (sensory irritation)
Carbon Disulfide	75-15-0	$6.2 \times 10^{+3}$	Nervous System; Reproductive/Developmental
Carbon Monoxide [a]	630-08-0	$2.3 \times 10^{+4}$	Cardiovascular System
Carbon Tetrachloride	56-23-5	$1.9 \times 10^{+3}$	Alimentary System (Liver); Nervous System Reproductive/Developmental
Chlorine	7782-50-5	$2.1 \times 10^{+2}$	Eyes; Respiratory System
Chloroform	67-66-3	$1.5 \times 10^{+2}$	Nervous System; Respiratory System; Reproductive/Developmental

[a] California Ambient Air Quality Standard

6.3 8-hour Reference Exposure Levels

OEHHA has developed 8-hour RELs for assessing potential noncancer health impacts for exposures to the general public that occur on a recurrent basis, but only during a portion of each day (OEHHA, 2008; http://www.oehha.ca.gov/air/allrels.html). Eight-hour RELs are compared to air concentrations that represent an average (daily) 8-hour exposure. They were designed to address off-site worker exposure at the MEIW, but may also be used at the Districts' discretion to characterize 8-hour residential noncancer exposures, particularly for non-continuous facility operations where exposure is based on air concentrations during facility operation (i.e., the zero emission hours are not included) rather than averaged over 24-hours/day, 7 days/week as assessed for chronic exposure. The 8-hour RELs can also be used to assess exposure of students and teachers while at school (OEHHA, 2008). These RELs were developed because of concerns that applying the chronic REL in some scenarios was

overly conservative. By definition, an 8-hour REL is an exposure that is not likely to cause adverse health effects in a human population, including sensitive subgroups, exposed to that concentration (in units of micrograms per cubic meter or $\mu g/m^3$) for an 8-hour exposure duration on a regular (including daily) basis.

The RELs, target organ systems, and the averaging time for substances that can present a potential hazard from inhalation for 8 hours on a daily basis are presented in Table 6.2. Chapter 8 discusses the methods used for determining noncancer 8-hour health impacts. Appendix I presents an example calculation used to determine an HQ and HI.

Any substances in Table 6.2 with Development or Reproductive System as a target organ system are represented in HARP and in the Appendix L REL tables under the single endpoint "Reproductive/Development".

Table 6.2 Eight-Hour Inhalation Reference Exposure Levels (RELs) and 8-Hour Hazard Index Target Organ System(s)

Substance	Chemical Abstract Service Number (CAS)	Chronic Inhalation REL ($\mu g/m^3$)	Chronic Inhalation Hazard Index Target Organ System(s)
Acetaldehyde	75-07-0	$3.0 \times 10^{+2}$	Respiratory System

1,3-Butadiene	106-99-0	$9.0 \times 10^{+0}$	Reproductive System
Caprolactam	105-60-2	$7.0 \times 10^{+0}$	Respiratory System
Formaldehyde	50-0-0	$9.0 \times 10^{+0}$	Respiratory System
Manganese & Manganese Compounds	7439-96-5	1.7×10^{-1}	Nervous System
Mercury & Inorganic Mercury Compounds	7439--97-6	6.0×10^{-2}	Nervous System; Development; Kidney
Nickel & Nickel Compounds	7440-02-0	6.0×10^{-2}	Respiratory System; Immune System

6.4 Chronic Reference Exposure Levels

OEHHA has developed chronic RELs for assessing noncancer health impacts from long-term exposure. (OEHHA, 2008; see also http://www.oehha.ca.gov/air/allrels.html) A chronic REL is a concentration level (expressed in units of micrograms per cubic meter ($\mu g/m^3$) for inhalation exposure and in a dose expressed in units of milligrams per kilogram-day (mg/kg-day) for oral exposures) at or below which no adverse health effects are anticipated following long-term exposure. Long-term exposure for these purposes has been defined by U.S. EPA as at least 12% of a lifetime, or about eight years for humans. Table 6.3 lists the chronic noncancer RELs that should be used in

the assessment of chronic health effects from inhalation exposure. Appendix L provides a consolidated listing of all the acute, 8-hour and chronic RELs and target organs that are approved for use by OEHHA and ARB for the Hot Spots Program. Periodically, new or updated RELs are adopted by OEHHA. See OEHHA's web site http://www.oehha.ca.gov/air/allrels.html to determine if any new or updated RELs have been adopted since the last guideline update.

The organ system(s) associated with each chronic REL are also presented in Table 6.3. Any substances in Table 6.3 with Development or Reproductive System as a target organ system are represented in HARP and in the Appendix L REL tables under the single endpoint "Reproductive/Development". Chapter 8 discusses the methods used for determining potential noncancer health impacts and Appendix I presents example calculations used to determine a HQ and HI.

Table 6.3 Chronic Inhalation Reference Exposure Levels (RELs) and Chronic Hazard Index Target Organ System(s)

Substance	Chemical Abstract Service Number (CAS)	Chronic Inhalation REL ($\mu g/m^3$)	Chronic Inhalation Hazard Index Target Organ System(s)
Acetaldehyde [a]	75-07-0	$1.4 \times 10^{+2}$	Respiratory System

[a] These peer-reviewed values were developed under the Toxic Air Contaminant (TAC) Program mandated by AB1807 (California Health and Safety Code Sec. 39650 *et seq*.).

[b] The OEHHA has adopted the World Health Organization Toxicity Equivalency Factor (TEF) scheme for evaluating the cancer risk and noncancer hazard due to exposure to samples containing mixtures of polychlorinated dibenzo-*p*-dioxins (PCDD) (also referred to as chlorinated dioxins and dibenzofurans), polychlorinated dibenzofurans (PCDF) and polychlorinated biphenyls (PCBs). The TEF values are revised from time to time to reflect new data and increased scientific knowledge. Currently OEHHA recommends use of the 2005 revision to the WHO TEF values (WHO_{05}-TEF). See Appendix E for more information about the scheme and for the methodology for calculating 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) equivalents for PCDD and PCDFs. For

convenience, OEHHA has calculated chronic REL values for speciated PCDDs, PCDFs and PCBs based on the WHO_{05} TEF values and the chronic REL for 2,3,7,8-TCDD using the procedure discussed in Appendix E. The chronic REL values can be used to calculate a hazard index when the mixtures are speciated from individual congener ground level concentrations. In those cases where speciation of dioxins and furans has not been performed, then 2,3,7,8-TCDD serves as the surrogate for dioxin and furan emissions.

N/A Not Applicable

6.5 Chronic Oral (Noninhalation) Reference Exposure Levels

As specified throughout the guidelines, estimates of long-term exposure resulting from facility air emissions of specific compounds must be analyzed for both inhalation and noninhalation (multipathway) pathways of exposure for humans. Facilities often emit substances under high temperature and pressure in the presence of particulate matter. While some of these substances are expected to remain in the vapor phase, other substances such as metals and semi-volatile organics can be either emitted as particles, form particles after emission from the facility, or adhere to existing particles. Some substances will partition between vapor and particulate phases. Substances in the particulate phase can be removed from the atmosphere by settling and, thus, potentially present a significant hazard via noninhalation pathways.

Particulate-associated chemicals can be deposited directly onto soil, onto the leaves or fruits of crops, or onto surface waters. Exposure via the oral route is the predominant noninhalation pathway, resulting in the noninhalation RELs being referred to as 'oral RELs' in this document. The oral RELs are used for both ingestion and dermal exposures, and are applied using the chronic non-inhalation exposures in the residential scenario and the worker scenarios. The oral RELs are expressed as doses in milligrams of substance (consumed and dermally absorbed) per kilogram body weight per day (mg/kg-day).

Table 6.4 lists the chronic noncancer RELs to be used in the assessment of chronic health effects from noninhalation pathways of exposure. Any substances in Table 6.4 with Development or Reproductive System as a target organ system are represented in HARP and in the Appendix L REL tables under the single endpoint "Reproductive/Development". Appendix L provides a consolidated listing of all chronic RELs and target organs that are approved for use by OEHHA and ARB for the Hot Spots Program. Periodically, new or updated RELs are adopted by OEHHA and these guidelines will be updated to reflect those changes. See OEHHA's web page at http://www.oehha.ca.gov/air/allrels.html to determine if any new or updated RELs have been adopted since the last guideline update. Chapter 8 discusses the methods used for determining potential noncancer health impacts and Appendix I presents example calculations used to determine a HQ and HI.

Table 6.4 Chronic Noninhalation 'Oral' Reference Exposure Levels (RELs) and Chronic Hazard Index Target Organ System(s)

Substance	Chemical Abstract Service No. (CAS)	Chronic Oral REL (mg/kg-day)	Chronic Oral Hazard Index Target Organ System(s)
Arsenic & Inorganic Arsenic Compounds	7440-38-2	3.5×10^{-6}	Development; Nervous System; Respiratory System; Cardiovascular System; Skin
Beryllium and Beryllium Compounds	7440-41-7	2.0×10^{-3}	Alimentary System (Gastrointestinal Tract)
Cadmium and Cadmium Compounds	7440-43-9	5.0×10^{-4}	Kidney
Chlorinated Dibenzo-*p*-dioxins [a]

a The OEHHA has adopted the World Health Organization Toxicity Equivalency Factor (TEF) scheme for evaluating the cancer risk and noncancer risk due to exposure to samples containing mixtures of polychlorinated dibenzo-*p*-dioxins (PCDD) (also referred to as chlorinated dioxins and dibenzofurans), polychlorinated dibenzofurans (PCDF), and polychlorinated biphenyls (PCBs). The TEF values are revised from time to time to reflect new data and increased scientific knowledge. Currently OEHHA recommends use of the 2005 revision to the WHO TEF values (WHO_{05}-TEF). See Appendix E for more information about the scheme and for the methodology for calculating 2,3,7,8-equivalents for PCDD and PCDFs. For convenience, OEHHA has calculated chronic 'oral' REL values for speciated PCDDs, PCDFs, and PCBs based on the WHO_{05} TEF values and the chronic 'oral' REL for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin using the procedure discussed in Appendix E. The chronic 'oral' REL values can be used to calculate a hazard index when the mixtures are speciated from individual congener ground level concentrations. In those cases where speciation of dioxins and furans has not been performed, then 2,3,7,8-TCDD serves as the surrogate for dioxin and furan emissions.

7 - Dose-Response Assessment for Carcinogens

7.1 Introduction

Dose-response assessment characterizes the quantitative relationship between the amount of exposure to a substance (the dose) and the incidence or occurrence of injury (the response). The process often involves establishing a toxicity value or criterion to use in assessing potential health risk. The toxicity criterion, or health guidance value, for carcinogens is the cancer potency slope (potency factor), which describes the potential risk of developing cancer per unit of average daily dose over a 70-year lifetime. Cancer inhalation and oral potency factors have been derived by the Office of Environmental Health Hazard Assessment (OEHHA) or by the United States Environmental Protection Agency (U.S. EPA) and approved by the State's Scientific Review Panel on Toxic Air Contaminants. They are available for many of the substances listed in Appendix A (List of Substances) as carcinogens. Table 7.1 and Appendix L list the inhalation and oral cancer potency factors that should be used in multipathway health risk assessments (HRAs) for the Hot Spots Program.

The details on the methodology of dose-response assessment for carcinogens and the approved cancer potency factors are provided in the Air Toxics Hot Spots Risk Assessment Guidelines. Part II. Technical Support Document for Cancer Potency Factors: Methodologies for derivation, listing of available values, and adjustments to allow for early life stage exposures. May, 2009. (OEHHA, 2009; see http://www.oehha.ca.gov/air/hot_spots/tsd052909.html).

7.2 Carcinogenic Potency

Cancer potency factors used for both the inhalation and oral routes in the Hot Spots program are generally the 95% upper confidence limits (UCL) on the modeled dose-response slope at the low dose range. The cancer slope factor assumes continuous lifetime exposure to a substance, and is expressed in units of inverse dose [i.e., $(mg/kg/day)^{-1}$]. Another common potency expression is in units of inverse concentration [$(\mu g/m^3)^{-1}$)] when the slope is based on exposure concentration rather than dose; this is termed the unit risk factor. To accommodate the use of age-specific exposure variates, the Hot Spots program has translated the unit risk factors based on concentration to units of inverse dose. This allows calculation of risk for age groupings, as exposure varies with age. It also allows for application of Age Sensitivity Factors for early life exposures.

It is assumed in cancer risk assessments that risk is directly proportional to dose and that, for most carcinogens, there is no threshold for carcinogenesis. The derivation of inhalation and oral cancer potency factors takes into account information on pharmacokinetics, when available, and on the mechanism of carcinogenic action.

Table 7.1 and Appendix L list inhalation and oral cancer potency factors that should be used in risk assessments for the Hot Spots Program. Chapter 8 describes procedures for use of potency factors in estimating potential cancer risk.

7.2.1 *Inhalation Cancer Potency Factors*

The risk assessment methodology and algorithms presented in Chapter 8 express the inhalation cancer slope factors in units of inverse dose (i.e., $(mg/kg/day)^{-1}$). Breathing rates, expressed in units of liters per kilogram of body weight-day (L/kg-day), are multiplied with the air concentrations, coupled with the appropriate unit conversion factor, to estimate dose in mg/kg-day. This allows estimation of average and high-end cancer risk point estimates. Estimation of a distribution of cancer risk based on variability in breathing rate can be obtained by Monte Carlo methods using the distributions of breathing rates in L/kg-day, which can then be converted to a dose distribution in mg/kg BW based on the intake rate. Unit risk factors [in the units of inverse concentration (i.e., $(\mu g/m^3)^{-1}$], which were used in previous guidelines for the Hot Spots program, are still listed in the TSD (OEHHA, 2009) and may prove useful in other risk assessment applications.

The average daily inhalation dose (mg/kg-day) multiplied by the cancer potency factor $(mg/kg\text{-}day)^{-1}$ will give the inhalation cancer risk (unitless), which is an expression of the chemical's cancer risk during a 70-year lifespan of exposure. For example, an inhalation cancer risk of 5×10^{-6} is the same as stating that an individual has an estimated probability of developing cancer from their exposure of 5 chances per million people exposed. A more complete description of how potential cancer risk is calculated from the exposure dose and cancer potency factors is provided in Chapter 8. Appendix I presents an example calculation for determining cancer risk.

A list of current inhalation potency factors is provided in Table 7.1. Periodically, new or revised cancer potency factors will be peer reviewed by the State's Scientific Review Panel on Toxic Air Contaminants (SRP) and adopted by the Director of OEHHA. For new or updated numbers, consult the OEHHA web site at (http://www.oehha.ca.gov/air/hot_spots/tsd052909.html) to determine if any new or updated cancer potency factors have been adopted since this guideline update. New cancer potency factors that have been approved by the SRP and adopted by the Director of OEHHA should be incorporated into Hot Spots risk assessment for facilities that emit those chemicals.

7.2.2 *Oral Cancer Potency Factors*

Under the Hot Spots Program, a few substances are evaluated for exposure and risk from non-inhalation pathways – these are referred to as multipathway substances. Multipathway substances have the potential to impact a receptor through inhalation and noninhalation (oral and dermal) exposure routes. These substances include heavy metals and semi-volatile organic substances such as dioxins, furans, and polycyclic aromatic hydrocarbons (PAHs). These substances commonly exist in the particle

phase or partially in the particle phase when emitted into the air. They can therefore be deposited onto soil, vegetation, and water. Noninhalation exposure pathways considered under the Hot Spots Program include the ingestion of soil, homegrown produce, meat, milk, surface water, breast milk, and fish as well as dermal exposure to contaminants deposited in the soil. See Table 5.1 for a list of the multipathway substances.

Table 7.1 and Appendix L list oral cancer potency factors in units of $(mg/kg\text{-}day)^{-1}$ that should be used for assessing the potential cancer risk for these substances through noninhalation exposure pathways. The cancer risk from these individual pathways is calculated by multiplying the dose (mg/kg-day) times the oral cancer potency factor $(mg/kg\text{-}day)^{-1}$ to yield the potential cancer risk (unitless) from non-inhalation exposures. Chapter 5 provides all of the algorithms to calculate exposure dose through all of the individual exposure pathways. Appendix I provides a sample calculation for dose and cancer risk using the inhalation exposure pathway.

Three carcinogens (cadmium, beryllium, and nickel), although subject to deposition, are only treated as carcinogenic by the inhalation route and not by the oral route. Therefore, there are no oral cancer potency factors for these substances. However, the oral doses of these substances need to be estimated because of their noncancer toxicity. See Chapters 6 and 8, and Appendices I and L for dose-response factors, and calculations to address these substances.

Table 7.1 Inhalation and Oral Cancer Potency Factors

Substance	Chemical Abstract Service Number (CAS)	Inhalation Potency Factor $(mg/kg\text{-}day)^{-1}$	Oral Slope Factor $(mg/kg\text{-}day)^{-1}$

Trichloroethylene	79-01-6	7.0×10^{-3}	1.5×10^{-2}
2,4,6-Trichlorophenol	88-06-2	7.0×10^{-2}	
Urethane	51-79-6	$1.0 \times 10^{+0}$	
Vinyl chloride	75-01-4	2.7×10^{-1}	

Notes for Table 7.1

Asbestos: [100 PCM fibers/m^3]$^{-1}$ A unit risk factor of 2.7 x 10^{-6} ($\mu g/m^3$)$^{-1}$ and an inhalation cancer potency factor of 2.2 x 10^{+2} (mg/kg BW*day)$^{-1}$ are available (see Appendix C for explanation).

BaP PAHs and PAH Derivatives: Many have potency equivalency factors relative to benzo[*a*]pyrene (see Appendix G). For multipathway chemicals, including PAHs, the oral slope factor is considered the same as the inhalation potency factor unless otherwise noted in the Table.

A Polychlorinated Dibenzo-*p*-dioxins, Polychlorinated Dibenzofurans and speciated poly chlorinated biphenyls: (see Appendix E). For convenience, OEHHA has calculated cancer potency factors for speciated polychlorinated dibenzo-*p*-dioxin, polychlorinated dibenzofuran and polychlorinated biphenyl congeners using the procedure in Appendix E.

B Diesel Exhaust is listed as a Toxic Air Contaminant by the Air Resources Board as "Particulate Matter from Diesel-Fueled Engines". (See Appendix D)

***** Creosote: Can be calculated using Potency Equivalency Factors contained in the benzo[*a*]pyrene Toxic Air Contaminant document and in Appendix G of these guidelines.

P1 Polychlorinated Biphenyls (PCBs): High Risk is for use in cases where congeners with more than four chlorines do not comprise less (are greater) than one-half percent of total PCBs. The high risk number is the default for unspeciated PCB mixtures.

P2 The low risk number is generally not applicable to the Hot Spots program. The Hot Spots program addresses PCBs emitted by stationary facilities. It cannot be assumed that such emissions would occur by simple evaporation. There is a dermal absorption factor applied in evaluation of the dermal pathway for PCBs so the medium risk would not apply to dermal exposure (OEHHA, 2009). The water pathway does not include an assumption that PCB isomers are water soluble, so the medium number would not apply to the water pathway.

P3 Polychlorinated Biphenyls (PCBs): Lowest Risk is for use in cases where congeners with more than four chlorines comprise less than one-half percent of total PCBs. In order for the low number to be used, scientific justification needs to be presented.

P4 Number in parentheses is the IUPAC #, the PCB nomenclature is IUPAC. For multipathway chemicals, including PCBs, the oral slope factor is considered the same as the inhalation potency factor unless otherwise noted in the Table.

8 - Risk Characterization for Carcinogens and Noncarcinogens and the Requirements for Hot Spots Risk Assessments

8.1 Introduction

Risk characterization is the final step of the health risk assessment (HRA). In this step, information developed through the exposure assessment is combined with information from the dose-response assessment to characterize risks to the general public from emissions. In the Hot Spots program, OEHHA conducts the dose-response assessment during the development of cancer potency factors and Reference Exposure Levels. These are used in conjunction with the exposure estimates to estimate cancer risk and evaluate hazard from noncancer toxicity of emitted chemicals. Under the Air Toxics Hot Spots (Hot Spots) Act, risk characterizations should present both individual and population-wide health risks (Health and Safety Code Section (HSC) 44306). Persons preparing HRAs for the Hot Spots Program should consult the local Air Pollution Control or Air Quality Management District (District) to determine if the District has special guidelines to assist with HRA format or other requirements of the Hot Spots Program.

OEHHA is recommending that a 30-year exposure duration be used as the basis for estimating cancer risk at the maximum exposed individual resident (MEIR) in the Hot Spots Program. This exposure duration represents the time of residency for 90 to 95% of Californians at a single location and should provide adequate public health protection against individual risk. We also recommend including the 9 and 70-year cancer risk at the MEIR as supplemental information. Note that a 70-year exposure duration is required to estimate cancer burden or provide an estimate of population-wide risk.

This chapter provides guidance on how to evaluate the risk characterization component of risk assessments required by the Hot Spots Program. A general summary of the risk characterization components includes the following items and information.

- The locations of the point of maximum impact (PMI), the MEIR, and the maximum exposed individual worker (MEIW) are to be identified. The PMI, MEIW, and MEIR for cancer risk and for noncancer hazard indices (averaging times for acute 1-hour, repeated 8-hour, and chronic hazard indices) may not be the same location; all should be identified.

- The location of any specified sensitive receptors (e.g., schools, hospitals, daycare, or eldercare facilities - contact the District or reviewing authority for more information) should be identified

- Estimates of population-wide cancer risk and noncancer hazard

This information must be clearly presented in cross-referenced text, tables, figures, and maps. Chapter 9 provides an outline that specifies the content and recommended format of HRA results. The HARP software is the recommended model for calculating HRA results for the Hot Spots Program. Information on obtaining the HARP software can be found under the Air Toxics Program on the ARB's web site at *www.arb.ca.gov*.

8.1.1 *Tiered Approach to Risk Assessment*

The tiered approach for risk assessment that is presented in detail in the TSD (OEHHA, 2012) and summarized here should be reviewed prior to conducting the health risk assessment. The tiered approach to risk assessment and the health impacts evaluation described here are included in the HARP software.

The tiered approach provides a risk assessor with flexibility and allows consideration of site-specific differences (Table 8.1). The four-tiered approach to risk assessment is intended to primarily apply to residential cancer risk assessment, both for inhalation and noninhalation pathways. Risk assessors can tailor the level of effort and refinement of an HRA by using either the point estimate exposure assumptions as the basis of the exposure and risk assessment, or both the point estimate and a stochastic treatment of exposure factor distributions.

Table 8.1 The Tiered Approach to Risk Assessment

Tier	Description	When Applied
Tier 1	Utilizes OEHHA default point estimates of exposure variates	All risk assessments must include a Tier 1 assessment
Tier 2	Utilizes site-specific point estimates for exposure variates (justified, and approved by OEHHA)	A Tier 2 approach may be presented in addition to Tier 1
Tier 3	Utilizes OEHHA distributions of exposure variates	A Tier 3 approach may be presented in addition to Tier 1
Tier 4	Utilizes site-specific distributions of exposure variates (justified, and approved by OEHHA)	A Tier 4 approach may be presented in addition to Tier 1

Tier 1 is a standard point estimate approach that uses the recommended exposure variate (e.g., breathing or water ingestion rate) point estimates presented in this document. Derivations of these values are described in detail in OEHHA (2012). The results of the Tier 1 evaluations are required to be presented in the risk characterization section for all HRAs prepared for the Hot Spots Program. Thus, persons preparing an HRA using Tier 2 through Tier 4 evaluations must also include the risk characterization results of a Tier 1 evaluation in the HRA.

As discussed in OEHHA (2012), if the risk characterization results from a Tier 1 assessment are above a regulatory level of concern, the risk assessor may want to proceed with more site-specific analysis as described in Tier 2, or use a more resource-intensive stochastic modeling effort described in Tier 3 and Tier 4 (for cancer risk). While further evaluation may provide more information to the risk manager on which to base decisions, the Tier 1 evaluation is useful in comparing risks among a large number of facilities and must be included in all HRAs.

Tier 2 analysis allows the use of available and justifiable site-specific exposure variates (e.g., fish consumption), when presenting the potential health impacts. The site-specific information applied in a Tier 2 assessment must be adequately justified and approved by OEHHA and the District. In Tier 3, a stochastic approach to exposure assessment is taken using the distributions for the exposure pathways presented in the TSD (OEHHA, 2012) and in Chapter 5 of this Guidance Manual. The exposure distributions apply only to a residential receptor and are used only for the determination of cancer risk. OEHHA has not developed exposure intake distributions for workers to use in the offsite worker exposure scenario. Tier 4 is also a stochastic approach for the residential exposure scenario but allows for utilization of site-specific exposure variate distributions if they are justifiable and more appropriate for the site under evaluation than those derived in OEHHA (2012). Alternative site-specific distributions must be approved by OEHHA and the District. For an off-site worker cancer risk evaluation, Tiers 3 and 4 do not apply. Tier 3 and Tier 4 analyses show what a distribution of potential cancer risk may be to an individual or population based on a distribution of exposure inputs (e.g., water ingestion rate) rather than specific point estimates of exposure.

Table 8.2 summarizes OEHHA's recommendations for use of the four Tiers in cancer and noncancer risk assessment.

Table 8.2 Tiers for Residential and Offsite Worker Cancer and Noncancer Hot Spots Risk Assessments

Tier	Cancer		Non Cancer Chronic and 8-Hour	
	Inhalation	Noninhalation	Inhalation	Noninhalation
Tier-1	X	X	X	X
Tier-2	X	X		X[b]
Tier-3	X[a]	X[a]		
Tier-4	X[a]	X[a]		

[a] Applies to residential exposure scenario only
[b] Applies to chronic noncancer exposure only

OEHHA has not developed a stochastic approach (Tier 3 or 4) for estimating noncancer health impacts using acute, 8-hour, and chronic Reference Exposure Levels (RELs). Tier 1 is the only option for determining noncancer health impacts from inhalation exposure since calculating the hazard quotient involves dividing the ground level air concentrations for the specified exposure duration by the appropriate RELs. However, chronic noninhalation noncancer risks involve a calculation of dose from oral or dermal pathways to which site-specific evaluations could be considered under a Tier 2 approach.

Small foot-print facilities – Tier 2 or Tier 4

Some facilities subject to the Air Toxics Hot Spots Act (e.g., some in the industry-wide categories such as gas stations or dry cleaners) have very small zones of impact. In some of these instances, there will be very few receptors within the zone of impact. It isn't possible to develop special recommendations for exposure variates for all possible exposure scenarios. Alternative breathing rates (point estimates or distributions) may be used as part of Tier 2 or Tier 4 risk assessments with appropriate supporting justification in the case of a very small zone of impact. OEHHA is willing to work with risk managers at ARB and the Districts on this issue.

8.2 Risk Characterization for Carcinogens

Cancer risk is calculated by multiplying the daily inhalation or oral dose (calculated in Chapter 5), by a cancer potency factor, the age sensitivity factor, the frequency of time spent at home (for residents only), and the exposure duration divided by averaging time, to yield the excess cancer risk (see section 8.2.4). As described below, the excess cancer risk is calculated separately for each age grouping and then summed to yield cancer risk at the receptor location. A brief description of the age sensitivity factors, exposure duration, and frequency of time spent at home are included in Sections 8.2.1 to 8.2.3 below. These factors are discussed in detail in OEHHA (2009) and OEHHA (2012).

8.2.1 *Adjustment for Early Life Stage Exposures to Carcinogens*

Studies have shown that young animals are more sensitive than adult animals to exposure to many carcinogens (OEHHA, 2009). Therefore, OEHHA developed age sensitivity factors (ASFs) to take into account the increased sensitivity to carcinogens during early-in-life exposure (Table 8.3). These factors were developed and described in detail in OEHHA (2009). In the absence of chemical-specific data, OEHHA recommends a default ASF of 10 for the third trimester to age 2 years, and an ASF of 3 for ages 2 through 15 years to account for potential increased sensitivity to carcinogens during childhood.

Table 8.3 Age Sensitivity Factors by Age Group for Cancer Risk Assessment

Age Group	Age Sensitivity Factor (unitless)
3rd Trimester	10
0<2 years	10
2<9 years	3
2<16 years	3
16<30 years	1
16-70 years	1

For specific carcinogens where data indicate enhanced sensitivity during life stages other than the immediate postnatal and juvenile periods, or for which data demonstrate ASFs different from the default ASFs, the chemical-specific data should be used in order to adequately protect public health.

The risk assessments generated under the Air Toxics Hot Spots Act are reviewed by OEHHA. If a risk assessor had data indicating there are no windows of susceptibility early in life or that a different ASF should be used for a specific carcinogen and wanted to use these data, OEHHA would review the material as part of the review of the risk assessment.

8.2.2 *Fraction of Time Spent at Home for Cancer Risk Assessment*

OEHHA and ARB evaluated information from activity patterns databases to estimate the fraction of time at home (FAH) during the day (OEHHA, 2012). This information can be used to adjust exposure duration and cancer risk from a specific facility's emissions, based on the assumption that exposure to the facility's emissions are not occurring away from home. From the third trimester to age <2 years, 85% of time is spent at home (Table 8.4). From age 2 through <16 years, 72% of time is spent at home. From age 16 years and greater, 73% of time is spent at home. Facilities with any school within the 1×10^{-6} (or greater) isopleth should use FAH = 1 for the child age groups (3rd Trimester, 0<2 years, and 2<16 years). See Appendix I for an example calculation using the FAH.

Table 8.4 Recommendations for Fraction of Time at Home (FAH) for Evaluating Residential Cancer Risk

Age Range	Fraction of Time at Residence
3rd Trimester, and 0<2 years	0.85[1]
2<16 years[2]	0.72[1]
16-70 years[3]	0.73

[1] Use FAH = 1 if a school is within the 1×10^{-6} (or greater) cancer risk isopleth

[2] Also use FAH = 0.72 for 2<9 yr age group.
[3] Also use FAH = 0.73 for 16<30 yr age group.

The FAH is calculated based on a diary of trips taken over a 24-hour period on the survey day. Ninety-five percent of the diary days were on weekdays. Participants can select "vacation" as one of their trips. However, vacation time represented only a fraction (0.68%) of the over 175,000 trips recorded in the survey. Because much of these vacation trips were presumed to be within-day trips and were only a small fraction of total trips, there is likely little overlap with the Exposure Frequency (EF) variate used in the dose equations in Chapter 5.

8.2.3 *Exposure Duration for Estimating Cancer Risk to Residents and Off-Site Workers*

OEHHA recommends that an exposure duration (residency time) of 30 years be used to estimate individual cancer risk for the maximally exposed individual resident (MEIR) (Table 8.5). OEHHA also recommends that the 30-year exposure duration be used as the basis for public notification and risk reduction audits and plans. The Districts, however, may opt to use the 70 year cancer risk for notification and risk reduction audits and plans.

Note that the 30-year exposure duration starts in the third trimester to accommodate the increased susceptibility of exposures in early life (OEHHA, 2009), and would apply to both the point estimate and stochastic approaches.

Table 8.5 Summary of Recommendations for Exposure Duration for Individual Cancer Risk at the MEIR and MEIW

Receptor	***Recommendation***
Resident (MEIR)	30 years
Resident (supplemental Information)	9 years for central tendency; 70 years for maximum (lifetime)
Worker (MEIW)	25 years

Exposure durations of 9-years and 70-years are also recommended to be evaluated for the MEIR to show the range of cancer risk based on residency periods. If a facility is notifying the public regarding cancer risk, the 9- and 70-year cancer risk estimates are useful for people who have resided in their current residence for periods shorter and longer than 30 years.

The 9-, 30-, and 70-year exposures are chosen to coincide with U.S. EPA's estimates of the average (9 years), high-end estimates (30-years) of residence time, and a lifetime residency (70 years). These estimates are also consistent with what is known about residence time in California. Together, the 9-, 30-, and 70-year cancer risk calculations provide a useful presentation of cancer risk and the relationship to duration of residency and, thus, exposure to a facility's emissions.

For the maximally exposed individual worker (MEIW), OEHHA recommends using an exposure duration of 25 years to estimate individual cancer risk for the off-site worker scenario (Table 8.5). This duration represents approximately the 95th percentile of job tenure with the same employer in the U.S.

8.2.4 *Calculating Residential and Offsite Worker Inhalation Cancer Risk*

Residential Receptors

For residential inhalation exposure, cancer risk must be separately calculated for specified age groups (Eq. 8.2.4A, see Section 8.2.1), because of age differences in sensitivity to carcinogens and age differences in intake rates (per kg body weight). Separate risk estimates for these age groups provide a health-protective estimate of cancer risk by accounting for greater susceptibility in early life, including both age-related sensitivity and amount of exposure. The following equation illustrates the formula for calculating residential inhalation cancer risk. See Appendix I for a detailed example calculation.

A. Equation 8.2.4 A: $$RISK_{inh\text{-}res} = DOSE_{air} \times CPF \times ASF \times ED/AT \times FAH$$

7. $RISK_{inh\text{-}res}$ = Residential inhalation cancer risk
8. $DOSE_{air}$ = Daily inhalation dose (mg/kg-day)
9. CPF = Inhalation cancer potency factor ($mg/kg\text{-}day^{-1}$)
10. ASF = Age sensitivity factor for a specified age group (unitless)
11. ED = Exposure duration (in years) for a specified age group
12. AT = Averaging time for lifetime cancer risk (years)
13. FAH = Fraction of time spent at home (unitless)

a: Recommended default values for EQ 8.2.4 A:

5. $DOSE_{air}$ = Calculated for each age group from Eq. 5.4.1
6. CPF = Substance-specific (see Table 7.1)
7. ASF = See Section 8.2.1
8. ED = 0.25 years for 3rd trimester, 2 years for 0<2, 7 years for 2<9, 14 years for 2<16, 14 years for 16<30, 54 years for 16-70
9. AT = 70 years*
10. FAH = See Table 8.4

*Although AT actually sums to 70.25 years when the 3rd trimester (0.25 years) is included, OEHHA recommends rounding AT = 70 years (and rounding residential exposure durations at 9- and 30-years rather than 9.25- and 30.25-years) to simplify the calculation without causing a significant adjustment. Note that the dose for the 3rd trimester is based on the breathing rate of pregnant women using the assumption that the dose to the fetus during the 3rd trimester is the same as that to the mother.

Cancer risks calculated above for individual age groups are summed to estimate cancer risk for 9-, 30- and 70-year exposures as shown below. Note that this example includes the Fraction of Time Spent at Home (FAH) for each age grouping.

Calculation of Inhalation Cancer Risk from the Third Trimester to Age Nine:

$$RISK_{inh\text{-}res} = (DOSE_{air}\ third\ trimester \times CPF \times 10 \times 0.25/70\ years \times FAH_{3rd\ tri\ <2}) + (DOSE_{air}\ age\ 0<2 \times CPF \times 10 \times 2/70 \times FAH_{3rd\ tri\ <2}) + (DOSE_{air}\ age\ 2<9 \times CPF \times 3 \times 7/70\ years \times FAH_{2<9})$$

Calculation of Inhalation Cancer Risk from Third Trimester to Age 30:

$$RISK_{inh\text{-}res} = (DOSE_{air}\ third\ trimester \times CPF \times 10 \times 0.25/70\ years \times FAH_{3rd\ tri\ <2}) + (DOSE_{air}\ age\ 0<2 \times CPF \times 10 \times 2/70 \times FAH_{3rd\ tri\ <2}) + (DOSE_{air}\ age\ 2<16 \times CPF \times 3 \times 14/70 \times FAH_{2<16}) + (DOSE_{air}\ age\ 16<30 \times CPF \times 1 \times 14/70\ years \times FAH_{16\text{-}30})$$

Calculation of Inhalation Cancer Risk from Third Trimester to Age 70:

$$RISK_{inh\text{-}res} = (DOSE_{air}\ third\ trimester \times CPF \times 10 \times 0.25/70\ years \times FAH_{3rd\ tri\ <2}) + (DOSE_{air}\ age\ 0<2 \times CPF \times 10 \times 2/70 \times FAH_{3rd\ tri\ <2}) + (DOSE_{air}\ age\ 2<16 \times CPF \times 3 \times 14/70 \times FAH_{2<16}) + (DOSE_{air}\ age\ 16<70 \times CPF \times 1 \times 54/70\ years \times FAH_{16\text{-}70})$$

Expressing cancer risk in "chances per million" is useful as a risk communication tool for the public, but cancer risk can also be expressed in other ways, such as "chances per 100,000" (cancer risk × 10^5) or "chances per 10 million" (cancer risk × 10^7). To convert the resulting cancer risk estimate to chances of developing cancer per million individuals exposed, multiply the cancer risk by 10^6:

$$Cancer\ risk \times 10^6 = chances\ per\ million$$

For exposure to multiple carcinogenic substances, Table 8.7 and Table I.5 in Appendix I are examples of how cancer risks of individual substances are summed to determine the total cancer risk.

Worker Receptors

For assessment of off-site worker cancer risk at the MEIW, the default assumes working age begins at 16 years. Note that the residential FAH factor in Eq. 8.2.4.A above does not apply for workers. The daily inhalation dose ($DOSE_{air}$) (as calculated in Chapter 5, EQ 5.4.1.2) is based on the adjusted 8-hour concentration at the MEIW (for non-continuous sources) and amount of time the offsite worker's schedule overlaps with the facility's emission schedule. The duration of exposure at the MEIW receptor is 25 years, as discussed in the TSD (OEHHA, 2012).

B. Equation 8.2.4 B: $RISK_{inh\text{-}work} = DOSE_{air} \times CPF \times ASF \times ED/AT$

1. $RISK_{inh\text{-}work}$ = Worker inhalation cancer risk

a: Recommended default values for EQ 8.2.4 B:

1. $DOSE_{air}$ = Calculated for workers in Eq. 5.4.1.2
2. CPF = Substance specific (see Table 7.1)
3. ASF = 1 for working age 16-70 yrs (See Section 8.2.1)
4. ED = 25 years
5. AT = 70 yrs for lifetime cancer risk

Work Locations with Daycare Facilities:

An additional risk management consideration for offsite worker cancer risk assessment of a Hot Spots facility is whether there are women of child bearing age at the MEIW location and whether the MEIW has a daycare center. In the case of women of child-bearing age at the MEIW, the Districts may wish to treat the off-site MEIW in the same way as the residential scenario to account for the higher susceptibility during the third trimester of pregnancy (i.e., use of an ASF=10 for third trimester exposure). If there is onsite daycare at the MEIW, then the risks to the children will be underestimated using the offsite adult worker scenario. In this case, the Districts may wish to include a cancer risk assessment for the children in the onsite daycare, assuming they could be there from 0 to age 6 years (ED = 6 years) and using the appropriate exposure factors to calculate $DOSE_{air}$, fraction of time at worksite (e.g., hrs at daycare per 24 hrs), and ASFs in EQ 8.2.4 B to account for the higher susceptibility of infants and children to carcinogens.

Children at a MEIW daycare may also be assessed for noninhalation exposures. Typically, soil ingestion and dermal exposure will be the most common noninhalation pathways. However, all pathways that are present at the daycare should be included. See section 8.2.6 for more discussion of multipathway risk assessment methods.

8.2.5 *Calculation of Noninhalation Cancer Risk*

A small subset of Hot Spots substances is subject to deposition onto the soil, plants, and water bodies (see Table 5.1). These substances need to be evaluated by the appropriate noninhalation pathways, as well as by the inhalation pathway, and the risk characterization results must be presented in all HRAs. These substances include semi-volatile organic chemicals and heavy metals.

For all multipathway substances, the exposure pathways that must be evaluated at every residential and worker site (in addition to inhalation) are soil ingestion and dermal exposure. If PAHs (and creosotes), lead, dioxins, furans, or PCBs are emitted, then the breast-milk consumption pathway becomes mandatory for residential receptors. OEHHA has developed transfer coefficients for these chemicals from the mother to breast milk (see OEHHA, 2012 for details). The other exposure pathways (e.g.,

ingestion of homegrown produce or fish) are only evaluated for residential receptors if the facility impacts that exposure medium and the receptor under evaluation can be exposed to that medium or pathway. For example, if the facility does not impact a fishable body of water within the isopleth of the facility, or the impacted water body does not sustain fish that are consumed by fishers, then the fish pathway will not be considered for that facility or receptor.

Table 8.6 identifies the residential receptor exposure pathways that are mandatory and those that are dependent on the available routes of exposure. Table 8.6 also identifies the three exposure pathways that are relevant for a worker receptor. The cancer risk estimates should be presented in the risk characterization section of the risk assessment for all the appropriate pathways.

Table 8.6 Mandatory and Site/Route Dependent Exposure Pathways

Mandatory Exposure Pathways	Site/Route Dependent Exposure Pathways
• Inhalation[w] • Soil Ingestion[w] • Dermal Exposure to Contaminated Soil[w] • Breast Milk Consumption[*]	• Homegrown Produce Ingestion • Angler-Caught Fish Ingestion • Drinking Water Ingestion • Home-Raised Animal Product Ingestion (Dairy (Cow's) Milk, Meat (Beef, Pork, Chicken) and Egg).

(w) Identifies the appropriate exposure pathways that should be evaluated for a worker. These pathways are inhalation, dermal exposure, and the soil ingestion pathway.

(*) If PAHs (including creosotes), lead, dioxins, furans, or PCBs are emitted, then the breast-milk consumption pathway becomes mandatory.

The noninhalation residential cancer risk is calculated using the same steps as inhalation cancer risk described in Section 8.2.4. A dose (see Chapters 4 and 5) from the pathway under evaluation (e.g., soil ingestion) is multiplied by the substance-specific oral slope factor, expressed in units of inverse dose (i.e., $(mg/kg/day)^{-1}$) (Table 7.1), the appropriate age sensitivity factor (ASF), and exposure duration divided by averaging time to yield the cancer risk for a specified age grouping. Cancer risk for each age group is summed as appropriate for the exposure duration. The FAH factor is relevant only to the inhalation pathway and is not appropriate to use in the noninhalation pathways.

Equation 8.2.5 illustrates the formula for calculating noninhalation cancer risk. Details (data, algorithms, and guidance) for each exposure pathway are presented in Chapter 5 and in OEHHA (2012).

A. Equation 8.2.5: $RISK_{noninh} = DOSE_{noninh} \times CPF_{oral} \times ASF \times ED/AT$

1. $RISK_{noninh}$ = Noninhalation pathway cancer risk
2. $DOSE_{noninh}$ = Daily dose (mg/kg-day) for a specified non-inhalation pathway for each age group
3. CPF_{oral} = Oral cancer potency (slope) factor (mg/kg-day^{-1})
4. ASF = Age sensitivity factor for a specified age group (unitless)
5. ED = Exposure duration (in years) for a specified age group
6. AT = Averaging time for lifetime cancer risk

a: Recommended default values for EQ 8.2.5:

1. $DOSE_{noninh}$ = Calculated in Chapter 5 dose algorithms for each age group and for each noninhalation route in Table 8.6 the receptor is exposed to
2. CPF_{oral} = Substance-specific (see Table 7.1)
3. ASF = See Section 8.2.1
4. ED = Residents: 0.25 years for 3rd trimester, 2 years for 0<2, 7 years for 2<9, 14 years for 2<16, 14 years for 16<30, 54 years for 16-70
   = Offsite worker: 25 yrs
5. AT = 70 years

Estimating cancer risk for 9-, 30- and 70-years by summing the individual age-group cancer risks is the same as that shown for the inhalation route in Section 8.2.4. The exception is that the FAH variate is only appropriate for the residential inhalation pathway and is not a factor for oral and dermal exposure pathways.

Calculation of Noninhalation Cancer Risk from Third Trimester to Age 30:

$RISK_{noninh\text{-}res}$ = ($DOSE_{noninh}$ third trimester × CPF × 10 × 0.25/70 years) + ($DOSE_{noninh}$ age 0<2 × CPF × 10 × 2/70) + ($DOSE_{noninh}$ age 2<16 × CPF × 3 × 14/70) + ($DOSE_{noninh}$ age 16<30 × CPF × 1 × 14/70 years)

To convert this estimated probability of risk to chances per million of developing cancer, multiply the estimated cancer risk for each noninhalation exposure route by 10^6. This result is useful communication tool to compare risks for each pathway of exposure.

$$\text{Cancer risk} \times 10^6 = \text{cancer risk expressed as chances per million}$$

For assessment of the offsite worker the typical noninhalation pathways that apply for worker cancer risk are the dermal exposure pathway and the soil ingestion pathway.

Children at a MEIW daycare may also be assessed for noninhalation exposures. Typically, soil ingestion and dermal exposure will be the most common noninhalation pathways. However, all pathways that are present at the daycare should be included.

8.2.6 *Multipathway Cancer Risk Methodology*

Under a Tier 1 assessment, it is necessary to calculate the total cancer risk from both inhalation and noninhalation exposures if multipathway substances are emitted from the facility. The calculation of cancer risk that includes exposure to a multipathway substance or substances has three steps:

1) Calculate cancer risk for the inhalation pathway (EQ 8.2.4 A for residents, EQ 8.2.4 B for off-site workers) for all substances, and the noninhalation pathways that apply (EQ 8.2.5) for all multipathway substances, using high-end point estimates of intake rates.
2) For each multipathway substance, identify the two exposure pathways with the highest risk. These are the dominant pathways that are to be assessed using high-end point estimates of intake rates for the total cancer risk. For all other pathways, the average point estimate of intake rates may be used to calculate the pathway cancer risk (See OEHHA (2012) for more information).
3) To calculate total cancer risk, all inhalation and noninhalation pathways are summed together for all substances.

The final cancer risk calculation using a combination of high-end and average exposure parameters is referred to as the derived risk in the HARP software. This is described in Chapter 1, Section 1.4.1 of OEHHA (2012). The inhalation route is almost always one of the two dominant pathways in a multipathway cancer risk assessment. Therefore, in most cases only one noninhalation pathway would be calculated using a high-end dose point estimate. For all other pathways, the average point estimate may be used to calculate the pathway cancer risk.

For example, if dermal exposure and soil ingestion risks are calculated, then the cancer risks from these pathways would be summed along with the inhalation cancer risks to give the total cancer risk for the single multipathway substance:

Cancer Risk (inhalation) + Cancer Risk (dermal) + Cancer Risk (soil) = Total Risk

The mother's milk pathway also becomes a mandatory pathway to assess risk in nursing infants if the mother is exposed to specific substances (see Table 5.1).

Many facilities will emit multiple carcinogenic substances. If multiple substances are emitted, the substance-specific cancer risks for all exposure pathways are summed to give the (total) multipathway cancer risk at the receptor location. The HARP software will display not only the multipathway risk for each carcinogenic substance, but also show a breakdown of the cancer risk from each exposure pathway. Table 8.7 shows the results of a multipathway risk assessment for a hypothetical facility. While not presented in the following table, it is critical to identify the driving exposure pathways and the driving substances in a multipathway cancer risk assessment when summarizing and presenting the HRA results. See Chapter 9 for more information.

Table 8.7 Multipathway Assessment of a Hypothetical Facility 30-Year Cancer Risk

Substance	Cancer Risk[a]	Cancer risk[b] (chances per million)
Arsenic	1.1×10^{-5} (i) 3×10^{-7} (ni)	11 (i) 0.3 (ni)
Benzene	2.92×10^{-4} (i)	292 (i)
2,3,7,8-TCDD (dioxin)	1.06×10^{-4} (i) 5.7×10^{-5} (ni)	106 (i) 57 (ni)
1,3-Butadiene	6.0×10^{-6} (i)	6 (i)
Total Facility Cancer Risk	**4.723×10^{-4}**	**472**

[a] As calculated in EQ 8.2.4 A or EQ 8.2.5
[b] Calculated as: cancer risk × 10^6 = chances per million
i = inhalation pathway contribution
ni = noninhalation pathway contribution

Cancer risk in Table 8.7 for the multipathway substances, arsenic and 2,3,7,8-TCDD, is arranged by the inhalation pathway risk and the sum of all noninhalation pathway risks. The total facility multipathway cancer risk is the sum of all inhalation and noninhalation pathways.

Cancer risks from different substances are treated additively in risk assessment generally, and in the Hot Spots Program in part because many carcinogens act through the common mechanism of DNA damage. The additive assumption is reasonable from a public health point of view. Other possible interactions of multiple carcinogens include synergism (effects are greater than additive) or antagonism (effects are less than additive). The type of interaction is both chemical and dose dependent and in most cases the data are not available to adequately characterize these interactions.

8.2.7 *Multipathway Cancer Risk for Infant Exposure to Mother's Milk*

The mother' milk pathway becomes mandatory if the nursing mother is exposed to one or more of the following multipathway substances: dioxins and furans, PCBs, PAHs including creosotes, and lead. The default assumption inherent in the intake rate is that the infant's only source of food is breast for the first year (e.g., is fully breastfed, see OEHHA, 2012, for details), which is one-half of the 0<2 year age group used in the Hot Spots program. Thus, the cancer risk by the mother's milk pathway will need to be calculated with a modified cancer risk equation using a different exposure duration:

A. Equation 8.2.7: $\mathbf{RISK_{mm} =}$ Dose-Im $\mathbf{\times CPF_{oral} \times ASF \times ED/AT}$

1. $RISK_{mm}$ = Infant cancer risk via mother's milk pathway
2. Dose-Im = Daily dose (mg/kg-day) to infant from mother's milk
3. CPF_{oral} = Oral cancer slope factor (mg/kg-day^{-1})
4. ASF = Age sensitivity factor for infant (unitless)
5. ED = Exposure duration (in years) for infant
6. AT = Averaging time for lifetime cancer risk

a: Recommended default values for EQ 8.2.7:

6. Dose-Im = Calculated from EQ 5.4.3.5.2, dose to infant via mother's milk
7. CPF_{oral} = Substance-specific (see Table 7.1)
8. ASF = 10 (See Section 8.2.1)
9. ED = 1 yr (1st yr of 0<2 yr age group)
10. AT = 70 years

Once the cancer risk is determined for the mother's milk pathway for each applicable substance, the pathway risk is summed with other pathway risks.

For Tier 1, the derived approach for cancer risk assessment should be used if the mother's milk pathway applies. As outlined in Section 8.2.6, the two dominant pathways will be calculated using high-end point estimates of intake rates; all additional pathways may be calculated using average point estimates of intake rates. There will be four mandatory pathways to assess (inhalation, mother's milk, soil ingestion and dermal exposure) for cancer risk when exposure to dioxins/furans, PCBs, PAHs including creosotes, and/or lead occurs. Therefore, if the infant is exposed to no other additional site-specific noninhalation pathway(s), only the two dominant pathways among the four will be assessed for cancer risk using high-end point estimates of intake rates; and the others would be assessed using the average point estimate of intake rate.

In short, multipathway cancer risk for a substance is estimated by summing the potential inhalation and noninhalation cancer risks for the receptor location of interest. See the discussion of Tier 1 in Section 8.2.6 or the TSD for more information on the method used to determine the multipathway cancer risk.

8.2.8 *Cancer Risk Characterization for Stochastic Risk Assessment*

Risk characterization for a stochastic risk assessment is similar to that described for the point-estimate approach. However, the stochastic risk assessment produces a distribution of risk that accounts for some of the natural variability in exposure-related factors, such as breathing rates or water intake. The cancer risk distribution for inhalation cancer risk, for example, is generated by multiplying randomly selected values from the breathing rate distribution by the ground level air concentration, and the cancer potency factor. A variation of the Monte Carlo method called Latin hypercube sampling is the method by which the values from the breathing rate distribution are

selected. If noninhalation pathways need to be evaluated, the same process is followed for each pathway and the risk is summed to give an overall inhalation and noninhalation cancer risk distribution. Further, the specification of Age Sensitivity Factors and the need to separately calculate risks require that a Monte Carlo sampling be conducted for each age group and the cancer risk distributions are then summed across age groups.

The HARP software will perform an HRA using a Monte Carlo analysis with either OEHHA-provided or user-provided data distributions and will include the statistics for the distributions. In risk assessments that have chosen to use the distribution of exposure variates, the cancer risk distribution for a 30-year residential exposure duration (MEIR) should be presented in the risk characterization section We also recommend including the 9 and 70-year cancer risk at the MEIR as supplemental information. Note that a 70-year exposure duration is required to estimate cancer burden or provide an estimate of population-wide risk. A stochastic approach has not been developed for acute, 8-hour, and chronic noncancer health impacts or worker (MEIW) exposures.

8.2.9 *Use of Individual Cancer Risk and Population-wide Cancer Risk*

Cancer risk for an individual receptor and a representation of population-wide cancer risk are both important components of a risk assessment. The individual receptor approach reflects the exposures that may occur to an individual receptor over a period of time at a specific location. The individual cancer risk approach has some inherent limitations in terms of illustrating and potentially protecting population-based public health. For example, a facility with a small emissions footprint may impact a few individuals with a high individual potential cancer risk; whereas, a facility with a larger emission footprint may have a lower potential cancer risk for an individual receptor but expose many more people to those levels. Since this larger emitting facility can impact many more people, the population-wide health impacts are magnified due to the larger number of people exposed to the facility's emissions. This potential for higher population impacts is not captured by the individual receptor risk methodology. Therefore, the individual and population-wide heath impacts should be presented for all facilities to provide a more complete illustration of the facility's health impacts.

8.2.9.1 Population Risk

For facilities with large emission footprints (e.g., refineries, ports, or rail yards, etc.), population-based health impacts are critical to provide a better illustration of the potential impacts of emissions since large numbers of people may be exposed to the emissions. The individual cancer risk approach has some inherent limitations in terms of protecting public health. A small facility with a single stack can impact a few individuals with an individual cancer risk that is unacceptable, whereas a large facility may have an individual cancer risk that is below the acceptable limit for individual risk but exposes many more people. Thus, the population-wide impacts are larger for the large facility. Population-wide risk is independent of individual risk, and assumes that a population (not necessarily the same individuals) will live in the impacted zone over a

70-year period. Thus, a 70-year exposure duration is required for estimates of population-wide risks.

To evaluate population risk, one method that regulatory agencies have used is the cancer burden method to account for the number of excess cancer cases that could occur in a population.

Cancer Burden

The cancer burden can be calculated by multiplying the cancer risk at a census block centroid by the number of people who live in the census block, and adding up the estimated number of potential cancer cases across the zone of impact. The result of this calculation is a single number that is intended to estimate of the number of potential cancer cases within the population that was exposed to the emissions for a lifetime (70 years).

The cancer burden is calculated on the basis of lifetime (70-year) risks (whereas individual cancer risk at the MEIR is based on 30-year residential exposure). Cancer burden is independent of how many people move in or out of the vicinity of an individual facility. For example, if 10,000 people are exposed to a carcinogen at a concentration with a 1×10^{-5} cancer risk for a lifetime the cancer burden is 0.1, and if 100,000 people are exposed to a 1×10^{-5} risk the cancer burden is 1.

Estimate of Population Wide Risk

An estimate of the number of people exposed at various cancer risk levels can provide perspective on the magnitude of the potential public health threat posed by a facility. This approach is intended as a replacement for or addition to the cancer burden calculation used by some Districts in the past. The new approach provides a much easier way for the general public to interpret results when compared to cancer burden estimates. A facility in a sparsely populated area can have a public health impact different from the same facility in a highly populated area; however, under the cancer burden method, those differences may not be seen. Some suggested approaches and methods for performance of a screening or refined population exposure analyses are provided in Section 4.6.

The District or reviewing authority should be consulted before beginning the population exposure estimates and, as results are generated, further consultation may be necessary. Note that a 70-year exposure duration is required to estimate cancer burden or provide an estimate of population-wide risk.

The zone of impact for estimating the number of persons exposed to a cancer risk from facility emissions should be set at a minimum of a 10^{-6} cancer risk level (see Section 4.6.1). Some Districts may prefer to use a cancer risk of 10^{-7} to define the carcinogenic zone of impact. The total number of persons exposed to a series of potential risk levels can be presented to aid risk managers in understanding the magnitude of the potential public health impacts.

The HARP software can provide population-level risk estimates as cancer burden or as the number of persons exposed to a selected (user-identified) cancer risk level at block level centroids.

8.2.9.2 Population Estimates for Noncancer Health Impacts

A noncancer chronic, 8-hour, and acute population estimate of the number of people exposed to acute, 8-hour, and chronic HQs or HIs exceeding 0.5 or 1.0, in increments of 1.0, should also be presented. For example, a facility with a maximum chronic HI of 4.0 would present the number of people exposed to a chronic HI of 0.5, 1.0, 2.0, 3.0, and 4.0. The isopleths used in this determination should be drawn using the smallest feasible grid size. The same methods that are described in Chapter 4 and Section 8.2.9 (for the population exposure estimate for cancer risk) should be used in the chronic, 8-hour and acute population estimates. Population estimates for acute, 8-hour, and chronic health impacts should be presented separately.

8.2.9.3 Factors That Can Impact Population Risk – Cumulative Impacts

Although the Hot Spots program is designed to address the impacts of single facilities and not aggregate or cumulative impacts, there are a number of known factors that influence the susceptibility of the exposed population and thus may influence population risk. Socioeconomic status influences access to health care, nutrition, and outcome after cancer diagnosis. Community unemployment can affect exposure and residency time near a facility. Factors that affect the vulnerability of the population are discussed in the report *Cumulative Impacts: Building a Scientific Foundation* (OEHHA, 2010). Information on many of these factors is relatively easy to obtain at the census tract level. The OEHHA recommends that these types of factors be considered by the risk manager, along with the quantitative measures of population risk. OEHHA is in the process of developing guidance on quantification of the impact of these factors.

8.2.10 *Cancer Risk Evaluation of Short Term Projects*

The local air pollution control districts sometimes use the risk assessment guidelines for the Hot Spots program in permitting decisions for short-term projects such as construction or waste site remediation. Frequently, the issue of how to address cancer risks from short-term projects arises.

Cancer potency factors are based on animal lifetime studies or worker studies where there is long-term exposure to the carcinogenic agent. There is considerable uncertainty in trying to evaluate the cancer risk from projects that will only last a small fraction of a lifetime. There are some studies indicating that dose rate changes the potency of a given dose of a carcinogenic chemical. In others words, a dose delivered over a short time period may have a different potency than the same dose delivered over a lifetime.

The OEHHA's evaluation of the impact of early-in-life exposure has reduced some of the uncertainty in evaluating the cancer risk to the general population for shorter-term exposures, as it helps account for susceptibility to carcinogens by age at exposure (OEHHA, 2009).

Due to the uncertainty in assessing cancer risk from very short-term exposures, we do not recommend assessing cancer risk for projects lasting less than two months at the MEIR. We recommend that exposure from projects longer than 2 months but less than 6 months be assumed to last 6 months (e.g., a 2-month project would be evaluated as if it lasted 6 months). Exposure from projects lasting more than 6 months should be evaluated for the duration of the project. In all cases, for assessing risk to residential receptors, the exposure should be assumed to start in the third trimester to allow for the use of the ASFs (OEHHA, 2009). Thus, for example, if the District is evaluating a proposed 5-year mitigation project at a hazardous waste site, the cancer risks for the residents would be calculated based on exposures starting in the third trimester through the first five years of life.

For the MEIW, we recommend using the same minimum exposure requirements used for the residential receptor (i.e., no evaluation for projects less than 2 months; projects longer than 2 months but less than 6 months are assumed to last 6 months; projects longer than 6 months would be evaluated for the duration of the project). Although the off-site worker scenario assumes that the workers are 16 years of age or older with an Age-Sensitivity Factor of 1, another risk management consideration for short-term project cancer assessment is whether there are women of child bearing age at the worksite and whether the MEIW receptor has a daycare center. In this case, the Districts may wish to treat the off-site MEIW in the same way as the residential scenario to account for the higher susceptibility during the third trimester of pregnancy, and for higher susceptibility of infants and children.

Finally, the risk manager may want to consider a lower cancer risk threshold for risk management for very short-term projects. Typical District guidelines for evaluating risk management of Hot Spots facilities range around a cancer risk of 1 per 100,000 exposed persons as a trigger for risk management. Permitting thresholds also vary for each District. There is valid scientific concern that the rate of exposure may influence the risk – in other words, a higher exposure to a carcinogen over a short period of time may be a greater risk than the same total exposure spread over a much longer time period. In addition, it is inappropriate from a public health perspective to allow a lifetime acceptable risk to accrue in a short period of time (e.g., a very high exposure to a carcinogen over a short period of time resulting in a 1×10^{-5} cancer risk). Thus, consideration should be given for very short term projects to using a lower cancer risk trigger for permitting decisions.

8.3 Noncancer Acute, 8-Hour, and Chronic Inhalation Health Impacts – the Hazard Index Approach

All substances in the Hot Spots Program that have noncancer health impacts at a receptor must be evaluated through the inhalation pathway. Estimates of noncancer inhalation health impacts are determined by dividing an airborne concentration at the receptor by the appropriate Reference Exposure Level (REL). This is termed the Hazard Index Approach. A REL is used as an indicator of potential noncancer health impacts and is defined as the concentration at which no adverse noncancer health effects are anticipated. When a health impact calculation is performed for a single substance, then it is called the hazard quotient (HQ). Each REL for a substance will have one or more target organ systems (e.g., respiratory system, nervous system, etc.) where the substance can have a noncancer health impact. Thus, all HQs have specified target organ systems associated with them. The sum of the Hazard Quotients of all chemicals emitted that impact the same target organ is termed the Hazard Index. Inhalation RELs for noncancer health impacts have been developed for acute, 8-hour, and chronic exposures to a number of Hot Spots substances. Acute RELs are designed to protect against the maximum 1-hour ground level concentration at the receptor. Eight-hour RELs are designed to protect people with daily 8-hour schedules, such as offsite workers, in an impacted zone. The 8-hour RELs should be used for typical daily work shifts of 8-9 hours. For further questions, assessors should contact OEHHA, the District, or reviewing authority to determine if the 8-hour RELs should be used in your HRA. Any discussions or directions to exclude the 8-hour REL evaluation should be documented in the HRA. Chronic RELs protect against long-term exposure to the annual average air concentration spread over 24 hours/day, 7 days/week.

OEHHA has added 8-hour RELs to the set of noncancer RELs that were previously comprised of acute and chronic RELs (OEHHA, 2008). Specifically, 8-hour RELs are air concentrations at or below which health impacts would not be expected even for sensitive subpopulations in the general population with repeated daily 8-hour exposures over a significant fraction of a lifetime. The 8-hour RELs can be used to evaluate the potential for health impacts (including effects of repeated exposures) in offsite workers, and to children and teachers exposed during school hours. Although not required in the HRA, they could also be applied by the Districts to a residential scenario where a facility operates only a portion of the day and exposure to residences is not adequately reflected by averaging concentrations over a 24 hour day. The number of chemicals with 8-hour RELs will increase as OEHHA re-evaluates RELs for chemicals under SB-25 to ensure that they are protective of children's health.

Acute, 8-hour, and chronic RELs are needed because the dose metrics and even the health impact endpoints may be different with the different exposure durations of acute, daily 8-hour, and chronic exposures. Also, although chronic REL values are lower or set the same as 8-hour RELs, there are some cases such as special meteorological situations (e.g., significant diurnal-nocturnal meteorological differences) or intermittent exposures where the 8-hour REL may be more protective than the chronic REL.

Chapter 4 describes air dispersion modeling and both Chapter 6 and Appendix L list the needed dose-response information to evaluate non-cancer hazards. Appendix I presents sample calculations for determining acute HQs and HIs, 8-hour HQs and HIs, and chronic multipathway HQs and HIs. Chapter 9 provides an outline of information required for risk characterization. The HARP software will calculate the HQ and HI for Hot Spots risk assessments.

8.3.1 *Calculation of Noncancer Inhalation Hazard Quotient and Hazard Index*

To calculate the acute HQ, the maximum 1-hour ground level concentration (in $\mu g/m^3$) of a substance at a receptor is divided by the acute 1-hour REL (in $\mu g/m^3$) for the substance:

$$\text{Acute Hazard Quotient} = \frac{\text{1-Hour Max Concentration } (\mu g/m^3)}{\text{Acute REL } (\mu g/m^3)}$$

To calculate the chronic HQ, the annual average ground level concentration of a substance is divided by the chronic REL for the substance:

$$\text{Chronic Hazard Quotient} = \frac{\text{Annual Average Concentration } (\mu g/m^3)}{\text{Chronic REL } (\mu g/m^3)}$$

To calculate the 8-hour HQ, the adjusted annual average ground level concentration of a substance (represented as "Adjusted C_{air}" in EQ 5.4.1.4 A) is divided by the 8-hour REL for the substance:

$$\text{8-hour Hazard Quotient} = \frac{\text{Adjusted Annual Average Concentration } (\mu g/m^3)}{\text{8-hour REL } (\mu g/m^3)}$$

The daily 8-hour average ground level concentrations used for calculating the 8-hour HQs are derived as described in Chapter 4.

An HQ of 1.0 or less indicates that adverse health effects are not expected to result from exposure to emissions of that substance. As the HQ increases above one, the probability of human health effects increases by an undefined amount. However, it should be noted that a HQ above one is not necessarily indicative of health impacts due to the application of uncertainty factors in deriving the RELs.

If a receptor is exposed to multiple substances that target the same organ system, then the HQs for the individual substances are summed to obtain a Hazard Index (HI) for that target organ.

Table 8.8 is an example of an HRA spreadsheet showing acute inhalation HQs arranged by target organ system for several substances. The bottom row shows the summed HQs by target organ system to derive the HIs.

Table 8.8 Individual Hazard Quotients and Total Hazard Index for Acute Inhalation Exposure

Substance	Reproductive/ Developmental	Nervous System	Cardiovascular System	Respiratory System	Eye
Ammonia				0.6	0.6
Arsenic	0.2	0.2	0.2		
Benzene	0.02				
Chlorine				0.7	0.7
Total Hazard Index	**0.22**	**0.2**	**0.2**	**1.3**	**1.3**

A more detailed example of calculating HQs and HIs and of determining noncancer health impacts is shown in Appendix I.

Hazard quotients or HIs for different target organs are not summed together (e.g., do not add the impacts for the eye to the cardiovascular system). Chapter 6 and Appendix L have lists of the organ systems affected by each substance. Unlike the cancer risk algorithms, no exposure duration adjustment (e.g., 9 yrs / 70 yrs) should be made for noncancer assessments.

There are limitations to this method of assessing cumulative noncancer health impacts. The impact on organ systems may not be additive if health effects occur by different mechanisms. However, the impact on organ systems could also be synergistic. An analysis by a trained health professional familiar with the substance's toxicological literature is usually needed to determine the public health significance of an HQ or HI above one. It is recommended that the Air District contact OEHHA if this situation presents itself. For assessing the noncancer health impacts of lead, different procedures are used; please see Appendix F.

8.3.2 *Calculating Noninhalation (oral) Noncancer Hazard Quotient and Hazard Index*

Similar to the situation with multipathway carcinogenic substances, multipathway substances that present a noncancer hazard are assessed by noninhalation routes of exposure (see Table 8.6). Noninhalation routes of exposure are assessed only for chronic exposure. There are no oral acute RELs since it is generally anticipated that health effects from a single exposure via the oral route at typical environmental levels resulting from deposition of facility emissions would be insignificant relative to the inhalation route. The multipathway substances with noninhalation RELs, called chronic oral RELs, are shown in Table 6.4. Similar to inhalation exposure, the hazard quotient

for a noninhalation pathway is obtained by dividing the dose in milligrams per kilogram-day (mg/kg-day) by the oral REL also expressed in units of mg/kg-day:

$$\text{Chronic Non-inhalation HQ} = \frac{\text{Chronic Noninhalation Dose (mg/kg-day)}}{\text{Chronic Oral REL (mg/kg-day)}}$$

The calculated chronic oral HQs are combined with the chronic inhalation HQs for determining the chronic HIs for each affected target organ (see Section 8.3.4). The point estimates and algorithms for calculating the oral dose for all applicable exposure pathways and receptors (e.g., workers or residents) are explained in Chapter 5.

The chronic oral dose calculated in mg/kg-day is based on a time-weighted average 70-year residential exposure combining the 0<2, 2<16 and 16-70 year age groups. Unlike the assessment of cancer risk, no exposure duration adjustment should be made when estimating HQs. In other words, the variates ED and AT in the cancer risk EQ 8.2.5 in Section 8.2.5 are not used for estimating the noncancer HQs. See Appendix I for an example calculation.

8.3.3 *Multipathway Noncancer Risk Methodology*

To determine multipathway chronic noncancer health impacts, it is necessary to calculate the total hazard index from both inhalation and noninhalation exposures. The calculation of HIs has several steps:

1) First, the inhalation HQ is calculated for each substance emitted (Section 8.3.1).
2) Second, if the substance has an oral REL, then the non-inhalation HQ is calculated as shown above using high-end point-estimates for intake rates for each noninhalation pathway that applies.
3) Third, if there are more than two noninhalation pathways to consider for a multipathway substance, then the oral HQ is calculated using high-end point estimates in the dose equation for the two dominant pathways. For any additional noninhalation pathways, the HQs are calculated using average point estimates in the dose equation. This step applies only to residential receptors.
4) Fourth, all noninhalation pathway HQs for a multipathway substance are then summed together by target organ to obtain the total noninhalation HQ for a multipathway substance.
5) The final step is to sum the inhalation and noninhalation HQs together by target organ to determine the HIs. This step is displayed in Table 8.9. If there is only one substance, then the multipathway HQ is the same as the HI.

Table 8.9 Substance-Specific Chronic Inhalation and Noninhalation Hazard Quotients and the Hazard Index by Target Organ System

Substance	Respiratory System	Hematologic System	Alimentary System	Endocrine System	Development	Reproductive System	Nervous System	Cardiovascular System	Skin
Ammonia	0.8								
Arsenic					0.04(i) 0.1(ni)		0.04(i) 0.1(ni)	0.04(i) 0.1(ni)	0.04(i) 0.1(ni)
Benzene		0.08			0.08		0.08		
2,3,7,8-TCDD (dioxin)	0.1(i) 0.2(ni)	0.1(i) 0.2(ni)	0.1(i) 0.2(ni)	0.1(i) 0.2(ni)	0.1(i) 0.2(ni)	0.1(i) 0.2(ni)			
Nickel	0.4(i)	0.4(i)	0.1(ni)						
Hazard Index	**1.50**	**0.78**	**0.40**	**0.3**	**0.52**	**0.30**	**0.22**	**0.14**	**0.14**

i = inhalation pathway contribution

ni = noninhalation pathway contribution

Table 8.9 shows the calculated chronic HIs by combining the chronic inhalation HQs and chronic oral HQs. The HQs or HIs for different target organs are not added together (e.g., do not add the impacts for the respiratory system to the nervous system). The noninhalation pathways for TCDD and arsenic in Table 8.9 have all the noninhalation pathways that apply incorporated into their HQ values. For example, the noninhalation value for arsenic (HQs = 0.1) includes at least the soil ingestion and dermal soil pathways in the HQs because these are the mandatory noninhalation pathways to take into account with exposure to a multipathway substance. For TCDD, the mother's milk pathway is an additional mandatory noninhalation pathway to take into account (See Table 5.1). If there are exposures to any of the site-specific pathways, then these would be included too. A more detailed example calculation of HIs is shown in Appendix I.

When exposure to more than two noninhalation pathways occur, using the high-end point estimates of intake rates for only the two dominant noninhalation pathways will lessen the issue of compounding high-end exposure estimates, while retaining a health-protective approach for the more important exposure pathways. It is unlikely that an individual receptor would be on the high-end of exposure for all the non-inhalation intake parameters (exposure pathways).

8.3.4 *Summary - Acute, 8-Hour and Chronic Hazard Index Calculation at the MEIR and MEIW*

Eight-hour RELs were developed principally for exposure of individuals during 8-hour work schedules. The 8-hour RELs should be used for typical daily work shifts of 8-9 hours. For further questions, assessors should contact OEHHA, the District, or reviewing authority to determine if the 8-hour RELs should be used in your HRA. Any discussions or directions to exclude the 8-hour REL evaluation should be documented in the HRA. There are currently only a limited number of substances with an 8-hour inhalation REL. Over time as the science supporting REL values for individual substances is reviewed and the RELs are revised by OEHHA, more 8-hour RELs will be developed.

Therefore, for the MEIR, we recommend:

- Estimating the acute Hazard Index based on the maximum 1-hour air concentration and 1-hour RELs
- Estimating the chronic Hazard Index based on the annual average air concentration and the chronic RELs, and the oral RELs for multipathway substances

An 8-hour hazard index based on the daily average 8-hour exposure is not required for the MEIR, but can be performed at the discretion of the District for exposure to non-continuously operating facilities using the adjusted annual average air concentration (See EQ 5.4.1.4 A and B or method in App. M). Eight-hour hazard assessments are not recommended for exposure to continuously operating facilities.

For the MEIW, we recommend:

- Estimating the acute Hazard Index based on the maximum 1-hour air concentration and 1-hour RELs
- Estimating the 8-hour Hazard Index based on daily average 8-hour exposure for those chemicals with 8-hour RELs
- Estimating the chronic Hazard Index based on the annual average air concentration and chronic RELs, and oral RELs for multipathway substances

Until there are 8-hour RELs for many of the Hot Spots substances that have a chronic REL value, we recommend determining the chronic HI for the MEIW to adequately protect the offsite worker.

8.3.5 *Evaluation of Background Criteria Pollutants*

The District should be contacted to determine if the contribution of background criteria pollutants to respiratory health effects is required to be included in an HRA for the Hot Spots Program. If inclusion is required, the methods for calculating the health impact from acute and chronic exposure (respiratory endpoint) is the standard HI approach (see Sections 8.3.1 and 8.3.4). There are currently no 8-hour RELs for criteria

pollutants, so 8-hour health impacts from criteria pollutants are not assessed in HRAs. The background criteria pollutant contribution should be calculated if the HI from the facility's emissions exceeds 0.5 in either the acute or chronic assessment for the respiratory endpoint.

The most recent criteria pollutant concentration data should be obtained from the ARB's ambient air monitoring network and can be found in the *California Almanac of Emissions and Air Quality* on their web site at www.arb.ca.gov. For determining the criteria pollutant contribution in HI calculations, the annual average concentration data should be taken from a monitoring site near the facility. If background contributions are unavailable, the District may direct the risk assessor to make an alternative assumption. The criteria pollutants that should be included in acute and chronic assessments for the respiratory endpoint are ozone, nitrogen dioxide, sulfur dioxide, sulfates, and hydrogen sulfide.

8.4 Uses of Exposure Duration Adjustments for Onsite Receptors

Onsite workers are protected by CAL OSHA and typically are not evaluated under the Hot Spots program. Exceptions may include a worker who also lives on the facility property such as at prisons, military bases, and universities that have worker housing within the facility. Another scenario where the District may require assessment of on-site worker exposure and risk is when a facility (e.g., airport) has multiple businesses owned by different entities within the facility/property (e.g., rental car agencies, restaurants, etc.). In these situations the evaluation of onsite cancer risks, and/or acute, 8-hour, and chronic noncancer hazard indices is appropriate under the Hot Spots program. If the onsite receptor under evaluation can be exposed through a noninhalation exposure pathway, then that exposure pathway must also be included. When a receptor lives and works on the facility, site, or property, then these receptors should be evaluated and reported under both residential and worker scenarios and the one that is most health-protective should be used for risk management decisions.

The cancer risk estimates for the on-site residents may use a 30-year exposure duration while the 25-year exposure duration is used for a worker. Under a Tier 2 analysis, alternate exposure durations may be evaluated and presented with all assumptions supported. See section 8.2.10 for more discussion of short-term exposures.

Other situations that may require on-site receptor assessment include the presence of locations where the public may have regular access for the appropriate exposure period (e.g., a lunchtime café, store, or museum for acute exposures). The District or reviewing authority should be consulted on the appropriate evaluations for the risk for all onsite receptors.

9 - Summary of the Requirements for a Modeling Protocol and a Health Risk Assessment Report

The AB 2588 program is a community right-to-know act. Although risk assessment is a technical field, AB 2588 risk assessments need to be clear and understandable to the educated lay person. An Executive Summary that explains the process and the results of the risk assessment in lay terms is necessary. Clear risk communication is imperative in situations where the facility is required to notify the surrounding community. In addition, the risk assessment is by law reviewed by the local Air Pollution Control or Air Quality Management District (District) and OEHHA in order to ensure that AB 2588 risk assessment procedures have been followed. This chapter clarifies the type of information that is needed for District and OEHHA review of modeling protocols and health risk assessments (HRAs).

The material presented here is intended to promote transparent, consistent presentation and efficient review of the modeling protocol and the health risk assessment report (products). We recommend that persons preparing these products consult with the local District to determine if the District has modeling or HRA guidelines that supersede these products. If the District does not have guidelines for these products, then we recommend Section 9.1 be used for modeling protocols and Section 9.2 be used for the presentation of HRAs. Persons preparing modeling protocols and HRAs should specify the guidelines that were used to prepare their products.

9.1 Submittal of a Modeling Protocol

It is strongly recommended that a modeling protocol be submitted to the District for review and approval prior to extensive analysis with an air dispersion model. The modeling protocol is a plan of the steps to be taken during the air dispersion modeling and risk assessment process. We encourage people who are preparing protocols to take advantage of the protocol step and fully discuss anticipated methodologies for any portion of your project that may need special consideration. Below, we have provided an example of the format that may be followed in the preparation of the modeling protocol. **Consult with the District to confirm format and content requirements or to determine the availability of District modeling guidelines before submitting the protocol.**

9.1.1 *Outline for a Modeling Protocol*

I. Introduction

Include the facility name, address, and a brief overview describing the facility's operations.

- Provide a description of the terrain and topography surrounding the facility and potential receptors.

- Indicate the format in which data will be provided. Ideally, the report and summary of data will be on paper and all data and model input and output files will be provided electronically (e.g., compact disk or CD).

- Identify the guidelines used to prepare the protocol (e.g., District Guidelines).

II. Emissions

For each pollutant and process whose emissions are required to be quantified in the HRA, list the annual average emissions (pounds/year and grams/second) and the maximum one-hour emissions (pounds/hour and grams/second)[1]. Maximum 1-hour emissions are used for acute noncancer health impacts while annual emissions are used for chronic exposures (i.e., chronic and 8-hour noncancer health impacts or cancer risk assessment).

- Identify the reference and method(s) used to determine emissions (e.g., source tests, emission factors, etc.). Clearly indicate any emission data that are not reflected in the previously submitted emission inventory report. In this event, a revised emission inventory report will need to be submitted to the District.

- Identify if this will be a multipathway assessment based on emitted substances.

[1] Except radionuclides, for which annual and hourly emissions are reported in Curies/year and millicuries/hour, respectively.

III. Models / Modeling Assumptions

Specify the model and modeling assumptions

- Identify the model(s) to be used, including the version number.
- Identify the model options that will be used in the analysis.
- Identify the modeling domain(s) and the spacing of receptor grid(s). Grid spacing should be sufficient in number and detail to capture the concentration at all of the receptors of interest.
- Indicate complex terrain options that may be used, if applicable.
- Identify the source type(s) that will be used to represent the facility's operations (e.g., point, area, or volume sources, flare options or other).
- Indicate the preliminary source characteristics (e.g., stack height, gas temperature, exit velocity, dimensions of volume source, etc.).
- Identify and support the use of urban or rural dispersion coefficients for those models that require dispersion coefficients. For other models, identify and support the parameters required to characterize the atmospheric dispersion due to land characteristics (e.g., surface roughness, Monin-Obukhov length).

IV. Meteorological Data

Specify the type, source, and year(s) of hourly meteorological data (e.g., hourly surface data, upper air mixing height information).

- State how the data are representative for the facility site.
- Describe QA/QC procedures.
- Identify any gaps in the data; if gaps exist, describe how the data gaps are filled.

V. Deposition

- Specify the method to calculate deposition (if applicable).

VI. Receptors

Specify the type and location of receptors. Include all relevant information describing how the individual and population-related receptors will be evaluated.

- Identify and describe the location(s) of known or anticipated potential sensitive receptors, the point of maximum impact (PMI), the maximum exposed individual residential (MEIR), and worker (MEIW) receptors. Identify any special considerations or grids that will be used to model these receptors. This information should correspond with information provided in Section III (e.g., fine receptor spacing of 20 meters at the fence line and centered on the maximum impacts; coarse receptor spacing of 100 meters out to 2,000 meters; extra coarse spacing of 1,000 meters out to 20,000 meters).

- Identify if spatial averaging will be used. Include necessary background information on each receptor including how the domain and spacing will be determined for each receptor or exposure pathway.

- Describe how the cancer burden or population impact estimates are calculated. Clarify the same information for the presentation of noncancer population impacts (e.g., centroids of the census tracts in the area within the zone of impact).

- Specify that actual UTM coordinates and the block/street locations (i.e., north side of 3,000 block of Smith Street), where possible, will be provided for specified receptor locations.

- Identify and support the use of any exposure adjustments (e.g., time at location, diurnal).

- Include the list of anticipated exposure pathways that will be included and indicate which substance will be evaluated in the multipathway assessment. Identify if sensitive receptors are present and which receptors will be evaluated in the HRA.

VII. Maps

Identify how the information will be graphically presented.

- Indicate which cancer risk isopleths will be plotted for the cancer zone of impact (e.g., 10^{-7}, 10^{-6} see Section 4.6.1).

- Indicate the hazard quotients or hazard indices to be plotted for the noncancer acute, 8 hour, and chronic zones of impact (e.g., 0.5, 1.0, etc.).

9.2 Health Risk Assessment Report

The purpose of this section is to provide an outline to assist with the preparation and review of HRAs. This outline specifies the key components that should be included in HRAs. All information used for the report must be presented in the HRA. Ideally, the HRA report and a summary of data used in the HRA will be on paper and all data and model input and output files will be provided electronically (e.g., CD). Persons preparing HRAs for the Hot Spots Program should consult the District to determine if HRA guidelines or special formats are to be followed when preparing and presenting the HRA's results.

If District guidelines or formats do not exist that supersede this outline, then the HRA should follow the format presented here. If the HRA is prepared for other programs, the reviewing authority should be consulted for clarification of format and content. We recommend that those persons preparing HRAs specify the guidelines that were used to prepare their product. **The HRA may be considered deficient by the reviewing authority if components that are listed here are not included**.

9.2.1 *Outline for the Health Risk Assessment Report*

I. Table of Contents

- Section headings with page numbers indicated.
- Tables of tables and Table of figures with page numbers indicated.
- Appendices with page numbers indicated.

II. Executive Summary

Overview of all relevant information regarding the project or facility.

- Facility identifier number (consult the District).

- Description of facility operations and a list identifying emitted substances including table of maximum 1-hour emissions, and annual average emissions.

- Provide a brief description of acute, 8-hour, chronic, and cancer health impacts of the emitted substances, based on OEHHA's descriptions in the appropriate Technical Support Documents.

- Text presenting overview of dispersion modeling and exposure assessment.

- Text describing estimated cancer risk for carcinogens, noncancer Hazard Quotients and Hazard Indices and a table showing target organ systems by substance for noncancer impacts.

- Summarize the individual and population-wide health impacts including the driving substance(s) and the driving exposure pathways:

    - Location (block/street location; e.g., north side of 3,000 block of Smith Street) and description of the off-site point of maximum impact (PMI), maximum exposed individual resident (MEIR), and maximum exposed individual worker (MEIW).

    - Location (block/street location; e.g., north side of 3,000 block of Smith Street) and description of any on-site receptors that were evaluated at the facility (consult District or agency).

    - Location (block/street location; e.g., north side of 3,000 block of Smith Street) and description of any sensitive receptors that are required by the district or reviewing authorities (consult District or agency).

      NOTE: When presenting information described in the following bullets, cancer risk should be presented separately for a residential 30-year, Tier–1 analysis. Results of other exposure assumptions (e.g., 9 or 70-year) or other tier evaluations should also be presented, and must be clearly labeled. For the Hot Spots Program, while the 30-year exposure duration is recommended as the basis for public notification and risk reduction audits and plans, the District has discretion to use the 70 year exposure scenario for its decisions. In addition, the 70 year cancer risk must be calculated to estimate population-wide impacts.

    - Text presenting an overview of the total cancer risk (including multipathway substances, if present) at the PMI, MEIR, MEIW, and sensitive receptors. Provide a table of cancer risk by substance for the MEIR and MEIW (if applicable). Include a statement indicating which of the substances appear to contribute most to (drive) the potential health impacts. In addition, identify the exposure pathways evaluated in the HRA.

    - Provide a map of the facility and surroundings and identify the location of the MEIR, MEIW, PMI, and other locations or receptors of interest.

    - Provide a map of 30-year and 70-year cancer risk zone of impact(s), if applicable.

    - Text presenting an overview of the acute and chronic noncancer hazard quotients and the (total) hazard indices for the PMI, MEIR, MEIW, and sensitive receptors. Additionally, include 8-hour hazard quotients and hazard indices for the MEIW. Include separate statements (for acute, 8-hour, and chronic exposures) indicating which

of the substances appear to drive the potential health impacts. In addition, clearly identify the primary target organ(s) that are impacted from acute, 8-hour, and chronic exposures.

- Identify any sensitive subpopulations (e.g., child daycare facilities, schools, nursing homes) of concern.

- Table and text presenting an overview of estimates of population exposure (e.g., cancer burden or population estimates from HARP) (consult District or agency) (see Section 8.4).

- Version of the Risk Assessment Guidelines and computer program(s) used to prepare the risk assessment (e.g., HARP).

III. Risk Assessment Procedures

A. Hazard identification

- Table and text identifying all substances emitted from the facility, plus any other substances required by the District or reviewing authority. Include the CAS number of the substance and the physical form of the substance if possible. [The Hot Spots substances are listed in Appendix A, and also in the ARB's Emission Inventory Criteria and Guidelines Regulations (Title 17, California Code of Regulations, Sections 93300-93300.5), and the Emission Inventory Criteria and Guidelines Report (EICG Report), which is incorporated by reference therein (ARB, 1997)].

- Table and text identifying all substances that are evaluated for cancer risk and/or noncancer acute, 8-hour, and chronic health impacts. In addition, identify any multipathway substances that present a cancer risk or chronic noncancer hazard via noninhalation routes of exposure.

- Describe the types and amounts of continuous or intermittent predictable emissions from the facility that occurred during the reporting year. As required by statute, releases from a facility include spilling, leaking, pumping, pouring, emitting, emptying, discharging, injecting, escaping (fugitive), leaching, dumping, or disposing of a substance into ambient air. Include the substance(s) released and a description of the processes that resulted in long-term and continuous releases.

B. Exposure Assessment

This section describes the information related to the air dispersion modeling process that needs to be reported in the risk assessment; the information is also presented in Chapter 4 (see Section 4.15). The District may have specific requirements regarding format and content (see Section 4.14). Sample calculations should be provided at each step to indicate how reported emissions

data were used. Reviewing agencies must receive input, output, and supporting files of various model analyses on computer-readable media (e.g., CD).

1. Information on the Facility and its Surroundings

Report the following information regarding the facility and its surroundings:

- Facility Name
- Location (UTM coordinates and street address)
- Land use type (see Section 2.4)
- Local topography
- Facility plot plan identifying:
  - source locations
  - property line
  - horizontal scale
  - building heights
  - emission sources

2. Source and Emission Inventory Information

a. Release Parameters

Report the following information for each release location in table format:

- Release location identification number
- Release name
- Release type (e.g., point, volume, area, line, pit, etc.)
- Source identification number(s) used by the facility for sources that emit out of this release location
- Release location using UTM coordinates
- Release parameters by release type (e.g., shown for point source):
- Stack height (m), stack diameter (building dimensions for downwash, exhaust gas exit velocity (m/s), exhaust gas volumetric flow rate (ACFM), exhaust gas exit temperature (K), etc.

b. Source Description and Operating Schedule

The description and operating schedule for each source should be reported in table form including the following information:

- Source identification number used by the facility
- Source name
- Number of operating hours per day and per year (e.g., 0800-1700, 2700 hr/yr)
- Number of operating days per week (e.g., Mon-Sat)

- Number of operating days or weeks per year (e.g., 52 wk/yr excluding major holidays)
- Release point identification number(s) for where source emissions are released
- Fraction of source emissions emitted at each release point by release point ID number

c. *Emission Control Equipment and Efficiency*

- Report emission control equipment and efficiency by source and by substance

d. *Emissions Data Grouped By Source*

Report emission rates for each toxic substance, grouped by source (i.e., emitting device or process identified in Inventory Report), in table form including the following information:

- Source name
- Source identification number
- Substance name and CAS number (from Inventory Guidelines)
- Annual average emissions for each substance (lb/yr)
- Hourly maximum emissions for each substance (lb/hr)

e. *Emissions Data Grouped by Substance*

Report facility total emission rate by substance for all emitted substances listed in the Air Toxics “Hot Spots” Program including the following information:

- Substance name and CAS number (from Inventory Guidelines)
- Annual average emissions for each substance (lb/yr)
- Hourly maximum emissions for each substance (lb/hr)

f. *Emission Estimation Methods*

Report the methods used in obtaining the emissions data indicating whether emissions were measured or estimated. Clearly indicate any emission data that are not reflected in the previously submitted emission inventory report and submit a revised emission inventory report to the district. A reader should be able to reproduce the risk assessment without the need for clarification.

g. List of Substances

Include tables listing all "Hot Spots" Program substances which are emitted, plus any other substances required by the District. Indicate substances to be evaluated for cancer risks and noncancer effects.

h. Exposed Population and Receptor Location

Report the following information regarding exposed population and receptor locations:

- Description of zone of impact including map showing the location of the facility, boundaries of zone of impact, census tracts, emission sources, sites of maximum exposure, and the location of all appropriate receptors. This should be a true map (one that shows roads, structures, etc.), drawn to scale, and not just a schematic drawing. USGS 7.5 minute maps or GIS based maps are usually the most appropriate choices. (If significant development has occurred since the user's survey, this should be indicated.)

- Separate maps for the cancer risk zone of impact and the hazard index (noncancer) zone of impact(s). The cancer zone of impact should include isopleths down to at least the 1/1,000,000 risk level. Because some districts use a level below 1/1,000,000 to define the zone of impact, the District should be consulted. For the noncancer zone of impact, three separate isopleths (to represent chronic, 8-hour, and acute HI) should be created to define the zone of impact for the hazard index from both inhalation and noninhalation pathways greater than or equal to 0.5. The point of maximum impact (PMI), maximum exposed individual at a residential receptor (MEIR), and maximum exposed individual worker (MEIW) for both cancer and noncancer risks should be located on the maps.

- Tables identifying population units and sensitive receptors (UTM coordinates, receptor IDs or index from the modeling, and street addresses of specified receptors)

- Heights or elevations of the receptor points.

- **Spatial averaging**: For each receptor type (e.g., PMI, MEIR, and MEIW, or other location of interest) that will utilize spatial averaging, the domain size and grid resolution must be clearly identified. If another domain or grid resolution other than 20 meters by 20 meters with 5-meter grid spacing will be used for a receptor, then care should be taken to determine the proper domain size and grid resolution that should be used. For a worker, the HRA shall support all assumptions used, including, but not limited to, documentation for all workers

showing the area where each worker routinely performs their duties. The final domain size should not be greater than the smallest area of worker movement. Other considerations for determining domain size and grid spacing resolution may include an evaluation of the concentration gradients across the worker area. The grid spacing used within the domain should be sufficient in number and detail to obtain a representative concentration across the area of interest. When spatial averaging over the deposition area of a pasture, garden, or water body, care should be taken to determine the proper domain size to make sure it includes all reasonable areas of potential deposition. The size and shape of the pasture, garden, or water body of interest should be identified and used for the modeling domain. The grid spacing or resolution used within the domain should be sufficient in detail to obtain a representative deposition concentration across the area of interest. One way to determine the grid resolution is to include an evaluation of the concentration gradients across the deposition area. The HRA shall support all assumptions used, including, but not limited to, documentation of the deposition area (e.g., size and shape of the pasture or water body, maps, representative coordinates, grid resolution, concentration gradients, etc.). The use or spatial averaging is subject to approval by the reviewing authority. This includes the size of the domain and grid resolution that is used for spatial averaging of a worksite or multipathway deposition area.

3. Meteorological Data

If meteorological data were not obtained directly from the District, then the report must clearly indicate the data source and time period used. Meteorological data not obtained from the District must be submitted in electronic form along with justification for their use including information regarding representativeness and quality assurance.

The risk assessment should indicate if the District required the use of a specified meteorological data set. All memos indicating the District's approval of meteorological data should be attached in an appendix.

4. Model Selection and Modeling Rationale

The report should include an explanation of the model chosen to perform the analysis and any other decisions made during the modeling process. The report should clearly indicate the name of the models that were used, the level of detail (screening or refined analysis) and the rationale behind the selection.

Also report the following information for each air dispersion model used:

- Version number
- Selected options and parameters in table form

- Identify the modeling domain(s) and the spacing of receptor grid(s). Grid spacing should be sufficient in number and detail to capture the concentration at all receptors of interest.

5. Air Dispersion Modeling Results

The report should include tables, text, and appendices that clearly present all of the following information

- Maximum hourly and annual average concentrations of chemicals at appropriate receptors such as the residential and worker MEI receptors

- Annual average and maximum one-hour (and 30-day average for lead only) concentrations of chemicals at appropriate receptors listed and referenced to computer printouts of model outputs

- Model printouts (numbered), annual concentrations, maximum hourly concentrations

- Disk with input/output files for air dispersion program (e.g., the AERMOD input file containing the regulatory options and emission parameters, receptor locations, meteorology, etc.)

- Include tables that summarize the annual average concentrations that are calculated for all the substances at each site. The use of tables that present the relative contribution of each emission point to the receptor concentration is recommended. (These tables should have clear reference to the computer model which generated the data. It should be made clear to any reader how data from the computer output were transferred to these tables.) [As an alternative, the above two tables could contain just the values for sites of maximum impact (i.e., PMI, MEIR and MEIW), and sensitive receptors, if required. All the values would be found in the Appendices.]

C. ***Health Values Used in Dose-Response and Dose Estimates***

- Provide tables of the acute, 8-hour and chronic inhalation RELs, chronic oral RELs (if applicable), and cancer potency factors for each substance that is quantified in the HRA.

- Identify the guidelines (title and date) that were used to obtain these factors, or indicate whether newly approved values obtained from the OEHHA website were used.

- Provide a table of target organ systems for each noncancer substance, including acute (1 hour), 8-hour, and chronic inhalation, and chronic oral (if applicable).

- Include tables of the estimated dose for each substance by each exposure pathway at the PMI, MEIR, MEIW, and at any sensitive receptor locations (required by the District).

D. ***Risk Characterization***

The Hot Spots Analysis and Reporting Program (HARP) will generate the risk characterization data needed for the outline below. Any data needed to support the risk characterization findings should be clearly presented and referenced in the text and appendices. A listing of HARP output files that meet these HRA requirements is provided in this outline under the section entitled "Appendices". All HARP files should be included in the HRA. Ideally, the HRA report and a summary of data used in the HRA will be on paper and all data and model input and output files will be provided electronically (e.g., CD). Information on obtaining copies of HARP is available on the California Air Resources Board's Internet web site under the Air Toxics Program at *www.arb.ca.gov.*

NOTE: The cancer risk for the PMI, MEIR, and sensitive receptors of interest must be presented in the HRA's text, tables, and maps. OEHHA recommends that cancer risk for a 30-year exposure duration be presented for the MEIR, and that cancer risk for 9-year and 70-year exposure durations for the MEIR be presented to provide the risk managers with supplemental information. Note that the assessment of population impacts must be based on a 70-year exposure duration; thus all risk assessments need to estimate cancer risk for a 70-year exposure duration in order to report the number of individuals residing in the risk isopleths, or to calculate cancer burden if the District so requires. In addition, some Districts may opt to make risk management decisions based on a 70-year exposure duration. The MEIW location should use a 25-year exposure period.

All HRAs must include the results of a Tier-1 exposure assessment (see Chapter 2 and 8, or the 2012 TSD). If the reviewing authority specifies that additional exposure periods should be presented, or if persons preparing the HRA would like to present additional information (i.e., exposure duration adjustments or the inclusions of risk characterizations using Tier-2 through Tier-4 exposure data), then this information should be presented in separate, clearly titled, sections, tables, and text.

The following information should be presented in this section of the HRA. If not fully presented here, then by topic, clearly identify the section(s) and pages within the HRA where this information is presented.

- Description of receptors to be quantified.

- Table and text providing the location [UTM coordinates, receptor ID number or index from the modeling, and the block/street address

(e.g., north side of 3,000 block of Smith Street)] and description of the PMI, MEIR, and MEIW for both cancer and noncancer risks.

- Separate tables and text providing description of the PMI and MEIR for 30-year cancer risk, and 9- or 70-year cancer risk.

- Tables and text describing MEIW 25-year cancer risk.

- Table and text providing the location [UTM coordinates, receptor ID number or index from the modeling, and the block/street address (e.g., north side of 3,000 block of Smith Street)] and description of any sensitive receptor that is of interest to the District or reviewing authorities (consult District or agency).

- Provide any exposure information that is used for risk characterization (e.g., concentrations at receptors, emissions information, census information, figures, zone of impact maps, etc.). If multipathway substances are emitted, identify the site/route dependent exposure pathways (e.g., water ingestion) for the receptor(s), where appropriate (e.g., MEIR).

- Provide a summary of the site-specific inputs used for each exposure pathway (e.g., water or grazing intake assumptions). This information may be presented in an appendix with the information clearly presented and cross-referenced to the text. In addition, provide reference to the appendix (section and page number) that contains the modeling (i.e., HARP/dispersion modeling) files that show the same information.

- If any exposure parameters were used other than those provided in the Air Toxics Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis (2012), they must be presented in detail. The derivation and data used must be presented so that it is clear to the reviewer. The justification for using site-specific exposure parameters must be clearly presented.

- Table and text presenting the potential multipathway cancer risk by substance, by pathway, and total, at the PMI, MEIR, MEIW, and sensitive receptor locations (required by the District).

- Table and text presenting the acute (inhalation only) and chronic noncancer (inhalation and oral) hazard quotients (by substance, exposure pathways, and target organs) and the (total) hazard indices by substance and target organs for the PMI, MEIR, MEIW, and sensitive receptors. For 8-hour exposure at the MEIW (inhalation only), table and text presenting hazard quotients (by substance, exposure pathways, and target organs) and the (total) hazard indices by substance and target organs. Note:

Chronic noncancer results should be shown with inhalation and oral contributions (shown separately) and for the combined (multipathway) impact.

- Identify any sensitive subpopulations (e.g., child daycare facilities, schools, nursing homes) of concern.

- Table and text presenting estimates of population exposure (e.g., population exposure estimates or cancer burden from HARP) (consult District or agency). Tables should indicate the number of persons exposed to a (total) cancer risk greater than 10^{-7}, 10^{-6}, 10^{-5}, 10^{-4}, etc., and total hazard quotient or hazard index greater than 0.5, 1.0, 2.0, and 3.0, etc. Provide a table that shows excess cancer burden for each population unit and the total excess cancer burden, if cancer burden calculation is required.

- Provide maps that illustrate the HRA results for the three sub-bullet points below. These maps should be an actual street map of the area impacted by the facility with elevation contours and actual UTM coordinates, and the facility boundaries clearly labeled. In some cases the elevation contours will make the map too crowded and should therefore not appear. This should be a true map (one that shows roads, structures, etc.), drawn to scale, and not just a schematic drawing. USGS 7.5-minute maps are usually the most appropriate choice (see Section 4.6).

    - The facility (emission points and boundaries), the locations of the PMI, MEIR, MEIW, and sensitive receptors.

    - Maps of the cancer zone of impacts (e.g., 10^{-6} or 10^{-7} levels - consult District or Agency). The map should clearly identify the zone of impact for the inhalation pathway, the minimum exposure pathways (soil ingestion, dermal exposure, and breast-milk consumption) if multipathway substances are emitted, and the zone of impact for all the applicable exposure pathways (minimum exposure pathways plus any additional site/route specific pathways) for multipathway analyses. Two maps may be needed to accomplish this. The legend of these maps should state the level(s) used for the zone of impact and identify the exposure pathways that were included in the assessment.

    - Maps of the noncancer hazard index (HI) zone of impacts (e.g., 0.5 or 1.0 - consult District or Agency). The noncancer maps should clearly identify the noncancer zones of impact. These include the acute (inhalation), 8-hour (inhalation), chronic (inhalation), and chronic (multipathway) zones of impact. For clarity, presentation of the noncancer zones of impact may require two or more maps. The

legend of these maps should state the level(s) used for the zone of impact and identify the exposure pathways.

- The risk assessor may want to include a discussion of the strengths and weaknesses of the risk analyses and associated uncertainty directly related to the facility HRA.

- If appropriate, comment on the possible alternatives for control or remedial measures. How do the risks compare?

- If possible, identify any community concerns that influence public perception of risk.

- Sample calculations may be needed for all analyses in the HRA if proprietary software other than HARP was used. The District should be consulted. These calculations should be clearly presented and referenced to the findings they are supporting in the HRA text.

- Version of the Risk Assessment Guidelines and computer program used to prepare the risk assessment.

- If software other than HARP is used for the health assessment modeling, all supporting material must be included with the HRA (e.g., all algorithms and parameters used in a clear, easy to review format).

E. ***References***

Include any references used for the HRA in this section.

F. ***Appendices***

The appendices should contain all data, sample calculations, assumptions, and all modeling and risk assessment files that are needed to reproduce the HRA results. Ideally, a summary of data used in the HRA will be on paper and all data and model input and output files will be provided electronically (e.g., CD), unless otherwise specified by the district or reviewing authority. All appendices and the information they contain should be referenced, clearly titled, and paginated.

Potential Appendix Topics (if not presented elsewhere in the HRA report):

- List of all receptors locations (UTM coordinates, receptor ID number or index from the modeling, and the block/street address (e.g., north side of 3,000 block of Smith Street)) for the PMI, MEIR, MEIW, and sensitive receptors.
- List of all emitted substances.
- All emissions files.

- List of dose-response factors (Reference Exposure Levels and cancer potency factors).
- All air dispersion modeling input and output files. Detailed discussions of meteorological data, regulatory options, emission parameters, receptor locations, etc.
- Census data.
- Maps.
- Identify the site/route dependent exposure pathways for the receptor(s), where appropriate (e.g., MEIR). Provide a summary of the site-specific inputs used for each pathway (e.g., water or grazing intake assumptions) and the data to support them.
- All calculations used to determine emissions, concentrations, and potential health impacts at the PMI, MEIR, MEIW, and sensitive receptors.
- All HRA model input and output (HARP) files for receptors of concern.
- (Total) cancer and noncancer impacts by receptor, substance, and exposure pathway (by endpoint for noncancer) at all receptors.
- Presentation of alternate risk assessment methods (e.g., alternate exposure durations, or Tier-2 to Tier-4 evaluations with supporting information).

Page Intentionally Left Blank

List of Abbreviations

A - Area
AB2588 - Air Toxics “Hot Spots” Information and Assessment Act, 1987
ACFM - Actual Cubic Feet per Minute
ADL - Annual Dermal Load
AQMD - Air Quality Management District (District)
ARB - Air Resources Board
ASF - Age Sensitivity Factor
AT - Average Time for Lifetime Cancer Risk
BAF - Bioaccumulation Factor
BG - Urban Block Groups
BLP - Buoyant Line and Point Source Dispersion Model
BMI - Breast Milk Intake
BPIP - Building Profile Input Program
BPIPPRM - Building Profile Input Program for PRIME
BSA - Body Surface Area
BW - Bodyweight
C_{air} - annual average air concentration
CALMPRO - Calms processor program
CAPCOA - California Air Pollution Control Officer’s Association
CAS - Chemical Abstracts Service
CERCLA - Comprehensive Environmental Response, Compensation and Liability Act
C_f - Average concentration of a substance in fish
C_m - Average concentration of a substance in mother’s milk (mislabeled on 114 as Cf)
C_{fa} - Average concentration of a substance in animal products
CONST2 - Constant in the Briggs’ stable plume rise equation using BLP
CONST3 - Constant in the Briggs’ neutral plume rise equation using BLP
CPF - Cancer Potency Factor
CRIT - Convergence criterion for the line source calculations using BLP
Cs - Concentration of Substance in the Soil
CTDMPLUS - Complex Terrain Dispersion Model
CTSCREEN - Complex Terrain Screening Model
Cv - Average concentration of a substance in and on vegetation
Cw - Concentration of a Substance in the Water
DECFAC - Pollutant decay factor for use with BLP
DF - Discount Factor
$DOSE_{air}$ - Daily inhaled dose
$DOSE_{fa}$ - Exposure through ingesting home-raised or farm animal products
$DOSE_{fish}$ - Exposure through ingestion of angler-caught fish
Dose-Im - Exposure through mother’s milk ingestion
$DOSE_p$ - Exposure through ingesting home-grown produce
$DOSE_{water}$ - Exposure through ingesting water

DTHTA - Vertical potential temperature gradient
DTSC - Department of Toxic Substance Control
EASA - Exposure Assessment and Stochastic Analysis
ED - Rural Enumeration Districts or Exposure Duration (in years)
EF - Exposure Frequency
EICG - Emission Inventory Criteria and Guidelines
EPA - Environmental Protection Agency
EQ - Equation
F - Fahrenheit
FAH - Fraction of Time at Home
FG - Fraction of diet provided by grazing
GIS - Geographic Information Systems
GLC - Ground-Level Concentrations
GRAF - Gastrointestinal Relative Absorption Factor
HARP - Hot Spots Analysis and Reporting Program
HESIS - Hazard Evaluation System and Information Service
HI - Hazard Index
HQ - Hazard Quotient
HRA - Health Risk Assessment
HSC - Health and Safety Code
IARC - International Agency for Research on Cancer
IDELS - Maximum variation in number of stability classes per hour (BLP option)
ISCST3 - Industrial Source Complex Short Term
IUPAC - International Union of Pure and Applied Chemistry
K - Kelvin
L - Fraction of locally-grown (source-impacted) feed that is not pasture (site-specific)
LOAEL - Lowest Observed Adverse Effects Level
LOD - Level of Detection
LSHEAR - Plume rise wind shear (BLP option)
LTRANS - Transitional point source plume rise (BLP option)
MAXIT - Maximum iterations allowed for line source calculations (BLP option)
MEIR - Maximally Exposed Individual Resident
MEIW - Maximally Exposed Individual Worker
METDB - Meteorological Database
METS - Metabolic Equivalents
MPRM - Meteorological Processor for Regulatory Models
MWAF - Molecular Weight Adjustment Factor
NAS - National Academy of Sciences
NCDC - National Climatic Data Center
NOAEL-No Observed Adverse Effects Level
NTP - National Toxicology Program
NWS - National Weather Station
OCD - Offshore and Coastal Dispersion Model
OEHHA - Office of Environmental Health Hazard Assessment
p - Population density
PAH - Polycyclic Aromatic Hydrocarbons

PCB - Polychlorinated Biphenyl
PCDD - Polychlorinated dibenzo-p-dioxins
PCDF - Polychlorinated dibenzofurans
PEXP - Vertical wind speed power law profile exponents
PM2.5 - Particulate Matter less than 2.5 microns in diameter
PM10 - Particulate Matter less than 10 microns in diameter
PMI - Point of Maximum Impact
QA - Quality Assurance
QC - Quality Control
RCRA - Resource Conservation and Recovery Act
REL - Reference Exposure Level
RfC - Reference Concentration
RfD - Reference Dose
SCRAM - Support Center for Regulatory Air Models
SDM - Shoreline Dispersion Model
SIR - Soil Ingestion Rate
SMAQMD - Sacramento Metropolitan Air Quality Management District
SRP - Scientific Review Panel
TAC - Toxic Air Contaminant
Tco – Biotransfer coefficient
TEF - Toxic Equivalency Factor
TERAN – Terrain option in BLP
TSD - Technical Support Document
TSP - Total Suspended Particulates
UCL - Upper Confidence Limits
USGS - U.S. Geological Survey
UTM - Universal Transvers Mercator
WAF - Worker Adjustment Factor
WHO - World Health Organization

NOTES TO APPENDIX A:

[1] Emittent ID (the emittent identification number) is the Chemical Abstract Service (CAS) number where available, or an ARB-assigned 4-digit emittent ID code.

A dash ("-") is shown for the Emittent ID for substances which are alphabetized under a group header or synonym elsewhere on the list. Refer to the cross reference indicated in parenthesis, "( )".

A double dash ("- -") is shown for the Emittent ID to indicate that the entry is a non-reportable group header for the substances immediately following it.

An asterisk ("*") is shown for the Emittent ID to indicate that the emissions of unspecified metal compounds shall be reported as the metal atom equivalent. See Note [7].

A pound sign ("#") is shown for the Emittent ID to indicate that the individual, component listed substances must be reported for this mixture or group.

[2] Individual substances listed under a group heading must be reported individually. Other, unspecified substances in the group must be summed and reported using the emittent ID of the group heading.

The square bracket designation, "[ ]", indicates that the substance is a component of the chemical group heading(s) within the brackets.

The braces designation, "{ }", indicates a synonym for the substance listed.

[3] The date the Board approved addition of the substance to the original list. The original list was approved by the Board in July 1988.

[4] The letter "c" indicates that for purposes of this section the substance shall be treated as a human carcinogen or potential human carcinogen.

[5] Applicable degree of accuracy (in lbs/year except where noted). Radionuclides must be reported in Curie units, and the accuracy must be considered accordingly. Refer to section VII.E. and Appendix B.

[6] Substances are required to be included on the Hot Spots list based on the following lists cited in Health & Safety Code section 44321:

1 = California Air Resources Board (44321(c));

2 = Environmental Protection Agency (44321(e));

3 = International Agency for Research on Cancer;

4 = Governor's List of Carcinogens and Reproductive Toxicants; (44321(a); Labor Code section 6382(b)(1)): (44321(b); HSC section 25249.8):

5 = National Toxicology Program (44321(a));

6 = Hazard Evaluation System and Information Service (44321(d));

7 = Added pursuant to HSC section 44321 (f).

[7] Emissions of unspecified metal compounds shall be reported as the amount of the metal atom equivalent, using the metal emittent identification number for the metal itself (or the emittent identification number indicated on the table, such as for reporting inorganic versus other-than-inorganic arsenic compounds).

For unspecified metal compounds which contain two or more listed metals (e.g., zinc chromate), each component metal shall be reported as the amount of the appropriate metal atom equivalent (i.e., the zinc portion of the weight as zinc equivalent and the chromate portion as hexavalent chromium equivalent.

For specific, individually listed metal compounds (e.g., Lead chromate), emissions shall be reported for the compound (as pounds of whole compound), using the emittent identification number for that compound.

[8] Compounds of the form "X-CN", where formal dissociation can occur. Report as the amount of Cyanide equivalent in the compound using an emittent identification code of 1073.

[9] Emissions of these mixtures shall be reported as emissions of total particulate matter and total organic gas, using the following emittent identification numbers:

9901 Diesel exhaust, particulate matter 9910 Gasoline exhaust, particulate matter

9902 Diesel exhaust, total organic gas

9911 Gasoline exhaust, total organic gas

Individually listed substances from gasoline exhaust must also be reported. Emissions of diesel engine exhaust particulate matter (diesel PM), shall be reported as diesel PM using emittent ID 9901.

[10] The emittent identification number 1105 has been discontinued for all facilities reporting for the first time and for all updates. Use the listed replacement emittent identification codes 1103 and 1104.

[11] Emissions of the individual, component listed substances must be reported in addition to the total gasoline vapors emissions.

[12] These lead compounds are listed here so that the inorganic lead fraction will be quantified and reported if these individual compounds cannot be quantified.

[13] PAH: (Polycyclic Aromatic Hydrocarbon) - An organic compound consisting of a fused ring structure containing at least two (2) benzene rings, and which may also contain additional fused rings not restricted exclusively to hexagonal rings.

The structure does not include any heteroatoms or substituent groups. The structure includes only carbon and hydrogen.

PAHs are a subgroup of POM and have a boiling point of greater than or equal to 100 C.

[14] PAH-DERIVATIVE: (Polycyclic Aromatic Hydrocarbon Derivative) - An organic compound consisting of a fused ring structure containing at least two (2) benzene rings, and which may also contain additional fused rings not restricted exclusively to hexagonal rings. The fused ring structure does not contain heteroatoms. The structure does contain one or more substituent groups.

PAH-Derivatives are a subgroup of POM and have a boiling point of greater than or equal to 100 C.

[15] POM: (Polycyclic Organic Matter) - Includes organic compounds with more than one benzene ring, and which have a boiling point of greater than or equal to 100 C.

[16] Radionuclides and other radioactive substances shall be reported in units of Curies per year (for annual average emissions) and in units of milliCuries per hour (for maximum hourly emissions).

[17] Emissions of Vanadium (fume or dust) shall be reported as the amount of the vanadium atom equivalent, using the identification number 7440622.

[18] The emittent identification number 1001 has been replaced with the CAS number 26148685.

NOTE: The notation “11/06” indicates most recently added substances.

Appendix B: Regulations and Legislation

B.1. Air Toxics Hot Spots Program Overview

(Air Resources Board, 2011: see http://www.arb.ca.gov/ab2588/overview.htm)

INTRODUCTION

The Air Toxics "Hot Spots" Information and Assessment Act (AB 2588, 1987, Connelly) was enacted in September 1987. Under this, stationary sources are required to report the types and quantities of certain substances their facilities routinely release into the air. Emissions of interest are those that result from the routine operation of a facility or that are predictable, including but not limited to continuous and intermittent releases and process upsets or leaks.

The goals of the Air Toxics "Hot Spots" Act are to collect emission data, to identify facilities having localized impacts, to ascertain health risks, and to notify nearby residents of significant risks. In September 1992, the "Hot Spots" Act was amended by Senate Bill (SB) 1731 (Calderon) to address the reduction of significant risks. The bill requires that owners of significant-risk facilities reduce their risks below the level of significance.

The Act requires that toxic air emissions from stationary sources (facilities) be quantified and compiled into an inventory according to criteria and guidelines developed by the ARB, that each facility be prioritized to determine whether a risk assessment must be conducted, that the risk assessments be conducted according to methods developed by the Office of Environmental Health Hazard Assessment (OEHHA), that the public be notified of significant risks posed by nearby facilities, and that emissions which result in a significant risk be reduced. Since the amendment of the statute in 1992 by enactment of SB 1731, facilities that pose a potentially significant health risks to the public are required to reduce their risks, thereby reducing the near-source exposure of Californians to toxic air pollutants. Owners of facilities found to pose significant risks by a district must prepare and implement risk reduction audit and plans within 6 months of the determination.

The Air Resources Board (ARB) is required to develop a program to make the emission data collected under the "Hot Spots" Program available to the public. If requested, districts must make health risk assessments available for public review. Districts must also publish annual reports which summarize the health risk assessment program, rank facilities according to the cancer risk posed, identify the facilities posing non-cancer health risks, and describe the status of the development of control measures.

The "Hot Spots" Program has complemented the ARB's existing air toxics identification and control programs. It has located sources of substances not previously under evaluation, and it has provided exposure information necessary to prioritize substances for control measures and develop regulatory action. Also, the preparation of the "Hot Spots" emission inventory made facility owners aware of their toxics problems. As a result, facilities have taken voluntary steps to reduce emissions of air toxics. Limited district and facility surveys have identified voluntary reductions of over 1.9 million pounds per year in the emission of air toxics from just 21 facilities in California. The benefits that come from this type of action are less risk to workers and to the public, reduced operation costs, demonstration of emission reduction options for other sources, and improved community relations.

The Act was further modified by AB 564, chaptered on September 19, 1996. The passage of AB 564 amended the Hot Spots statute in several ways, including adding provisions that: exempt specified low priority facilities from further compliance with the Hot Spots program; reinstate exempted facilities if specified criteria are met; specify an alternative evaluation process for facilities subject to district permit programs; and other changes to exempt specified facilities from further compliance with the Hot Spots Program.

B.2. Health and Safety Code Related to Air Toxics Hot Spots.

PART 6. AIR TOXICS "HOT SPOTS" INFORMATION AND ASSESSMENT
(Part 6 added by Stats. 1987, Ch. 1252, Sec. 1. Operative July 1, 1988, pursuant to Section 44384. Note: Sections 44380 and 44384 became operative Jan. 1, 1988.)

CHAPTER 1: LEGISLATIVE FINDINGS AND DEFINITIONS

44300. This part shall be known and may be cited as the Air Toxics "Hot Spots" Information and Assessment Act of 1987.

44301. The Legislature finds and declares all of the following:

(a) In the wake of recent publicity surrounding planned and unplanned releases of toxic chemicals into the atmosphere, the public has become increasingly concerned about toxics in the air.

(b) The Congressional Research Service of the Library of Congress has concluded that 75 percent of the United States population lives in proximity to at least one facility that manufactures chemicals. An incomplete 1985 survey of large chemical companies conducted by the Congressional Research Service documented that nearly every chemical plant studied routinely releases into the surrounding air significant levels of substances proven to be or potentially hazardous to public health.

(c) Generalized emissions inventories compiled by air pollution control districts and air quality management districts in California confirm the findings of the Congressional Research Service survey as well as reveal that many other facilities and businesses which do not actually manufacture chemicals do use hazardous substances in sufficient quantities to expose, or in a manner that exposes, surrounding populations to toxic air releases.

(d) These releases may create localized concentrations or air toxics "hot spots" where emissions from specific sources may expose individuals and population groups to elevated risks of adverse health effects, including, but not limited to, cancer and contribute to the cumulative health risks of emissions from other sources in the area. In some cases where large populations may not be significantly affected by adverse health risks, individuals may be exposed to significant risks.

(e) Little data is currently available to accurately assess the amounts, types, and health impacts of routine toxic chemical releases into the air. As a result, there exists significant uncertainty about the amounts of potentially hazardous air pollutants which are released, the location of those releases, and the concentrations to which the public is exposed.

(f) The State of California has begun to implement a long-term program to identify, assess, and control ambient levels of hazardous air pollutants, but additional legislation is needed to provide for the collection and evaluation of information concerning the amounts, exposures, and short- and long-term health effects of hazardous substances regularly released to the surrounding atmosphere from specific sources of hazardous releases.

(g) In order to more effectively implement control strategies for those materials posing an unacceptable risk to the public health, additional information on the sources of potentially hazardous air pollutants is necessary.
(h) It is in the public interest to ascertain and measure the amounts and types of hazardous releases and potentially hazardous releases from specific sources that may be exposing people to those releases, and to assess the health risks to those who are exposed.

44302. The definitions set forth in this chapter govern the construction of this part.

44303. "Air release" or "release" means any activity that may cause the issuance of air contaminants, including the actual or potential spilling, leaking, pumping, pouring, emitting, emptying, discharging, injecting, escaping, leaching, dumping, or disposing of a substance into the ambient air and that results from the routine operation of a facility or that is predictable, including, but not limited to, continuous and intermittent releases and predictable process upsets or leaks.

44304. "Facility" means every structure, appurtenance, installation, and improvement on land which is associated with a source of air releases or potential air releases of a hazardous material.

44306. "Health risk assessment" means a detailed comprehensive analysis prepared pursuant to Section 44361 to evaluate and predict the dispersion of hazardous substances in the environment and the potential for exposure of human populations and to assess and quantify both the individual and populationwide health risks associated with those levels of exposure.

44307. "Operator" means the person who owns or operates a facility or part of a facility.

44308. "Plan" means the emissions inventory plan which meets the conditions specified in Section 44342.

44309. "Report" means the emissions inventory report specified in Section 44341.

CHAPTER 2: FACILITIES SUBJECT TO THIS PART

44320. This part applies to the following:
(a) Any facility which manufactures, formulates, uses, or releases any of the substances listed pursuant to Section 44321 or any other substance which reacts to form a substance listed in Section 44321 and which releases or has the potential to release total organic gases, particulates, or oxides of nitrogen or sulfur in the amounts specified in Section 44322.
(b) Except as provided in Section 44323, any facility which is listed in any current toxics use or toxics air emission survey, inventory, or report released or compiled by a district. A district may, with the concurrence of the state board, waive the application of this part pursuant to this subdivision for any facility which

the district determines will not release any substance listed pursuant to Section 44321 due to a shutdown or a process change.

44321. For the purposes of Section 44320, the state board shall compile and maintain a list of substances that contains, but is not limited to, all of the following:

(a) Substances identified by reference in paragraph (1) of subdivision (b) of Section 6382 of the Labor Code and substances placed on the list prepared by the National Toxicology Program and issued by the United States Secretary of Health and Human Services pursuant to paragraph (4) of subsection (b) of Section 241 of Title 42 of the United States Code. For the purposes of this subdivision, the state board may remove from the list any substance which meets both of the following criteria:
  (1) No evidence exists that it has been detected in air.
  (2) The substance is not manufactured or used in California, or, if manufactured or used in California, because of the physical or chemical characteristics of the substance or the manner in which it is manufactured or used, there is no possibility that it will become airborne.

(b) Carcinogens and reproductive toxins referenced in or compiled pursuant to Section 25249.8, except those which meet both of the criteria identified in subdivision (a).

(c) Substances designated by the state board as toxic air contaminants pursuant to subdivision (b) of Section 39657 and substances on the candidate list of potential toxic air contaminants and the list of designated toxic air contaminants prepared by the state board pursuant to Article 3 (commencing with Section 39660) of Chapter 3.5 of Part 2, including, but not limited to, all substances currently under review and scheduled or nominated for review and substances identified and listed for which health effects information is limited.

(d) Substances for which an information or hazard alert has been issued by the repository of current data established pursuant to Section 147.2 of the Labor Code.

(e) Substances reviewed, under review, or scheduled for review as air toxics or potential air toxics by the Office of Air Quality Planning and Standards of the Environmental Protection Agency, including substances evaluated in all of the following categories or their equivalent: preliminary health and source screening, detailed assessment, intent to list, decision not to regulate, listed, standard proposed, and standard promulgated.

(f) Any additional substances recognized by the state board as presenting a chronic or acute threat to public health when present in the ambient air, including, but not limited to, any neurotoxicants or chronic respiratory toxicants not included within subdivision (a), (b), (c), (d), or (e).

44322. This part applies to facilities specified in subdivision (a) of Section 44320 in accordance with the following schedule:

(a) For those facilities that release, or have the potential to release, 25 tons per year or greater of total organic gases, particulates, or oxides of nitrogen or sulfur, this part becomes effective on July 1, 1988.

(b) For those facilities that release, or have the potential to release, more than 10 but less than 25 tons per year of total organic gases, particulates, or oxides of nitrogen or sulfur, this part becomes effective July 1, 1989.
(c) For those facilities that release, or have the potential to release, less than 10 tons per year of total organic gases, particulates, or oxides of nitrogen or sulfur, the state board shall, on or before July 1, 1990, prepare and submit a report to the Legislature identifying the classes of those facilities to be included in this part and specifying a timetable for their inclusion.

44323. A district may prepare an industrywide emissions inventory and health risk assessment for facilities specified in subdivision (b) of Section 44320 and subdivisions (a) and (b) of Section 44322, and shall prepare an industrywide emissions inventory for the facilities specified in subdivision (c) of Section 44322, in compliance with this part for any class of facilities that the district finds and determines meets all of the following conditions:
(a) All facilities in the class fall within one four-digit Standard Industrial Classification Code.
(b) Individual compliance with this part would impose severe economic hardships on the majority of the facilities within the class.
(c) The majority of the class is composed of small businesses.
(d) Releases from individual facilities in the class can easily and generically be characterized and calculated.

44324. This part does not apply to any facility where economic poisons are employed in their pesticidal use, unless that facility was subject to district permit requirements on or before August 1, 1987. As used in this section, "pesticidal use" does not include the manufacture or formulation of pesticides.

44325. Any solid waste disposal facility in compliance with Section 41805.5 is in compliance with the emissions inventory requirements of this part.

CHAPTER 3: AIR TOXICS EMISSION INVENTORIES

44340.
(a) The operator of each facility subject to this part shall prepare and submit to the district a proposed comprehensive emissions inventory plan in accordance with the criteria and guidelines adopted by the state board pursuant to Section 44342.
(b) The proposed plan shall be submitted to the district on or before August 1, 1989, except that, for any facility to which subdivision (b) of Section 44322 applies, the proposed plan shall be submitted to the district on or before August 1, 1990. The district shall approve, modify, and approve as modified, or return for revision and resubmission, the plan within 120 days of receipt.
(c) The district shall not approve a plan unless all of the following conditions are met:
(1) The plan meets the requirements established by the state board pursuant to Section 44342.

(2) The plan is designed to produce, from the list compiled and maintained pursuant to Section 44321, a comprehensive characterization of the full range of hazardous materials that are released, or that may be released, to the surrounding air from the facility. Air release data shall be collected at, or calculated for, the primary locations of actual and potential release for each hazardous material. Data shall be collected or calculated for all continuous, intermittent, and predictable air releases.
(3) The measurement technologies and estimation methods proposed provide state-of-the-art effectiveness and are sufficient to produce a true representation of the types and quantities of air releases from the facility.
(4) Source testing or other measurement techniques are employed wherever necessary to verify emission estimates, as determined by the state board and to the extent technologically feasible. All testing devices shall be appropriately located, as determined by the state board.
(5) Data are collected or calculated for the relevant exposure rate or rates of each hazardous material according to its characteristic toxicity and for the emission rate necessary to ensure a characterization of risk associated with exposure to releases of the hazardous material that meets the requirements of Section 44361. The source of all emissions shall be displayed or described.

44341. Within 180 days after approval of a plan by the district, the operator shall implement the plan and prepare and submit a report to the district in accordance with the plan. The district shall transmit all monitoring data contained in the approved report to the state board.

44342. The state board shall, on or before May 1, 1989, in consultation with the districts, develop criteria and guidelines for site-specific air toxics emissions inventory plans which shall be designed to comply with the conditions specified in Section 44340 and which shall include at least all of the following:

(a) For each class of facility, a designation of the hazardous materials for which emissions are to be quantified and an identification of the likely source types within that class of facility. The hazardous materials for quantification shall be chosen from among, and may include all or part of, the list specified in Section 44321.
(b) Requirements for a facility diagram identifying each actual or potential discrete emission point and the general locations where fugitive emissions may occur. The facility diagram shall include any nonpermitted and nonprocess sources of emissions and shall provide the necessary data to identify emission characteristics. An existing facility diagram which meets the requirements of this section may be submitted.
(c) Requirements for source testing and measurement. The guidelines may specify appropriate uses of estimation techniques including, but not limited to, emissions factors, modeling, mass balance analysis, and projections, except that source testing shall be required wherever necessary to verify emission estimates to the extent technologically feasible. The guidelines shall specify conditions and

locations where source testing, fence-line monitoring, or other measurement techniques are to be required and the frequency of that testing and measurement.

(d) Appropriate testing methods, equipment, and procedures, including quality assurance criteria.

(e) Specifications for acceptable emissions factors, including, but not limited to, those which are acceptable for substantially similar facilities or equipment, and specification of procedures for other estimation techniques and for the appropriate use of available data.

(f) Specification of the reporting period required for each hazardous material for which emissions will be inventoried.

(g) Specifications for the collection of useful data to identify toxic air contaminants pursuant to Article 2 (commencing with Section 39660) of Chapter 3.5 of Part 2.

(h) Standardized format for preparation of reports and presentation of data.

(i) A program to coordinate and eliminate any possible overlap between the requirements of this chapter and the requirements of Section 313 of the Superfund Amendment and Reauthorization Act of 1986 (Public Law 99-499). The state board shall design the guidelines and criteria to ensure that, in collecting data to be used for emissions inventories, actual measurement is utilized whenever necessary to verify the accuracy of emission estimates, to the extent technologically feasible.

44343. The district shall review the reports submitted pursuant to Section 44341 and shall, within 90 days, review each report, obtain corrections and clarifications of the data, and notify the Office of Environmental Health Hazard Assessment, the Department of Industrial Relations, and the city or county health department of its findings and determinations as a result of its review of the report.

44344. Except as provided in Section 44391, emissions inventories developed pursuant to this chapter shall be updated every four years, in accordance with the procedures established by the state board. Those updates shall take into consideration improvements in measurement techniques and advancing knowledge concerning the types and toxicity of hazardous material released or potentially released.

44344.4.

(a) Except as provided in subdivision (d) and in Section 44344.7, a facility shall be exempt from further compliance with this part if the facility's prioritization scores for cancer and noncancer health effects are both equal to or less than one, based on the results of the most recent emissions inventory or emissions inventory update. An exempt facility shall no longer be required to pay any fee or submit any report to the district or the state board pursuant to this part.

(b) Except for facilities that are exempt from this part pursuant to subdivision (a), a facility for which the prioritization scores for cancer and noncancer health effects are both equal to or less than 10, based on the results of the most recent emissions inventory or emissions inventory update, shall not be required to pay any fee or submit any report to the district or the state board pursuant to this part,

except for the quadrennial emissions inventory update required pursuant to Section 44344. A district may, by regulation, establish a fee to be paid by a facility operator in connection with the operator's submission to the district of a quadrennial emissions inventory update pursuant to this subdivision. The fee shall not be greater than one hundred twenty-five dollars ($125). A district may increase the fee above that amount upon the adoption of written findings that the costs of processing the emission inventory update exceed one hundred twenty-five dollars ($125). However, the district shall not adopt a fee greater than that supported by the written findings.

(c) For the purposes of this part, "prioritization score" means a facility's numerical score for cancer health effects or noncancer health effects, as determined by the district pursuant to Section 44360 in a manner consistent with facility prioritization guidelines prepared by the California Air Pollution Control Officers Association and approved by the state board.

(d) Notwithstanding subdivision (a) and Section 44344.7, if a district has good cause to believe that a facility may pose a potential threat to public health and that the facility therefore does not qualify for an exemption claimed by the facility pursuant to subdivision (a), the district may require the facility to document the facility's emissions and health impacts, or the changes in emissions expected to occur as a result of a particular physical change, a change in activities or operations at the facility, or a change in other factors. The district may deny the exemption if the documentation does not support the claim for the exemption.

44344.5.

(a) The operator of any new facility that previously has not been subject to this part shall prepare and submit an emissions inventory plan and report.

(b) Notwithstanding subdivision (a), a new facility shall not be required to submit an emissions inventory plan and report if all of the following conditions are met:

(1) The facility is subject to a district permit program established pursuant to Section 42300.

(2) The district conducts an assessment of the potential emissions or their associated risks, whichever the district determines to be appropriate, attributable to the new facility and finds that the emissions will not result in a significant risk. A risk assessment conducted pursuant to this paragraph shall comply with paragraph (2) of subdivision (b) of Section 44360.

(3) The district issues a permit authorizing construction or operation of the new facility.

44344.6. A district shall redetermine a facility's prioritization score, or evaluate the prioritization score as calculated and submitted by the facility, within 90 days from the date of receipt of a quadrennial emissions inventory update pursuant to Section 44344 or subdivision (b) of Section 44344.4, within 90 days from the date of receipt of an emissions inventory update submitted pursuant to Section 44344.7, or within 90 days from the date of receiving notice that a facility has completed the implementation of a plan prepared pursuant to Section 44392.

44344.7.

(a) A facility exempted from this part pursuant to subdivision (a) of Section 44344.4 shall, upon receipt of a notice from the district, again be subject to this part and the operator shall submit an emissions inventory update for those sources and substances for which a physical change in the facility or a change in activities or operations has occurred, as follows:
  (1) The facility emits a substance newly listed pursuant to Section 44321.
  (2) A sensitive receptor has been established or constructed within 500 meters of the facility after the facility became exempt.
  (3) The facility emits a substance for which the potency factor has increased.

(b) The operator of a facility exempted from this part pursuant to subdivision (a) of Section 44344.4 shall submit an emissions inventory update for those sources and substances for which a particular physical change in the facility or a change in activities or operations occurs if, as a result of the particular change, either of the following has occurred:
  (1) The facility has begun emitting a listed substance not included in the previous emissions inventory.
  (2) The facility has increased its emissions of a listed substance to a level greater than the level previously reported for that substance, and the increase in emissions exceeds 100 percent of the previously reported level.

(c) Notwithstanding subdivision (b), a physical change or change in activities or operations at a facility shall not cause the facility to again be subject to this part if all of the following conditions are met:
  (1) The physical change or change in activities or operations is subject to a district permit program established pursuant to Section 42300.
  (2) The district conducts an assessment of the potential changes in emissions or their associated risks, whichever the district determines to be appropriate, attributable to the physical change or change in activities or operations and finds that the changes in emissions will not result in a significant risk. A risk assessment conducted pursuant to this paragraph shall comply with paragraph (2) of subdivision (b) of Section 44360.
  (3) The district issues a permit for the physical change or change in activities or operations.

44345.

(a) On or before July 1, 1989, the state board shall develop a program to compile and make available to other state and local public agencies and the public all data collected pursuant to this chapter.

(b) In addition, the state board, on or before March 1, 1990, shall compile, by district, emissions inventory data for mobile sources and area sources not subject to district permit requirements, and data on natural source emissions, and shall incorporate these data into data compiled and released pursuant to this chapter.

44346.

(a) If an operator believes that any information required in the facility diagram specified pursuant to subdivision (b) of Section 44342 involves the release of a trade secret, the operator shall nevertheless make the disclosure to the district, and shall notify the district in writing of that belief in the report.

(b) Subject to this section, the district shall protect from disclosure any trade secret designated as such by the operator, if that trade secret is not a public record.

(c) Upon receipt of a request for the release of information to the public which includes information which the operator has notified the district is a trade secret and which is not a public record, the following procedure applies:

(1) The district shall notify the operator of the request in writing by certified mail, return receipt requested.

(2) The district shall release the information to the public, but not earlier than 30 days after the date of mailing the notice of the request for information, unless, prior to the expiration of the 30-day period, the operator obtains an action in an appropriate court for a declaratory judgment that the information is subject to protection under this section or for a preliminary injunction prohibiting disclosure of the information to the public and promptly notifies the district of that action.

(d) This section does not permit an operator to refuse to disclose the information required pursuant to this part to the district.

(e) Any information determined by a court to be a trade secret, and not a public record pursuant to this section, shall not be disclosed to anyone except an officer or employee of the district, the state, or the United States, in connection with the official duties of that officer or employee under any law for the protection of health, or to contractors with the district or the state and its employees if, in the opinion of the district or the state, disclosure is necessary and required for the satisfactory performance of a contract, for performance of work, or to protect the health and safety of the employees of the contractor.

(f) Any officer or employee of the district or former officer or employee who, by virtue of that employment or official position, has possession of, or has access to, any trade secret subject to this section, and who, knowing that disclosure of the information to the general public is prohibited by this section, knowingly and willfully discloses the information in any manner to any person not entitled to receive it is guilty of a misdemeanor. Any contractor of the district and any employee of the contractor, who has been furnished information as authorized by this section, shall be considered an employee of the district for purposes of this section.

(g) Information certified by appropriate officials of the United States as necessary to be kept secret for national defense purposes shall be accorded the full protections against disclosure as specified by those officials or in accordance with the laws of the United States.

(h) As used in this section, "trade secret" and "public record" have the meanings and protections given to them by Section 6254.7 of the Government Code and Section 1060 of the Evidence Code. All information collected pursuant to this chapter, except for data used to calculate emissions data required in the facility

diagram, shall be considered "air pollution emission data," for the purposes of this section.

CHAPTER 4: RISK ASSESSMENT

44360.

(a) Within 90 days of completion of the review of all emissions inventory data for facilities specified in subdivision (a) of Section 44322, but not later than December 1, 1990, the district shall, based on examination of the emissions inventory data and in consultation with the state board and the State Department of Health Services, prioritize and then categorize those facilities for the purposes of health risk assessment. The district shall designate high, intermediate, and low priority categories and shall include each facility within the appropriate category based on its individual priority. In establishing priorities pursuant to this section, the district shall consider the potency, toxicity, quantity, and volume of hazardous materials released from the facility, the proximity of the facility to potential receptors, including, but not limited to, hospitals, schools, day care centers, worksites, and residences, and any other factors that the district finds and determines may indicate that the facility may pose a significant risk to receptors. The district shall hold a public hearing prior to the final establishment of priorities and categories pursuant to this section.

(b)

(1) Within 150 days of the designation of priorities and categories pursuant to subdivision (a), the operator of every facility that has been included within the highest priority category shall prepare and submit to the district a health risk assessment pursuant to Section 44361. The district may, at its discretion, grant a 30-day extension for submittal of the health risk assessment.

(2) Health risk assessments required by this chapter shall be prepared in accordance with guidelines established by the Office of Environmental Health Hazard Assessment. The office shall prepare draft guidelines which shall be circulated to the public and the regulated community and shall adopt risk assessment guidelines after consulting with the state board and the Risk Assessment Committee of the California Air Pollution Control Officers Association and after conducting at least two public workshops, one in the northern and one in the southern part of the state. The adoption of the guidelines is not subject to Chapter 3.5 (commencing with Section 11340) of Part 1 of Division 3 of Title 2 of the Government Code. The scientific review panel established pursuant to Section 39670 shall evaluate the guidelines adopted under this paragraph and shall recommend changes and additional criteria to reflect new scientific data or empirical studies.

(3) The guidelines established pursuant to paragraph (2) shall impose only those requirements on facilities subject to this subdivision that are necessary to ensure that a required risk assessment is accurate and complete and shall specify the type of site-specific factors that districts may take into account in determining when a single health risk assessment may be allowed under subdivision (d). The guidelines shall, in addition, allow the operator of a

facility, at the operator's option, and to the extent that valid and reliable data are available, to include for consideration by the district in the health risk assessment any or all of the following supplemental information:

(A) Information concerning the scientific basis for selecting risk parameter values that are different than those required by the guidelines and the likelihood distributions that result when alternative values are used.

(B) Data from dispersion models, microenvironment characteristics, and population distributions that may be used to estimate maximum actual exposure.

(C) Risk expressions that show the likelihood that any given risk estimate is the correct risk value.

(D) A description of the incremental reductions in risk that occur when exposure is reduced.

(4) To ensure consistency in the use of the supplemental information authorized by subparagraphs (A), (B), (C), and (D) of paragraph (3), the guidelines established pursuant to paragraph (2) shall include guidance for use by the districts in considering the supplemental information when it is included in the health risk assessment.

(c) Upon submission of emissions inventory data for facilities specified in subdivisions (b) and (c) of Section 44322, the district shall designate facilities for inclusion within the highest priority category, as appropriate, and any facility so designated shall be subject to subdivision (b). In addition, the district may require the operator of any facility to prepare and submit health risk assessments, in accordance with the priorities developed pursuant to subdivision (a).

(d) The district shall, except where site specific factors may affect the results, allow the use of a single health risk assessment for two or more substantially identical facilities operated by the same person.

(e) Nothing contained in this section, Section 44380.5, or Chapter 6 (commencing with Section 44390) shall be interpreted as requiring a facility operator to prepare a new or revised health risk assessment using the guidelines established pursuant to paragraph (2) of subdivision (a) of this section if the facility operator is required by the district to begin the preparation of a health risk assessment before those guidelines are established.

44361.

(a) Each health risk assessment shall be submitted to the district. The district shall make the health risk assessment available for public review, upon request. After preliminary review of the emissions impact and modeling data, the district shall submit the health risk assessment to the Office of Environmental Health Hazard Assessment for review and, within 180 days of receiving the health risk assessment, the State office shall submit to the district its comments on the data and findings relating to health effects. The district shall consult with the state board as necessary to adequately evaluate the emissions impact and modeling data contained within the risk assessment.

(b) For the purposes of complying with this section, the Office of Environmental Health Hazard Assessment may select a qualified independent contractor to review the data and findings relating to health effects. The office shall not select an independent contractor to review a specific health risk assessment who may have a conflict of interest with regard to the review of that health risk assessment. Any review by an independent contractor shall comply with the following requirements:
(1) Be performed in a manner consistent with guidelines provided by the office.
(2) Be reviewed by the office for accuracy and completeness.
(3) Be submitted by the office to the district in accordance with this section.

(c) The district shall reimburse the Office of Environmental Health Hazard Assessment or the qualified independent contractor designated by the office pursuant to subdivision (b), within 45 days of its request, for its actual costs incurred in reviewing a health risk assessment pursuant to this section.

(d) If a district requests the Office of Environmental Health Hazard Assessment to consult with the district concerning any requirement of this part, the district shall reimburse the office, within 45 days of its request, for the costs incurred in the consultation.

(e) Upon designation of the high priority facilities, as specified in subdivision (a) of Section 44360, the Office of Environmental Health Hazard Assessment shall evaluate the staffing requirements of this section and may submit recommendations to the Legislature, as appropriate, concerning the maximum number of health risk assessments to be reviewed each year pursuant to this section.

44362.

(a) Taking the comments of the Office of Environmental Health Hazard Assessment into account, the district shall approve or return for revision and resubmission and then approve, the health risk assessment within one year of receipt. If the health risk assessment has not been revised and resubmitted within 60 days of the district's request of the operator to do so, the district may modify the health risk assessment and approve it as modified.

(b) Upon approval of the health risk assessment, the operator of the facility shall provide notice to all exposed persons regarding the results of the health risk assessment prepared pursuant to Section 44361 if, in the judgment of the district, the health risk assessment indicates there is a significant health risk associated with emissions from the facility. If notice is required under this subdivision, the notice shall include only information concerning significant health risks attributable to the specific facility for which the notice is required. Any notice shall be made in accordance with procedures specified by the district.

44363.

(a) Commencing July 1, 1991, each district shall prepare and publish an annual report which does all of the following:
   (1) Describes the priorities and categories designated pursuant to Section 44360 and summarizes the results and progress of the health risk assessment program undertaken pursuant to this part.
   (2) Ranks and identifies facilities according to the degree of cancer risk posed both to individuals and to the exposed population.
   (3) Identifies facilities which expose individuals or populations to any noncancer health risks.
   (4) Describes the status of the development of control measures to reduce emissions of toxic air contaminants, if any.

(b) The district shall disseminate the annual report to county boards of supervisors, city councils, and local health officers and the district board shall hold one or more public hearings to present the report and discuss its content and significance.

44364. The state board shall utilize the reports and assessments developed pursuant to this part for the purposes of identifying, establishing priorities for, and controlling toxic air contaminants pursuant to Chapter 3.5 (commencing with Section 39650) of Part 2.

44365.

(a) If the state board finds and determines that a district's actions pursuant to this part do not meet the requirements of this part, the state board may exercise the authority of the district pursuant to this part to approve emissions inventory plans and require the preparation of health risk assessments.

(b) This part does not prevent any district from establishing more stringent criteria and requirements than are specified in this part for approval of emissions inventories and requiring the preparation and submission of health risk assessments. Nothing in this part limits the authority of a district under any other provision of law to assess and regulate releases of hazardous substances.

44366.

(a) In order to verify the accuracy of any information submitted by facilities pursuant to this part, a district or the state board may proceed in accordance with Section 41510.

CHAPTER 5: FEES AND REGULATIONS

44380.

(a) The state board shall adopt a regulation which does all of the following:
   (1) Sets forth the amount of revenue which the district must collect to recover the reasonable anticipated cost which will be incurred by the state board and the Office of Environmental Health Hazard Assessment to implement and administer this part.

(2) Requires each district to adopt a fee schedule which recovers the costs of the district and which assesses a fee upon the operator of every facility subject to this part, except as specified in subdivision (b) of Section 44344.4. A district may request the state board to adopt a fee schedule for the district if the district's program costs are approved by the district board and transmitted to the state board by April 1 of the year in which the request is made.

(3) Requires any district that has an approved toxics emissions inventory compiled pursuant to this part by August 1 of the preceding year to adopt a fee schedule, as described in paragraph (2), which imposes on facility operators fees which are, to the maximum extent practicable, proportionate to the extent of the releases identified in the toxics emissions inventory and the level of priority assigned to that source by the district pursuant to Section 44360.

(b) Commencing August 1, 1992, and annually thereafter, the state board shall review and may amend the fee regulation.

(c) The district shall notify each person who is subject to the fee of the obligation to pay the fee. If a person fails to pay the fee within 60 days after receipt of this notice, the district, unless otherwise provided by district rules, shall require the person to pay an additional administrative civil penalty. The district shall fix the penalty at not more than 100 percent of the assessed fee, but in an amount sufficient in its determination, to pay the district's additional expenses incurred by the person's noncompliance. If a person fails to pay the fee within 120 days after receipt of this notice, the district may initiate permit revocation proceedings. If any permit is revoked, it shall be reinstated only upon full payment of the overdue fee plus any late penalty, and a reinstatement fee to cover administrative costs of reinstating the permit.

(d) Each district shall collect the fees assessed pursuant to subdivision (a). After deducting the costs to the district to implement and administer this part, the district shall transmit the remainder to the Controller for deposit in the Air Toxics Inventory and Assessment Account, which is hereby created in the General Fund. The money in the account is available, upon appropriation by the Legislature, to the state board and the Office of Environmental Health Hazard Assessment for the purposes of administering this part.

(e) For the 1997-98 fiscal year, air toxics program revenues for the state board and the Office of Environmental Health Hazard Assessment shall not exceed two million dollars ($2,000,000), and for each fiscal year thereafter, shall not exceed one million three hundred fifty thousand dollars ($1,350,000). Funding for the Office of Environmental Health Hazard Assessment for conducting risk assessment reviews shall be on a fee-for-service basis.

44380.1. A facility shall be granted an exemption by a district from paying a fee in accordance with Section 44380 if all of the following criteria are met:

(a) The facility primarily handles, processes, stores, or distributes bulk agricultural commodities or handles, feeds, or rears livestock.

(b) The facility was required to comply with this part only as a result of its particulate matter emissions.

(c) The fee schedule adopted by the district or the state board for these types of facilities is not solely based on toxic emissions weighted for potency or toxicity.

44380.5. In addition to the fee assessed pursuant to Section 44380, a supplemental fee may be assessed by the district, the state board, or the Office of Environmental Health Hazard Assessment upon the operator of a facility that, at the operator's option, includes supplemental information authorized by paragraph (3) of subdivision (b) of Section 44360 in a health risk assessment, if the review of that supplemental information substantially increases the costs of reviewing the health risk assessment by the district, the state board, or the office. The supplemental fee shall be set by the state board in the regulation required by subdivision (a) of Section 44380 and shall be set in an amount sufficient to cover the direct costs to review the information supplied by an operator pursuant to paragraph (3) of subdivision (b) of Section 44360.

44381.

(a) Any person who fails to submit any information, reports, or statements required by this part, or who fails to comply with this part or with any permit, rule, regulation, or requirement issued or adopted pursuant to this part, is subject to a civil penalty of not less than five hundred dollars ($500) or more than ten thousand dollars ($10,000) for each day that the information, report, or statement is not submitted, or that the violation continues.
(b) Any person who knowingly submits any false statement or representation in any application, report, statement, or other document filed, maintained, or used for the purposes of compliance with this part is subject to a civil penalty of not less than one thousand dollars ($1,000) or more than twenty-five thousand dollars ($25,000) per day for each day that the information remains uncorrected.

44382. Every district shall, by regulation, adopt the requirements of this part as a condition of every permit issued pursuant to Chapter 4 (commencing with Section 42300) of Part 4 for all new and modified facilities.

44384. Except for Section 44380 and this section, all provisions of this part shall become operative on July 1, 1988.

CHAPTER 6: FACILITY RISK REDUCTION AUDIT AND PLAN

44390. For purposes of this chapter, the following definitions apply:

(a) "Airborne toxic risk reduction measure" or "ATRRM" means those in-plant changes in production processes or feedstocks that reduce or eliminate toxic air emissions subject to this part. ATRRM's may include:
    (1) Feedstock modification.
    (2) Product reformulations.
    (3) Production system modifications.
    (4) System enclosure, emissions control, capture, or conversion.
    (5) Operational standards and practices modification.

(b) Airborne toxic risk reduction measures do not include measures that will increase risk from exposure to the chemical in another media or that increase the risk to workers or consumers.
(c) "Airborne toxic risk reduction audit and plan" or "audit and plan" means the audit and plan specified in Section 44392.

44391.
(a) Whenever a health risk assessment approved pursuant to Chapter 4 (commencing with Section 44360) indicates, in the judgment of the district, that there is a significant risk associated with the emissions from a facility, the facility operator shall conduct an airborne toxic risk reduction audit and develop a plan to implement airborne toxic risk reduction measures that will result in the reduction of emissions from the facility to a level below the significant risk level within five years of the date the plan is submitted to the district. The facility operator shall implement measures set forth in the plan in accordance with this chapter.
(b) The period to implement the plan required by subdivision (a) may be shortened by the district if it finds that it is technically feasible and economically practicable to implement the plan to reduce emissions below the significant risk level more quickly or if it finds that the emissions from the facility pose an unreasonable health risk.
(c) A district may lengthen the period to implement the plan required by subdivision (a) by up to an additional five years if it finds that a period longer than five years will not result in an unreasonable risk to public health and that requiring implementation of the plan within five years places an unreasonable economic burden on the facility operator or is not technically feasible.
(d)
  (1) The state board and districts shall provide assistance to smaller businesses that have inadequate technical and financial resources for obtaining information, assessing risk reduction methods, and developing and applying risk reduction techniques.
  (2) Risk reduction audits and plans for any industry subject to this chapter which is comprised mainly of small businesses using substantially similar technology may be completed by a self-conducted audit and checklist developed by the state board. The state board, in coordination with the districts, shall provide a copy of the audit and checklist to small businesses within those industries to assist them to meet the requirements of this chapter.
(e) The audit and plan shall contain all the information required by Section 44392.
(f) The plan shall be submitted to the district, within six months of a district's determination of significant risk, for review of completeness. Operators of facilities that have been notified prior to January 1, 1993, that there is a significant risk associated with emissions from the facility shall submit the plan by July 1, 1993. The district's review of completeness shall include a substantive analysis of the emission reduction measures included in the plan, and the ability

of those measures to achieve emission reduction goals as quickly as feasible as provided in subdivisions (a) and (b).

(g) The district shall find the audit and plan to be satisfactory within three months if it meets the requirements of this chapter, including, but not limited to, subdivision (f). If the district determines that the audit and plan does not meet those requirements, the district shall remand the audit and plan to the facility specifying the deficiencies identified by the district. A facility operator shall submit a revised audit and plan addressing the deficiencies identified by the district within 90 days of receipt of a deficiency notice.

(h) Progress on the emission reductions achieved by the plan shall be reported to the district in emissions inventory updates. Emissions inventory updates shall be prepared as required by the audit and plan found to be satisfactory by the district pursuant to subdivision (g).

(i) If new information becomes available after the initial risk reduction audit and plan, on air toxics risks posed by a facility, or emission reduction technologies that may be used by a facility that would significantly impact risks to exposed persons, the district may require the plan to be updated and resubmitted to the district.

(j) This section does not authorize the emission of a toxic air contaminant in violation of an airborne toxic control measure adopted pursuant to Chapter 3.5 (commencing with Section 39650) or in violation of Section 41700.

44392. A facility operator subject to this chapter shall conduct an airborne toxic risk reduction audit and develop a plan which shall include at a minimum all of the following:

(a) The name and location of the facility.

(b) The SIC code for the facility.

(c) The chemical name and the generic classification of the chemical.

(d) An evaluation of the ATRRM's available to the operator.

(e) The specification of, and rationale for, the ATRRMs that will be implemented by the operator. The audit and plan shall document the rationale for rejecting ATRRMs that are identified as infeasible or too costly.

(f) A schedule for implementing the ATRRMs. The schedule shall meet the time requirements of subdivision (a) of Section 44391 or the time period for implementing the plan set by the district pursuant to subdivision (b) or (c) of Section 44391, whichever is applicable.

(g) The audit and plan shall be reviewed and certified as meeting this chapter by an engineer who is registered as a professional engineer pursuant to Section 6762 of the Business and Professions Code, by an individual who is responsible for the processes and operations of the site, or by an environmental assessor registered pursuant to Section 25570.3.

44393. The plan prepared pursuant to Section 44391 shall not be considered to be the equivalent of a pollution prevention program or a source reduction program, except insofar as the audit and plan elements are consistent with source reduction, as defined in Section 25244.14, or subsequent statutory definitions of pollution prevention.

44394. Any facility operator who does not submit a complete airborne toxic risk reduction audit and plan or fails to implement the measures set forth in the plan as set forth in this chapter is subject to the civil penalty specified in subdivision (a) of Section 44381, and any facility operator who, in connection with the audit or plan, knowingly submits any false statement or representation is subject to the civil penalty specified in subdivision (b) of Section 44381.

B.3. Toxic Air Contaminants Program Overview

(Air Resources Board, 2011: see http://www.arb.ca.gov/toxics/background.htm)

AB 1807 Program

In 1983, the California Legislature established a two-step process of risk identification and risk management to address the potential health effects from air toxic substances and protect the public health of Californians. During the first step (identification), the ARB and the Office of Environmental Health Hazard Assessment (OEHHA) determine if a substance should be formally identified as a toxic air contaminant (TAC) in California. During this process, the ARB and the OEHHA staff draft a report that serves as the basis for this determination. The ARB staff assesses the potential for human exposure to a substance and the OEHHA staff evaluates the health effects. A thorough public process assures accountability and public input. Public workshops are conducted to allow for direct exchanges of information with interested constituencies. The draft risk assessments themselves are published and widely distributed with a public notice requesting comment to further assure involvement. The final risk assessment (identification) report includes a record of the public comments and how they were addressed. After the ARB and the OEHHA staff hold several comment periods and workshops, the report is then submitted to an independent, nine member, Scientific Review Panel (SRP), who review the report for its scientific accuracy. If the SRP approves the report, they develop specific scientific findings which are officially submitted to the ARB. The ARB staff then prepares a hearing notice and draft regulation to formally identify the substance as a TAC. Based on the input from the public and the information gathered from the report, the Board will decide whether to identify a substance as a TAC. Any person may petition the Board to review a previous determination by providing new evidence.

In the second step (risk management), the ARB reviews the emission sources of an identified TAC to determine if any regulatory action is necessary to reduce the risk. The analysis includes a review of controls already in place, the available technologies and associated costs for reducing emissions, and the associated risk. Public outreach is an essential element in the development of a control plan and any control measure to ensure that the ARB efforts are cost-effective and appropriately balance public health protection and economic growth.

In 1993, the California Legislature amended the AB 1807 program for the identification and control of TACs (AB 2728). Specifically, AB 2728 required the ARB to identify the 189 federal hazardous air pollutants as TACs. For those substances that have not previously been identified under AB 1807 and identified under AB 2728, health effects values will need to be developed. This report will serve as a basis for that evaluation. For substances that were not identified as TACs and are on the TAC Identification List, this report will provide information to evaluate which substances may be entered into the air toxics identification process.

B.4. Senate Bill 352. Schoolsites: sources of pollution

CHAPTER 668
FILED WITH SECRETARY OF STATE OCTOBER 3, 2003
APPROVED BY GOVERNOR OCTOBER 2, 2003

THE PEOPLE OF THE STATE OF CALIFORNIA DO ENACT AS FOLLOWS:

SECTION 1.
The Legislature finds and declares all of the following:

(a) Many studies have shown significantly increased levels of pollutants, particularly diesel particulates, in close proximity to freeways and other major diesel sources. A recent study of Los Angeles area freeways measured diesel particulate levels up to 25 times higher near freeways than those levels elsewhere. Much of the pollution from freeways is associated with acute health effects, exacerbating asthma and negatively impacting the ability of children to learn.
(b) Cars and trucks release at least forty different toxic air contaminants, including, but not limited to, diesel particulate, benzene, formaldehyde, 1,3-butadiene and acetaldehyde. Levels of these pollutants are generally concentrated within 500 feet of freeways and very busy roadways.
(c) Current state law governing the siting of schools does not specify whether busy freeways should be included in environmental impact reports of nearby "facilities." Over 150 schools are already estimated to be within 500 feet of extremely high traffic roadways.
(d) A disproportionate number of economically disadvantaged pupils may be attending schools that are close to busy roads, putting them at an increased risk of developing bronchitis from elevated levels of several pollutants associated with traffic. Many studies have confirmed that increased wheezing and bronchitis occurs among children living in high traffic areas.
(e) It is therefore the intent of the Legislature to protect school children from the health risks posed by pollution from heavy freeway traffic and other nonstationary sources in the same way that they are protected from industrial pollution.

SECTION 2.

Section 17213 of the Education Code is amended to read:
17213. The governing board of a school district may not approve a project involving the acquisition of a schoolsite by a school district, unless all of the following occur:
(a) The school district, as the lead agency, as defined in Section 21067 of the Public Resources Code, determines that the property purchased or to be built upon is not any of the following:
(1) The site of a current or former hazardous waste disposal site or solid waste disposal site, unless if the site was a former solid waste disposal site, the governing board of the school district concludes that the wastes have been removed.

(2) A hazardous substance release site identified by the Department of Toxic Substances Control in a current list adopted pursuant to Section 25356 of the Health and Safety Code for removal or remedial action pursuant to Chapter 6.8 (commencing with Section 25300) of Division 20 of the Health and Safety Code.

(3) A site that contains one or more pipelines, situated underground or aboveground, that carries hazardous substances, acutely hazardous materials, or hazardous wastes, unless the pipeline is a natural gas line that is used only to supply natural gas to that school or neighborhood.

(b) The school district, as the lead agency, as defined in Section 21067 of the Public Resources Code, in preparing the environmental impact report or negative declaration has consulted with the administering agency in which the proposed schoolsite is located, pursuant to Section 2735.3 of Title 19 of the California Code of Regulations, and with any air pollution control district or air quality management district having jurisdiction in the area, to identify both permitted and nonpermitted facilities within that district's authority, including, but not limited to, freeways and other busy traffic corridors, large agricultural operations, and railyards, within one-fourth of a mile of the proposed schoolsite, that might reasonably be anticipated to emit hazardous air emissions, or to handle hazardous or acutely hazardous materials, substances, or waste. The school district, as the lead agency, shall include a list of the locations for which information is sought.

(c) The governing board of the school district makes one of the following written findings:

(1) Consultation identified none of the facilities or significant pollution sources specified in subdivision (b).

(2) The facilities or other pollution sources specified in subdivision (b) exist, but one of the following conditions applies:

(A) The health risks from the facilities or other pollution sources do not and will not constitute an actual or potential endangerment of public health to persons who would attend or be employed at the school.

(B) The governing board finds that corrective measures required under an existing order by another governmental entity that has jurisdiction over the facilities or other pollution sources will, before the school is occupied, result in the mitigation of all chronic or accidental hazardous air emissions to levels that do not constitute an actual or potential endangerment of public health to persons who would attend or be employed at the proposed school. If the governing board makes this finding, the governing board shall also make a subsequent finding, prior to the occupancy of the school, that the emissions have been mitigated to these levels.

(C) For a schoolsite with a boundary that is within 500 feet of the edge of the closest traffic lane of a freeway or other busy traffic corridor, the governing board of the school district determines, through analysis pursuant to paragraph (2) of subdivision (b) of Section 44360 of the Health and Safety Code, based on appropriate air dispersion modeling, and after considering any potential mitigation measures, that the air quality at the proposed site

is such that neither short-term nor long-term exposure poses significant health risks to pupils.

(D) The governing board finds that neither of the conditions set forth in subparagraph (B) or (C) can be met, and the school district is unable to locate an alternative site that is suitable due to a severe shortage of sites that meet the requirements in subdivision (a) of Section 17213. If the governing board makes this finding, the governing board shall adopt a statement of Overriding Considerations pursuant to Section 15093 of Title 14 of the California Code of Regulations.

(d) As used in this section:

(1) "Hazardous air emissions" means emissions into the ambient air of air contaminants that have been identified as a toxic air contaminant by the State Air Resources Board or by the air pollution control officer for the jurisdiction in which the project is located. As determined by the air pollution control officer, hazardous air emissions also means emissions into the ambient air from any substance identified in subdivisions (a) to (f), inclusive, of Section 44321 of the Health and Safety Code.

(2) "Hazardous substance" means any substance defined in Section 25316 of the Health and Safety Code.

(3) "Acutely hazardous material" means any material defined pursuant to subdivision (a) of Section 25532 of the Health and Safety Code.

(4) "Hazardous waste" means any waste defined in Section 25117 of the Health and Safety Code.

(5) "Hazardous waste disposal site" means any site defined in Section 25114 of the Health and Safety Code.

(6) "Administering agency" means any agency designated pursuant to Section 25502 of the Health and Safety Code.

(7) "Handle" means handle as defined in Article 1 (commencing with Section 25500) of Chapter 6.95 of Division 20 of the Health and Safety Code.

(8) "Facilities" means any source with a potential to use, generate, emit or discharge hazardous air pollutants, including, but not limited to, pollutants that meet the definition of a hazardous substance, and whose process or operation is identified as an emission source pursuant to the most recent list of source categories published by the California Air Resources Board.

(9) "Freeway or other busy traffic corridors" means those roadways that, on an average day, have traffic in excess of 50,000 vehicles in a rural area as defined in Section 50101 of the Health and Safety Code, and 100,000 vehicles in an urban area, as defined in Section 50104.7 of the Health and Safety Code.

SECTION 3.

Section 21151.8 of the Public Resources Code is amended to read:

21151.8.

(a) An environmental impact report or negative declaration may not be approved for any project involving the purchase of a schoolsite or the construction of a new

elementary or secondary school by a school district unless all of the following occur:

(1) The environmental impact report or negative declaration includes information that is needed to determine if the property proposed to be purchased, or to be constructed upon, is any of the following:
   (A) The site of a current or former hazardous waste disposal site or solid waste disposal site and, if so, whether the wastes have been removed.
   (B) A hazardous substance release site identified by the Department of Toxic Substances Control in a current list adopted pursuant to Section 25356 of the Health and Safety Code for removal or remedial action pursuant to Chapter 6.8 (commencing with Section 25300) of Division 20 of the Health and Safety Code.
   (C) A site that contains one or more pipelines, situated underground or aboveground, that carries hazardous substances, acutely hazardous materials, or hazardous wastes, unless the pipeline is a natural gas line that is used only to supply natural gas to that school or neighborhood, or other nearby schools.
   (D) A site that is within 500 feet of the edge of the closest traffic lane of a freeway or other busy traffic corridor.

(2) The school district, as the lead agency, in preparing the environmental impact report or negative declaration has notified in writing and consulted with the administering agency in which the proposed schoolsite is located, pursuant to Section 2735.3 of Title 19 of the California Code of Regulations, and with any air pollution control district or air quality management district having jurisdiction in the area, to identify both permitted and nonpermitted facilities within that district's authority, including, but not limited to, freeways and busy traffic corridors, large agricultural operations, and railyards, within one-fourth of a mile of the proposed schoolsite, that might reasonably be anticipated to emit hazardous emissions or handle hazardous or acutely hazardous materials, substances, or waste. The notification by the school district, as the lead agency, shall include a list of the locations for which information is sought.

(3) The governing board of the school district makes one of the following written findings:
   (A) Consultation identified no facilities of this type or other significant pollution sources specified in paragraph (2).
   (B) The facilities or other pollution sources specified in paragraph (2) exist, but one of the following conditions applies:
      (i) The health risks from the facilities or other pollution sources do not and will not constitute an actual or potential endangerment of public health to persons who would attend or be employed at the proposed school.
      (ii) Corrective measures required under an existing order by another agency having jurisdiction over the facilities or other pollution sources will, before the school is occupied, result in the mitigation of all chronic or accidental hazardous air emissions to levels that do not constitute an actual or potential endangerment of public health to persons who

would attend or be employed at the proposed school. If the governing board makes a finding pursuant to this clause, it shall also make a subsequent finding, prior to occupancy of the school, that the emissions have been so mitigated.

(iii) For a schoolsite with a boundary that is within 500 feet of the edge of the closest traffic lane of a freeway or other busy traffic corridor, the governing board of the school district determines, through analysis pursuant to paragraph (2) of subdivision (b) of Section 44360 of the Health and Safety Code, based on appropriate air dispersion modeling, and after considering any potential mitigation measures, that the air quality at the proposed site is such that neither short-term nor long-term exposure poses significant health risks to pupils.

(C) The facilities or other pollution sources specified in paragraph (2) exist, but conditions in clause (i), (ii) or (iii) of subparagraph (B) cannot be met, and the school district is unable to locate an alternative site that is suitable due to a severe shortage of sites that meet the requirements in subdivision (a) of Section 17213 of the Education Code. If the governing board makes this finding, the governing board shall adopt a statement of Overriding Considerations pursuant to Section 15093 of Title 14 of the California Code of Regulations.

(4) Each administering agency, air pollution control district, or air quality management district receiving written notification from a lead agency to identify facilities pursuant to paragraph (2) shall provide the requested information and provide a written response to the lead agency within 30 days of receiving the notification. The environmental impact report or negative declaration shall be conclusively presumed to comply with this section as to the area of responsibility of any agency that does not respond within 30 days.

(b) If a school district, as a lead agency, has carried out the consultation required by paragraph (2) of subdivision (a), the environmental impact report or the negative declaration shall be conclusively presumed to comply with this section, notwithstanding any failure of the consultation to identify an existing facility or other pollution source specified in paragraph (2) of subdivision (a).

(c) As used in this section and Section 21151.4, the following definitions shall apply:

(1) "Hazardous substance" means any substance defined in Section 25316 of the Health and Safety Code.

(2) "Acutely hazardous material" means any material defined pursuant to subdivision (a) of Section 25532 of the Health and Safety Code.

(3) "Hazardous waste" means any waste defined in Section 25117 of the Health and Safety Code.

(4) "Hazardous waste disposal site" means any site defined in Section 25114 of the Health and Safety Code.

(5) "Hazardous air emissions" means emissions into the ambient air of air contaminants that have been identified as a toxic air contaminant by the State Air Resources Board or by the air pollution control officer for the jurisdiction in which the project is located. As determined by the air pollution control officer, hazardous air emissions also means emissions into the ambient air from any

substances identified in subdivisions (a) to (f), inclusive, of Section 44321 of the Health and Safety Code.

(6) "Administering agency" means an agency designated pursuant to Section 25502 of the Health and Safety Code.

(7) "Handle" means handle as defined in Article 1 (commencing with Section 25500) of Chapter 6.95 of Division 20 of the Health and Safety Code.

(8) "Facilities" means any source with a potential to use, generate, emit or discharge hazardous air pollutants, including, but not limited to, pollutants that meet the definition of a hazardous substance, and whose process or operation is identified as an emission source pursuant to the most recent list of source categories published by the California Air Resources Board.

(9) "Freeway or other busy traffic corridors" means those roadways that, on an average day, have traffic in excess of 50,000 vehicles in a rural area, as defined in Section 50101 of the Health and Safety Code, and 100,000 vehicles in an urban area, as defined in Section 50104.7 of the Health and Safety Code.

B.5. Senate Bill 25, Children's Environmental Health Protection.

CHAPTER 731
FILED WITH SECRETARY OF STATE OCTOBER 10, 1999
APPROVED BY GOVERNOR OCTOBER 7, 1999

THE PEOPLE OF THE STATE OF CALIFORNIA DO ENACT AS FOLLOWS:

SECTION 1.
The Legislature finds and declares all of the following:

(a) Infants and children have a higher ventilation rate than adults relative to their body weight and lung surface area, resulting in a greater dose of pollution delivered to their lungs.
(b) Children have narrower airways than adults. Thus, irritation or inflammation caused by air pollution that would produce only a slight response in an adult can result in a potentially significant obstruction of the airway in a young child.
(c) Children spend significantly more time outdoors, especially in the summer, when ozone air pollution levels are typically highest. National statistics show that children spend an average of 50 percent more time outdoors than adults.
(d) Air pollution is known to exacerbate asthma and be a trigger for asthma attacks in infants and children, 500,000 of whom are afflicted with this chronic lung disease in California.
(e) Infant's and children's developing organs and tissues are more susceptible to damage from some environmental contaminants than are adult organs and tissues.
(f) It is the intent of the Legislature in enacting this act, to require that the state's air quality standards and airborne toxic control measures be reviewed to determine if they adequately protect the health of infants and children, and that these standards and measures be revised if they are determined to be inadequate.
(g) It is also the intent of the Legislature in enacting this act to require the State Air Resources Board and the Office of Environmental Health Hazard Assessment to consider the health impacts to all populations of children, including special subpopulations of infants and children that comprise a meaningful portion of the general population, such as children with asthma, cystic fibrosis, or other respiratory conditions or diseases, in setting or revising standards pursuant to this act.

SECTION 2.
Part 3 (commencing with Section 900) is added to Division 1 of the Health and Safety Code, to read:
PART 3. CHILDREN'S ENVIRONMENTAL HEALTH CENTER 900. There is hereby created the Children's Environmental Health Center within the Environmental Protection Agency. The primary purposes of the center shall include all of the following:

(a) To serve as the chief advisor to the Secretary for Environmental Protection and to the Governor on matters within the jurisdiction of the Environmental Protection

Agency relating to environmental health and environmental protection as each of those matters relates to children.

(b) To assist the boards, departments, and offices within the Environmental Protection Agency to assess the effectiveness of statutes, regulations, and programs designed to protect children from environmental hazards.

(c) To coordinate within the Environmental Protection Agency and with other state agencies, regulatory efforts, research and data collection, and other programs and services that impact the environmental health of children, and coordinate with appropriate federal agencies conducting related regulatory efforts and research and data collection.

(d) In consultation with the State Air Resources Board and the Office of Environmental Health Hazard Assessment, and notwithstanding Section 7550.5 of the Government Code, to report to the Legislature and the Governor no later than December 31, 2001, on the progress of the state board and the office toward implementing the act that added this part during the 1999-2000 Regular Session and to make recommendations for any statutory or regulatory changes that may be necessary to carry out the intent of that act to protect the public health, including infants and children, from air pollutants and toxic air contaminants.

SECTION 3.
Section 39606 of the Health and Safety Code is amended to read:
39606.

(a) The state board shall do both of the following:
  (1) Based upon similar meteorological and geographic conditions and consideration for political boundary lines whenever practicable,divide the state into air basins to fulfill the purposes of this division.
  (2) Adopt standards of ambient air quality for each air basin in consideration of the public health, safety, and welfare, including,but not limited to, health, illness, irritation to the senses, aesthetic value, interference with visibility, and effects on the economy. These standards may vary from one air basin to another. Standards relating to health effects shall be based upon the recommendations of the Office of Environmental Health Hazard Assessment.

(b) In its recommendations for submission to the state board pursuant to paragraph (2) of subdivision (a), the Office of Environmental Health Hazard Assessment, to the extent that information is available, shall assess the following:
  (1) Exposure patterns, including, but not limited to, patterns determined by relevant data supplied by the state board, among infants and children that are likely to result in disproportionately high exposure to ambient air pollutants in comparison to the general population.
  (2) Special susceptibility of infants and children to ambient air pollutants in comparison to the general population.
  (3) The effects on infants and children of exposure to ambient air pollutants and other substances that have a common mechanism of toxicity.
  (4) The interaction of multiple air pollutants on infants and children, including the interaction between criteria air pollutants and toxic air contaminants.

(c) In assessing the factors specified in subdivision (b), the office shall use current principles, practices, and methods used by public health professionals who are experienced practitioners in the field of human health effects assessment. The scientific basis or scientific portion of the method used by the office to assess the factors set forth in subdivision (b) shall be subject to peer review as described in Section 57004 or in a manner consistent with the peer review requirements of Section 57004. Any person may submit any information for consideration by the entity conducting the peer review, which may receive oral testimony.

(d)

(1) No later than December 31, 2000, the state board in consultation with the office, shall review all existing health-based ambient air quality standards to determine whether, based on public health, scientific literature, and exposure pattern data, the standards adequately protect the health of the public, including infants and children, with an adequate margin of safety. The state board shall publish a report summarizing these findings.

(2) The state board shall revise the highest priority ambient air quality standard determined to be inadequate to protect infants and children with an adequate margin of safety, based on its report, no later than December 31, 2002. Following the revision of the highest priority standard, the state board shall revise any additional standards determined to be inadequate to protect infants and children with an adequate margin of safety, at the rate of at least one per year. The standards shall be established at levels that adequately protect the health of the public, including infants and children, with an adequate margin of safety (e) Nothing in this section shall restrict the authority of the state board to consider additional information in establishing ambient air quality standards or to adopt an ambient air quality standard designed to protect vulnerable populations other than infants and children.

SECTION 4.

Section 39617.5 is added to the Health and Safety Code, to read:

39617.5.

(a) Not later than January 1, 2003, the state board shall do all of the following:

(1) Evaluate the adequacy of the current monitoring network for its ability to gather the data necessary to determine the exposure of infants and children to air pollutants including criteria air pollutants and toxic air contaminants.

(2) Identify areas where the exposure of infants and children to air pollutants is not adequately measured by the current monitoring network.

(3) Recommend changes to improve air pollution monitoring networks and data collection to more accurately reflect the exposure of infants and children to air pollutants.

(b) In carrying out this section, the state board, in cooperation with the districts, shall expand its existing monitoring program in six communities around the state in nonattainment areas, as selected by the state board, to include special monitoring of children's exposure to air pollutants and toxic contaminants. The expanded program shall include placing air pollution monitors near schools, day care centers, and outdoor recreational facilities that are in close proximity to, or

downwind from, major industrial sources of air pollutants and toxic air contaminants, including, freeways and major traffic areas. The purpose of the air pollution monitors shall be to conduct sampling of air pollution levels affecting children. Monitoring may include the use of fixed, mobile, and other monitoring devices, as appropriate.

(c) The expanded monitoring program shall include the following:
  (1) Monitoring during multiple seasons and at multiple locations within each community at schools, day care centers, recreational facilities, and other locations where children spend most of their time.
  (2) A combination of upgrading existing fixed monitoring sites, establishing new fixed monitoring sites, and conducting indoor and outdoor sampling and personal exposure measurements in each community to provide the most comprehensive data possible on the levels of children's exposure to air pollutants and toxic air contaminants.

(d) Data collected from expanded air quality monitoring activities conducted pursuant to this section may be used for any purpose authorized by law, including, but not limited to, determinations as to whether an area has attained or has not attained the state and national ambient air quality standards, if the monitoring devices from which the data was collected meet the monitoring requirements specified in Section 58.14 of Title 40 of the Code of Federal Regulations for special purpose monitors, all other monitoring requirements of Part 58 of Title 40 of the Code of Federal Regulations, and all applicable requirements specified in regulations adopted by the state board.

SECTION 5.
Section 39660 of the Health and Safety Code is amended to read:
39660.

(a) Upon the request of the state board, the office, in consultation with and with the participation of the state board, shall evaluate the health effects of and prepare recommendations regarding substances, other than pesticides in their pesticidal use, which may be or are emitted into the ambient air of California and that may be determined to be toxic air contaminants.

(b) In conducting this evaluation, the office shall consider all available scientific data, including, but not limited to, relevant data provided by the state board, the State Department of Health Services, the Occupational Safety and Health Division of the Department of Industrial Relations, the Department of Pesticide Regulation, international and federal health agencies, private industry, academic researchers, and public health and environmental organizations. The evaluation shall be performed using current principles, practices, and methods used by public health professionals who are experienced practitioners in the fields of epidemiology, human health effects assessment, risk assessment, and toxicity.

(c)
  (1) The evaluation shall assess the availability and quality of data on health effects, including potency, mode of action, and other relevant biological factors, of the substance, and shall, to the extent that information is available, assess all of the following:

(A) Exposure patterns among infants and children that are likely to result in disproportionately high exposure to ambient air pollutants in comparison to the general population.
(B) Special susceptibility of infants and children to ambient air pollutants in comparison to the general population.
(C) The effects on infants and children of exposure to toxic air contaminants and other substances that have a common mechanism of toxicity.
(D) The interaction of multiple air pollutants on infants and children, including the interaction between criteria air pollutants and toxic air contaminants.

(2) The evaluation shall also contain an estimate of the levels of exposure that may cause or contribute to adverse health effects. If it can be established that a threshold of adverse health effects exists, the estimate shall include both of the following factors:
(A) The exposure level below which no adverse health effects are anticipated.
(B) An ample margin of safety that accounts for the variable effects that heterogeneous human populations exposed to the substance under evaluation may experience, the uncertainties associated with the applicability of the data to human beings, and the completeness and quality of the information available on potential human exposure to the substance. In cases in which there is no threshold of significant adverse health effects, the office shall determine the range of risk to humans resulting from current or anticipated exposure to the substance.

(3) The scientific basis or scientific portion of the method used by the office to assess the factors set forth in this subdivision shall be reviewed in a manner consistent with this chapter by the Scientific Review Panel on Toxic Air Contaminants established pursuant to Article 5 (commencing with Section 39670). Any person may submit any information for consideration by the panel, which may receive oral testimony.

(d) The office shall submit its written evaluation and recommendations to the state board within 90 days after receiving the request of the state board pursuant to subdivision (a). The office may, however, petition the state board for an extension of the deadline, not to exceed 30 days, setting forth its statement of the reasons that prevent the office from completing its evaluation and recommendations within 90 days. Upon receipt of a request for extension of, or noncompliance with, the deadline contained in this section, the state board shall immediately transmit to the Assembly Committee on Rules and the Senate Committee on Rules, for transmittal to the appropriate standing, select, or joint committee of the Legislature, a statement of reasons for extension of the deadline, along with copies of the office's statement of reasons that prevent it from completing its evaluation and recommendations in a timely manner.

(e)

(1) The state board or a district may request, and any person shall provide, information on any substance that is or may be under evaluation and that is manufactured, distributed, emitted, or used by the person of whom the request is made, in order to carry out its responsibilities pursuant to this chapter. To the extent practical, the state board or a district may collect the

information in aggregate form or in any other manner designed to protect trade secrets.

(2) Any person providing information pursuant to this subdivision may, at the time of submission, identify a portion of the information submitted to the state board or a district as a trade secret and shall support the claim of a trade secret, upon the written request of the state board or district board. Subject to Section 1060 of the Evidence Code, information supplied that is a trade secret, as specified in Section 6254.7 of the Government Code, and that is so marked at the time of submission, shall not be released to any member of the public. This section does not prohibit the exchange of properly designated trade secrets between public agencies when those trade secrets are relevant and necessary to the exercise of their jurisdiction if the public agencies exchanging those trade secrets preserve the protections afforded that information by this paragraph.

(3) Any information not identified as a trade secret shall be available to the public unless exempted from disclosure by other provisions of law. The fact that information is claimed to be a trade secret is public information. Upon receipt of a request for the release of information that has been claimed to be a trade secret, the state board or district shall immediately notify the person who submitted the information, and shall determine whether or not the information claimed to be a trade secret is to be released to the public. The state board or district board, as the case may be, shall make its determination within 60 days after receiving the request for disclosure, but not before 30 days following the notification of the person who submitted the information. If the state board or district decides to make the information public, it shall provide the person who submitted the information 10 days' notice prior to public disclosure of the information.

(f) The office and the state board shall give priority to the evaluation and regulation of substances based on factors related to the risk of harm to public health, amount or potential amount of emissions, manner of, and exposure to, usage of the substance in California, persistence in the atmosphere, and ambient concentrations in the community. In determining the importance of these factors, the office and the state board shall consider all of the following information, to the extent that it is available:

(1) Research and monitoring data collected by the state board and the districts pursuant to Sections 39607, 39617.5, 39701, and 40715, and by the United States Environmental Protection Agency pursuant to paragraph (2) of subsection (k) of Section 112 of the federal act (42 U.S.C. Sec. 7412(k)(2)).

(2) Emissions inventory data reported for substances subject to Part 6 (commencing with Section 44300) and the risk assessments prepared for those substances.

(3) Toxic chemical release data reported to the state emergency response commission pursuant to Section 313 of the Emergency Planning and Community Right-To-Know Act of 1986 (42 U.S.C. Sec. 11023) and Section 6607 of the Pollution Prevention Act of 1990 (42 U.S.C. Sec. 13106).

(4) Information on estimated actual exposures to substances based on geographic and demographic data and on data derived from analytical methods that measure the dispersion and concentrations of substances in ambient air.

SECTION 6.
Article 4.5 (commencing with Section 39669.5) is added to Chapter 3.5 of Part 2 of Division 26 of the Health and Safety Code, to read:
Article 4.5. Special Provisions For Infants And Children
39669.5. The Legislature finds and declares that certain toxic air contaminants may pose risks that cause infants and children to be especially susceptible to illness and that certain actions are necessary to ensure their safety from toxic air contaminants.

(a) By July 1, 2001, the following shall occur
  (1) The office, in consultation with the state board, shall establish a list of up to five toxic air contaminants identified or designated by the state board pursuant to Section 39657 that may cause infants and children to be especially susceptible to illness. In developing the list, the office shall take into account public exposures to toxic air contaminants, whether by themselves or interacting with other toxic air contaminants or criteria pollutants, and the factors listed in subdivision (c) of Section 39660. The office shall submit a report containing the list and its reasons for including the toxic air contaminants on the list to the Scientific Review Panel on Toxic Air Contaminants established pursuant to Article 5 (commencing with Section 39670).
  (2) The scientific review panel, in a manner consistent with this chapter, shall review the list of toxic air contaminants submitted by the office pursuant to paragraph (1). As part of the review, any person may submit any information for consideration by the panel, which may receive oral testimony.

(b)
  (1) Within two years of the establishment of the list required pursuant to subdivision (a), the state board shall review and, as appropriate, revise any control measures adopted for the toxic air contaminants identified on the list, to reduce exposure to those toxic air contaminants pursuant to Article 4 (commencing with Section 39665), to protect public health, and particularly infants and children.
  (2) Within three years of the establishment of the list required pursuant to subdivision (a), for up to five of those toxic air contaminants for which no control measures have been previously adopted, the state board shall prepare a report on the need for regulations, following the procedure specified in Section 39665. The state board shall adopt within that same three-year timeframe, as appropriate, any new control measures to reduce exposure to those toxic air contaminants pursuant to Article 4 (commencing with Section 39665), to protect public health, particularly infants and children.

(c) Beginning July 1, 2004, the office shall annually evaluate at least 15 toxic air contaminants identified or designated by the state board pursuant to Section 39657, and provide threshold exposure levels and nonthreshold health values, as

appropriate, for those toxic air contaminants. The activities required pursuant to this subdivision shall continue until all toxic air contaminants are evaluated. The levels shall be established pursuant to the procedures adopted for health and risk assessments pursuant to paragraph (2) of subdivision (b) of Section 44360, and taking into account the factors listed in subdivision (c) of Section 39660. Based on this evaluation, and after review by the scientific review panel as prescribed in paragraph (2) of subdivision (a), the office shall update the list established pursuant to subdivision (a), by July 1, 2005, and each year thereafter. Within three years of the initial or subsequent listing update, for up to five of the toxic air contaminants contained on that list for which no control measures have been previously adopted, or for at least five of the toxic air contaminants if more than five toxic air contaminants have been identified, the state board shall prepare a report on the need for regulation, following the procedure specified in Section 39665. The state board shall adopt within that three-year timeframe, as appropriate, new control measures, pursuant to Article 4 (commencing with Section 39665), to reduce exposure to those toxic air contaminants, to protect public health, and particularly infants and children.

(d) Toxic air contaminants evaluated and listed pursuant to this section shall not include substances in those uses that are not subject to regulation by the state board pursuant to this chapter.

SECTION 7.
Section 40451 of the Health and Safety Code is amended to read:
40451.

(a) The south coast district shall use the Pollutant Standards Index developed by the Environmental Protection Agency and shall report and forecast pollutant levels daily for dissemination in the print and electronic media.

(b) Using existing communication facilities available to it, the south coast district shall notify all schools and, to the extent feasible and upon request, daycare centers in the South Coast Air Basin whenever any federal primary ambient air quality standard is predicted to be exceeded.

(c) Whenever it becomes available, the south coast district shall disseminate to schools, amateur adult and youth athletic organizations, and all public agencies operating parks and recreational facilities in the south coast district the latest scientific information and evidence regarding the need to restrict exercise and other outdoor activities during periods when federal primary air quality standards are exceeded.

(d) Once every two months and annually, the south coast district shall report on the number of days and locations that federal and state ambient air quality standards were exceeded and the number of days and locations of these occurrences.

SECTION 7.5.
Section 40451 of the Health and Safety Code is amended to read:
40451.

(a) The south coast district shall use the Pollutant Standards Index developed by the United States Environmental Protection Agency and shall report and forecast

pollutant levels daily for dissemination in the print and electronic media. Commencing July 1, 2001, the south coast district shall also include in its report and forecast levels of PM2.5 in excess of the 24-hour federal ambient air standard, as adopted in July 1997, or any standard adopted by the United States Environmental Protection Agency that succeeds that standard.

(b) Using existing communication facilities available to it, the south coast district shall notify all schools and, to the extent feasible and upon request, daycare centers in the South Coast Air Basin whenever any federal primary ambient air quality standard is predicted to be exceeded. Commencing July 1, 2001, using communication facilities available to it, the south coast district shall also notify all schools in the South Coast Air Basin when the ambient level of PM2.5 is predicted to exceed the 24-hour federal ambient air standard, as adopted in July 1997, or any standard adopted by the United States Environmental Protection Agency that succeeds that standard.

(c) Whenever it becomes available, the south coast district shall disseminate to schools, amateur adult and youth athletic organizations, and all public agencies operating parks and recreational facilities in the south coast district the latest scientific information and evidence regarding the need to restrict exercise and other outdoor activities during periods when federal primary air quality standards and the 24-hour federal ambient air standard for PM2.5, as adopted in July 1997, or any standards adopted by the United States Environmental Protection Agency that succeed those standards, are exceeded.

(d) Once every two months and annually, the south coast district shall report on the number of days and locations that federal and state ambient air quality standards were exceeded. Commencing July 1, 2001, the south coast district shall also include in that report the number of days and locations on and at which the 24-hour federal ambient air standard for PM2.5, as adopted in July 1997, or any standard adopted by the United States Environmental Protection Agency that succeeds that standard, is exceeded.

SECTION 8.

Section 7.5 of this bill incorporates amendments to Section 40451 of the Health and Safety Code proposed by both this bill and SB 1195. It shall only become operative if

(1) both bills are enacted and become effective on or before January 1, 2000,

(2) each bill amends Section 40451 of the Health and Safety Code, and

(3) this bill is enacted after SB 1195, in which case Section 7 of this bill shall not become operative.

SECTION 9.

Notwithstanding Section 17610 of the Government Code, if the Commission on State Mandates determines that this act contains costs mandated by the state, reimbursement to local agencies and school districts for those costs shall be made pursuant to Part 7 (commencing with Section 17500) of Division 4 of Title 2 of the Government Code. If the statewide cost of the claim for reimbursement does not exceed one million dollars ($1,000,000), reimbursement shall be made from the State Mandates Claims Fund.

Appendix C:

Asbestos Conversion Factors & Cancer Potency Factor

C-1. Overview

The purpose of this appendix is to provide information about the asbestos conversion factors and inhalation cancer potency factor. The table below summarizes the available conversion factors and inhalation cancer potency factor for asbestos. The subsequent sections of this appendix provide information on how the conversion factors and cancer potency factor were derived.

PCM Fibers to TEM Structure Conversion Factor	1 PCM Fiber = 320 TEM Structures
Mass to Fiber Conversion Factor	0.003 μg = 100 asbestos PCM Fibers
Asbestos Inhalation Cancer Potency Factor	$2.2 \times 10^{+2}$ $(mg/kg\text{-}day)^{-1}$

C-2. PCM Fiber to TEM Structure Conversion Factor

Two analytical methods have been used for the analysis of asbestos samples: phase contrast microscopy (PCM), the primary method used historically to analyze asbestos samples, and transmission electron microscopy (TEM), the current state-of-the-art method.

PCM analysis was developed earlier and has been preferred in the past over TEM because it could be done more quickly and was less expensive. However, one major limitation of PCM analysis, especially in outdoor environments, is that the analyst cannot distinguish asbestos from non-asbestos fibers, such as cellulose, talc, or gypsum. Also, PCM cannot detect fibers that have a diameter of about 0.3 microns or less, which could substantially underestimate the asbestos fiber concentrations. These limitations make PCM impractical for the analysis of ambient asbestos samples.

TEM is the preferred analytical method for outdoor asbestos samples because of its ability to detect small fibers (greater than or equal to 0.0002 microns in diameter) and to distinguish between asbestos fibers and non-asbestos fibers. The term “TEM structures” is often used to describe asbestos fibers detected by this method. TEM is the method recommended by the Office of Environmental Health Hazard Assessment (OEHHA). However, TEM measurements cannot be directly related to the cancer

potency factors because the studies upon which OEHHA's risk assessment was based used PCM analysis. Thus, the TEM measurements must be converted to PCM-equivalent units. The actual relationship between PCM and TEM measurements is quite variable: ARB (1990) found a range of 100 to 1000 for the ratio of TEM structures to PCM fibers for three occupational studies. For the purpose of the Air Toxics Hot Spots Program, asbestos should be converted using the geometric center of the range as defined by ARB (1990). To convert PCM fibers to TEM structures or vice versa use the following relationship:

1 PCM Fiber = 320 TEM structures

C-3. Mass to Fiber Conversion Factor

Asbestos is reported in units of pounds per year under the Air Toxics Hot Spots Program. To convert asbestos fibers to mass, the following relationship is used:

0.003 μg = 100 asbestos fibers PCM.

This conversion factor was derived from information published by the United States Environmental Protection Agency (U.S. EPA) (U.S. EPA, 1986). The number of asbestos PCM fibers associated with a given mass of asbestos can vary appreciably. In addition, U.S. EPA has stated that this conversion factor is the geometric mean of measured relationships between optical fiber counts and mass airborne chrysotile in several published studies, that the range of the conversion factor between the different studies is large (0.0005 - 0.015 μg asbestos/100 asbestos PCM fibers), and that the factor carries with it an appreciable uncertainty. Additionally, if the asbestos was analyzed using TEM, the TEM structures must be converted to PCM fibers first.

C-4. Asbestos Inhalation Cancer Potency Factor

The unit risk factor for asbestos fibers is 1.9×10^{-4} in units of $(100 \text{ PCM fibers/m}^3)^{-1}$. The unit risk factor is based on epidemiological studies in which PCM fiber measurements were used. This unit risk factor is listed in Chapter 7 and in the Asbestos Toxic Air Contaminant (TAC) identification document (CDHS, 1986) and in OEHHA, 2009. The asbestos cancer potency factor is for mesothelioma. Since the unit risk factor is in units of concentration or dose, complications arise when the emitted asbestos quantities are reported in mass units (pounds/year and maximum pounds/hour) for the Air Toxics Hot Spots Program.

For the purpose of an Air Toxics Hot Spots Risk Assessment, the cancer potency factor $(\text{mg/kg body weight})^{-1}$ may be calculated from the fiber cancer potency factor using the relationship of 0.003 μg = 100 fibers PCM, 70 kg body weight, 20 m^3 breathed per day, and a factor of 1000 to convert μg asbestos into mg:

$$1.9\times10^{-4}\left(100\,PCM\,fibers/m^3\right)^{-1}\times\frac{70kg}{20m^3}\times\frac{1000}{0.003\mu g/100fibers}=2.2\times10^{+2}\left(mg/kg\,bodyweight\right)^{-1}$$

In order to use this cancer potency factor under the Air Toxics Hot Spots Program, the measured asbestos concentration should be expressed as microgram per cubic meter. For example, if the measured asbestos concentrations are in units of TEM structures per cubic meter, the asbestos concentration should be first converted to PCM fibers per cubic meters and then into units of microgram per cubic meters using the conversion factors as shown in the sections above.

See Chapter 8 for more information on calculating cancer risk and Appendix I for an example of how cancer risk is calculated for the inhalation pathway. Note, while the example in Appendix I uses non-asbestos substances, it is still applicable since it illustrates the steps that are used for asbestos, including use of Age Sensitivity Factors.

Appendix D:

Risk Assessment Procedures to Evaluate Particulate Emissions from Diesel-Fueled Engines

D-1. Introduction

The objective of this appendix is to discuss procedures for estimating the cancer and noncancer health risk from exposure to particulate matter (PM) emissions from diesel-fueled engines (diesel exhaust). It will also clarify the requirements and recommendations for acute noncancer and multipathway cancer and chronic risk assessment for diesel PM. In addition to the notification and risk reduction requirements under the Hot Spots Program, this appendix should facilitate the use of the *Risk Reduction Plan to Reduce Particulate Matter Emissions from Diesel-Fueled Engines and Vehicles* (ARB, 2000) (Diesel Guidelines). The Diesel Guidelines were developed by the Air Resources Board (ARB) with assistance from the Office of Environmental Health Hazard Assessment (OEHHA) in October 2000. The Diesel Guidelines are intended to assist local Air Pollution Control and Air Quality Management Districts (Districts) and sources of diesel PM emissions in making consistent risk management decisions.

In advance of performing a health risk assessment (HRA), it is recommended that the District and the stationary source of diesel emissions reach a consensus on the HRA approach for estimating health impacts from diesel exhaust. See Chapter 9 for an outline of a modeling protocol.

D-2. Calculations/Risk Assessment Procedures

In August 1998, the ARB identified diesel exhaust as a toxic air contaminant (TAC) (ARB, 1998). In the identification report, OEHHA provided an inhalation noncancer chronic reference exposure level (REL) of 5 micrograms per cubic meter ($\mu g/m^3$) and a range of inhalation cancer potency factors of 1.3×10^{-4} to 2.4×10^{-3} $(\mu g/m^3)^{-1}$. The Scientific Review Panel on Toxic Air Contaminants recommended a "reasonable estimate" inhalation unit risk factor of 3.0×10^{-4} $(\mu g/m^3)^{-1}$. From the unit risk factor an inhalation cancer potency factor of 1.1 $(mg/kg\text{-}day)^{-1}$ may be calculated. These noncancer and cancer health factors were developed based on whole (gas and particulate matter) diesel exhaust. The surrogate for whole diesel exhaust is diesel PM. PM_{10} (particulate matter, ten microns or less in size) is the basis for the risk calculations.

D-2.1 Cancer

An inhalation cancer risk is required for every HRA (The methods for calculating inhalation cancer risk can be found in Chapters 5, 7, and 8.). When comparing whole diesel exhaust to speciated components of diesel exhaust (e.g., PAHs, metals), the cancer risk from inhalation exposure to whole diesel exhaust will outweigh the

multipathway cancer risk from the speciated components. For this reason, there will be few situations where an analysis of multipathway risk is necessary.

The District may elect to require a multipathway analysis if reliable data are available and the District decides that it is necessary. If the District elects to require a multipathway analysis, the components of the diesel exhaust will need to be speciated since there is no oral cancer potency factor for diesel PM. It is recommended that the District be consulted on the procedures for conducting a multipathway analysis for diesel exhaust. The District may wish to use speciation data from the ARB. If so, a resource for speciation data is available on the ARB's website at www.arb.ca.gov/emisinv/speciate/speciate.htm.

If a multipathway analysis is required, the speciated data should be compared with the substances in Table 5.1. Any substances in the speciation profile that are listed in Table 5.1 and have an oral cancer potency factor in Table 7.1 should be included in the multipathway analysis. Multipathway cancer risks are estimated following the procedures in Chapters 5 and 8 of this document. These procedures require summing the cancer risk from each carcinogen to estimate the total facility cancer risk.

D-2.2 Noncancer Chronic

To determine noncancer chronic inhalation health impacts from exposure to diesel exhaust use the methods described in Chapters 6 and 8.

The District may elect to require a multipathway analysis if reliable data are available and they feel it is necessary. If the District elects to require a multipathway analysis, the components of the diesel exhaust will need to be speciated since there is no oral reference exposure level for diesel PM. A resource for speciation data at the ARB is identified above. It is recommended that the District be consulted on the procedures for conducting a multipathway analysis. If a multipathway analysis is required, the speciated data should be compared with the substances in Table 5.1. Any substances in the speciation profile that are listed in Table 5.1 and have an oral chronic REL in Table 6.4 should be included in the multipathway analysis. Multipathway chronic risks are estimated following the procedures in Chapters 5 and 8 of this document.

Note that the effect estimate for cardiovascular mortality from exposure to ambient PM when applied to diesel PM results in many more cardiovascular deaths than lung cancer deaths.

D-2.3 Noncancer Acute

There may be certain unusual situations where an evaluation of the acute health effects may be warranted. One possible situation is when a nearby receptor is located above the emission release point (e.g. on a hillside or in a multistory apartment building). Since there is no acute REL for diesel exhaust, the components of the exhaust will need to be speciated to determine the potential acute health impacts. It is recommended that the District be consulted on the procedures for conducting an acute analysis. If an acute analysis is required, the speciated data should be compared with the substances in Table 6.1. Any substances in the speciation profile that are listed in Table 6.1 should be included in the acute analysis. A resource for speciation data at the ARB is identified above. Acute risks are estimated following the procedures in Chapters 6 and 8 of this document.

Appendix E:

Toxicity Equivalency Factors for Polychlorinated Dibenzo-p-Dioxins, Dibenzofurans and Polychlorinated Biphenyls

Polychlorinated dibenzo-p-dioxins and dibenzofurans (dioxins and furans) and polychlorinated biphenyls (PCBs) vary considerably in their potency for causing both cancer and noncancer health impacts. A Toxics Equivalents Factors (TEF) scheme, based on both cancer and noncancer toxicity studies, has been developed to relate the potency of various dioxin and furan congeners and PCB congeners to the potency of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD). A detailed explanation of the World Health Organization's 2005 Toxicity Equivalents Factor (WHO_{05}-TEF) scheme (van den Berg et al., 2006), the latest scheme adopted by OEHHA, is available in OEHHA (2011). Where the dioxin and furan and PCB mixtures are not speciated, the cancer risk and noncancer hazard index are based on the most potent congeners. A facility may choose to speciate dioxin and furan and PCB emissions in order to obtain a more accurate picture of the risks.

There are two mathematically equivalent procedures for estimating the cancer risk or the non-cancer hazard quotient using the TEF scheme. In the first method, the concentration or dose of 2,3,7,8-TCDD equivalents is calculated based on the individual congener concentration or dose multiplied by the TEF for that congener. Cancer risk is estimated by multiplying the cancer slope for 2,3,7,8-TCDD by the "TCDD equivalents" concentration or dose. The noncancer hazard quotient would be calculated by dividing the "TCDD equivalents" concentration by the REL. In the second method, TEF-adjusted potency factors or RELs are used with individual congeners.

Using the first procedure, the concentration of each congener listed in Table E-1 is multiplied by the WHO_{05}-TEF for that congener to estimate the concentration of 2,3,7,8-TCDD "toxic equivalents" of the mixture. For example, for 1,2,3,4,7,8-hexachlorodibenzodioxin, the concentration ($\mu g/m^3$) may be multiplied by 0.1 to give the concentration equivalent to 2,3,7,8-TCDD. Congeners not listed in the table are assumed to have no dioxin-like toxicity. The 2,3,7,8-TCDD equivalent concentrations for each congener in the mixture are summed and treated as 2,3,7,8-TCDD for the purposes of calculating cancer and noncancer risks. Thus, to estimate cancer risk, the "toxic equivalents" concentration is multiplied by the breathing rate to give dose (see equation 5.4.1.1), and then multiplied by the cancer potency factor for 2,3,7,8-TCDD (Table 7.1) to give the cancer risk for the entire mixture.

To estimate the chronic non-cancer inhalation hazard index, the ground level concentration of the 2,3,7,8-TCDD equivalents of the mixture is divided by the chronic reference exposure level for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin to give an inhalation hazard index for the entire mixture. Similarly, the oral chronic hazard index of the mixture is calculated by estimating the 2,3,7,8-TCDD equivalents dose and dividing by the oral chronic REL for 2,3,7,8-TCDD. The inhalation and oral hazard indices are then summed to get a total chronic Hazard Index.

In order to determine the inhalation chronic hazard index by the second procedure, the ground level concentration of each dioxin and furan congener is divided by the chronic REL for each congener in Table 6.3 and the hazard quotients summed to give the inhalation chronic hazard index. The oral chronic hazard quotient is calculated by determining the oral dose of each congener and dividing by the individual chronic oral REL (Table 6.4) for each congener. The oral hazard quotients are then summed to give the oral chronic hazard index for dioxins and furans and PCBs. The oral hazard index is then added to the inhalation hazard index to give the total chronic hazard index for dioxins and furans and PCBs.

In those cases where speciation of dioxins and furans has not been performed, then 2,3,7,8-TCDD serves as the surrogate for dioxin and furan emissions. Given that 2,3,7,8-TCDD is the most potent congener in the class, the resulting risk estimate for an unspeciated mixture may be deemed significant enough to trigger health concerns. In this case, it would then be advisable to speciate the mixture and run a screening estimate using the speciated data.

As noted above, the TEF scheme includes TEFs for individual coplanar PCB congeners (see Table E-1) (OEHHA, 2011). These are the congeners that have dioxin-like biological effects. Where data are available on individual PCB congeners emitted by a facility, then the congener-specific TEFs are used. 2,3,7,8-TCDD also serves as the surrogate for the coplanar PCB congeners. To calculate the noncancer inhalation and oral RELs for individual PCB congeners shown in Tables 6.3 and 6.4, respectively, the inhalation and oral RELs for 2,3,7,8-TCDD were divided by the PCB congener TEFs in Table E-1. If only total PCB data are available, then the PCB slope factors for high, low and lowest risk provided in Table 7.1 can be used for cancer risk determination. The high risk potency factor is the default for unspeciated PCB mixtures.

As of February, 2015, there is no approved method that can be used to assess the noncancer hazard of an unspeciated PCB mixture. Persons preparing HRAs for the Hot Spots Program should consult with OEHHA and the local Air Pollution Control or Air Quality Management District if an assessment of the noncancer hazard for unspeciated PCB mixtures is needed.

TABLE E-1. WHO/05 TOXIC EQUIVALENCY FACTORS (TEFS)

Congener		TEF_{WHO-05}
PCDDs		
2,3,7,8-TCDD		1
1,2,3,7,8-PeCDD		1
1,2,3,4,7,8-HxCDD		0.1
1,2,3,6,7,8-HxCDD		0.1

Appendix F:

Overview of the Lead Risk Assessment Procedures

F.1 Introduction

The objective of this appendix is to provide a method for estimating potential cancer and noncancer health effects due to airborne lead exposure. This appendix should facilitate the use of the *Risk Management Guidelines for New, Modified, and Existing Sources of Lead* (Lead RM Guidelines) (ARB, 2001) for analysis of lead exposure. The Lead RM Guidelines were developed by the Air Resources Board (ARB) with assistance from Office of Environmental Health Hazard Assessment (OEHHA) and Department of Health Services (DHS) in March 2001 to assist local air districts and sources of lead in making consistent risk management decisions for new, modified, and existing sources of lead.

In April 1997, the ARB identified inorganic lead as a toxic air contaminant (TAC) (ARB, 1997). Lead is unique among other TACs identified by ARB in several ways. First, infants and children are particularly susceptible to the health effects of lead, and the risk assessment is based on health effects in children. Second, the chronic noncancer effects are related to blood lead levels (BLLs) as opposed to ambient air concentrations. These BLLs reflect current and past exposure from a number of sources; air emissions may only be a small part of the total exposure. Third, based on recommendations of the OEHHA and the Scientific Review Panel on Toxic Air Contaminants (SRP), the ARB did not identify a threshold level for chronic noncancer health effects due to lead exposure. Threshold levels are levels below which no adverse health effects are expected to occur. Since acute, 8-hour or chronic Reference Exposure Levels (RELs) are based on threshold levels, none were developed for lead. Thus, a hazard index approach is not used for lead. Instead, air concentrations are compared to defined air lead levels associated with specified percentages of children with BLL $\geq$ 10 µg/dL. Acceptable risk is based on minimizing the number of children at or above a BLL of 10 µg/dL.

F.2 Methods for Estimation of Health Risk Effects

Methods for estimating site-specific noncancer and cancer potential health impacts from exposure to lead emissions are given in the Lead RM Guidelines. The noncancer health effects pose greater public health significance than the cancer health effects. Minimizing noncancer health effects of lead will therefore also minimize cancer health effects.

Chronic noncancer health risks are estimated based on neurodevelopmental health risks to children and would also be protective of adults. These health effects can be evaluated using a tiered approach based on blood lead level distribution in the population.

Potential multipathway cancer risks are estimated following the procedures in Chapters 5 and 8 of this document. These procedures require summing individual cancer risk from each carcinogen to estimate the total facility cancer risk.

In advance of performing a health risk assessment (HRA), it is recommended that the Air Pollution Control or Air Quality Management District (District) and the stationary source of lead air emissions reach a consensus on the HRA approach for estimating chronic noncancer and cancer health risks. See Chapter 9 for an outline of a modeling protocol.

F.2.1 Tiered Approach for Estimating Noncancer Risks due to Lead Exposure

The Lead Risk Management Guidelines provide three tiers of analysis to determine baseline BLL distributions for estimating risk. Although there is a simple risk management option provided in the Lead RM Guidelines, in a risk assessment for the Air Toxics Hot Spots program one of the following tiers must be used to report estimates of the percent of children estimated to be above 10 μg/dL blood lead. The tiered approach is based on an assessment of neurodevelopmental risk, with the BLL distribution in the population as the most significant factor. The BLL distribution consists of two components: 1) the baseline BLL distribution due to all sources of exposure; and 2) the exposure due to emissions from a facility.

Tier I is a default approach that requires minimal site-specific information on concentrations of lead in environmental media other than air. Tier I uses two default BLL distributions, one for a high exposure scenario and one for an average exposure scenario. The exposure scenario is determined using the median age of the homes in the census tract and the ratio of area income to the poverty level. The default baseline BLL distribution for each of the exposure scenarios is based on a review of neighborhood and community blood lead studies. The assessor determines the 30-day average lead concentration due to the facility averaged over the 1 square kilometer area centered on the Maximum Offsite Concentration (MOC). The percentage of children with BLLs greater than or equal to 10 micrograms per deciliter ($\geq$ 10 μg/dL) is determined using Table F-1 (also found on page 17 in the Lead RM Guidelines), the air lead concentration, and the determined exposure scenario. The 10 μg/dL threshold level has been identified by the Centers for Disease Control and Prevention (CDC) as a level where potential health effects may occur. The public health goal of management practices should be to implement procedures/practices to prevent BLLs at or above this level. The estimated percentage of children with BLLs $\geq$ 10 μg/dL is then used with risk management levels given in Chapter III, Section D of the Lead RM Guidelines to assist in making risk management decisions.

TABLE F-1 PERCENTAGE OF CHILDREN WITH BLOOD LEAD LEVELS ≥ 10 μG/DL FOR VARIOUS AIR LEAD CONCENTRATIONS AT TWO EXPOSURE SCENARIOS

Air Lead Concentration in the Maximum Exposure Area (30-day average) [μg/m^3]	Percent ≥ 10 μg/dL	
	High Exposure Scenario	Average Exposure Scenario
Baseline*	5.1	1.2
0.02	5.4	1.4
0.06	6.1	1.7
0.10	6.8	2.2
0.20	8.9	3.4
0.25	9.8	4.1
0.50	15.9	8.9
0.75	22.4	15.4
1.0	29.1	23.0
1.5	42.5	39.0

* The baseline represents BLLs due to lead in soil, dust, water, food, and background air lead concentrations.

Tier II requires the development of site-specific baseline BLL distributions within the impacted population using site-specific estimates of lead levels in environmental media, including soil, dust, water, and/or food, using the U.S. EPA Integrated Exposure Uptake Biokinetic (IEUBK) model. The IEUBK model calculates the probability of an individual exceeding a specific BLL based on site-specific information. The aggregate of the individual BLLs is used to estimate the neurodevelopmental risk in the maximum exposure area. A detailed discussion of this tier is beyond the scope of this overview; see Appendix D in the Lead RM Guidelines for a discussion of the IEUBK model and its use.

Tier III involves actual blood lead sampling of the population impacted by the facility to define the baseline BLLs. In Tier III, the facility is responsible for conducting BLL testing to establish a site-specific BLL distribution. The Lead RM Guidelines recommend the neurodevelopmental risk be calculated as the probability of children in an affected exposure area having a BLL ≥ 10 μg/dL using the results of the blood lead sampling. It is highly unlikely that this option would be used due to the cost incurred and the fact that the sampled population must consent to the sampling and an appropriate sampling strategy must be developed to adequately characterize the blood lead levels of the impacted population.

For further information on the tiered approach using the Tier I, Tier II, or Tier III, please see Chapter II of the *ARB Risk Management Guidelines for New, Modified, and Existing Sources of Lead* (ARB, 2001). This document can be downloaded from the ARB web site at http://www.arb.ca.gov/toxics/lead/lead.htm or can be requested by calling (916) 323-4327.

F.2.2 Methods for Estimating Potential Cancer Risks due to Lead

While lead has a unique noncancer assessment methodology, the determination of potential multipathway cancer risk is the same as other carcinogens. Chapters 5, 7, and 8, and Appendices I and L provide all the needed information for calculating potential cancer risk. The health risk assessment should report the multipathway cancer risks from lead emissions.

Chapter III in the Lead RM Guidelines provides methods for determining risk management of lead exposure, using the results from the cancer risk calculation, and the local District's defined significance levels.

Appendix G:

PAH Potency Factors and Selection of Potency Equivalency Factors (PEF) for PAHs based on Benzo(*a*)pyrene Potency

The Office of Environmental Health Hazard Assessment (OEHHA) has developed a Potency Equivalency Factor (PEF) procedure to assess the relative potencies of PAHs and PAH derivatives as a group. Benzo(a)pyrene (BaP) was chosen as the primary representative of the class of polycyclic aromatic hydrocarbons (PAHs) because of the large amount of toxicological data available on BaP (versus the relatively incomplete database for other PAHs), and because it serves as the referent PAH for the Potency Equivalency Factors. This procedure can address the impact of carcinogenic PAHs in ambient air since they are usually present together. This procedure was approved by the Scientific Review Panel (SRP) on Toxic Air Contaminants (TAC) as part of the Health Effects Assessment of Benzo(a)pyrene during the TAC identification process (OEHHA, 1993).

Due to the variety of data available on the carcinogenicity and mutagenicity of PAHs, an order of preference for the use of available data in assessing relative potency was developed. If a health effects evaluation and quantitative risk assessment leading to a cancer potency value had been conducted on a specific PAH, then those values were given the highest preference. Cancer potency values for PAHs developed by this process are shown in Table G-1.

TABLE G-1: POTENCIES OF PAHS AND DERIVATIVES[1]

Chemicals	Cancer potency factors $(mg/kg\text{-}day)^{-1}$	Unit risks $(\mu g/m^3)^{-1}$
Benzo[*a*]pyrene	11.5	1.1×10^{-3}
Dibenz[*a*,*h*]anthracene	4.1	1.2×10^{-4}
7,12-dimethylbenzanthracene	250	7.1×10^{-2}
3-methylcholanthrene	22	6.3×10^{-3}
Naphthalene[2]	0.12	3.4×10^{-5}
5-nitroacenaphthene	0.13	3.7×10^{-5}

[1] Source: OEHHA (1993); Collins *et al*. (1998); OEHHA (2009). It is assumed that unit risks for inhalation have the same relative activities as cancer potencies for oral intake.

If potency values have not been developed for specific compounds, a carcinogenic activity relative to BaP, rather than a true potency, can be developed. These relative activity values are referred to as Potency Equivalency Factors or PEFs. For air contaminants, the relative potency to BaP based on data from inhalation studies would be optimal. Otherwise, intrapulmonary or intratracheal administration studies would be most relevant, since such studies are in the target organ of interest. Next in order of

preference is information on activity by the oral route and skin painting. Intraperitoneal and subcutaneous administration rank at the bottom of the *in vivo* tests considered useful for PEF development because of their lack of relevance to environmental exposures. Next, in decreasing order of preference, are genotoxicity data, which exist for a large number of compounds. In many cases genotoxicity information is restricted to mutagenicity data. Finally, there are data on structure-activity relationships among PAH compounds. Structure-activity considerations may help identify a PAH as carcinogenic, but at this time have not been established as predictors of carcinogenic potency.

Using this order of preference, PEFs were derived for 21 PAHs and are presented in Table G-2 (OEHHA, 1993: Collins *et al*., 1998).

The cancer potency comparisons show that some PAHs are more potent than BaP, while other PAHs analyzed were less or much less potent. These comparisons indicated that considering all PAHs to be equivalent in potency to BaP would likely overestimate the cancer potency of a PAH mixture, but such an assumption would be health protective and likely to be helpful in a screening estimate of PAH risks (OEHHA, 1993). If one assumes that PAHs are as carcinogenic as they are genotoxic, then their hazard relative to BaP would be dependent on their concentration in the environment. In light of the limited information available on other PAHs, BaP remains an important representative or surrogate for this group of air pollutants.

Detailed descriptions on the criteria used for developing individual PEFs can be found in OEHHA (2009). OEHHA continues to review all recent literature pertaining to the carcinogenicity and mutagenicity of PAHs. New cancer potency values for PAHs may be developed if an adequate health effects evaluation and quantitative risk assessment can be performed. Also, some current PEFs may be modified based on new data. Any changes to the potency values and PEFs for PAHs will be reflected in the HARP program when they occur. It is incumbent on the risk assessor to access the most recent version of the HARP program to ensure that the most up-to-date PAH potency values are used.

TABLE G-2. OEHHA PEF WEIGHTING SCHEME FOR PAHS AND THEIR RESULTING CANCER POTENCY VALUES.[1]

PAH or derivative	PEF	Unit Risk $(\mu g/m^3)^{-1}$	Inhalation Slope Factor $(mg/kg\text{-}day)^{-1}$	Oral Slope Factor $(mg/kg\text{-}day)^{-1}$
benzo[*a*]pyrene (index compound)	**1.0**	**1.1×10^{-3}**	**3.9**	**$1.2 \times 10^{+1}$**
benz[*a*]anthracene	0.1	1.1×10^{-4}	3.9×10^{-1}	1.2
benzo[b]fluoranthene	0.1	1.1×10^{-4}	3.9×10^{-1}	1.2
benzo[*j*]fluoranthene	0.1	1.1×10^{-4}	3.9×10^{-1}	1.2
benzo[k]fluoranthene	0.1	1.1×10^{-4}	3.9×10^{-1}	1.2
dibenz[*a*,*j*]acridine	0.1	1.1×10^{-4}	3.9×10^{-1}	1.2
dibenz[*a*,*h*]acridine	0.1	1.1×10^{-4}	3.9×10^{-1}	1.2
7H-dibenzo[c,*g*]carbazole	1.0	1.1×10^{-3}	3.9	$1.2 \times 10^{+1}$
dibenzo[*a*,*e*]pyrene	1.0	1.1×10^{-3}	3.9	$1.2 \times 10^{+1}$
dibenzo[*a*,*h*]pyrene	10	1.1×10^{-2}	$3.9 \times 10^{+1}$	$1.2 \times 10^{+2}$
dibenzo[*a*,*i*]pyrene	10	1.1×10^{-2}	$3.9 \times 10^{+1}$	$1.2 \times 10^{+2}$

Appendix H:

Recommendations for Estimating Concentrations of Longer Averaging Periods from the Maximum One-Hour Concentration for Screening Purposes

H.1 Introduction

The U.S. Environmental Protection Agency (U.S. EPA) AERSCREEN air dispersion model can be used to estimate the maximum one-hour concentration downwind from an emissions source. The AERSCREEN model results (or AERMOD with screening meteorological data) can also be used to estimate concentrations for longer averaging periods, such as the maximum annual average concentration. In addition, it is permissible to use the AERMOD air dispersion model in a screening mode with identical meteorological conditions as used in the AERSCREEN model to superimpose results from multiple sources.

This method to assess short-term and long-term impacts may be used as a first-level screening indicator to determine if a more refined analysis is necessary. In the event that representative meteorological data are not available, the screening assessment may be the only computer modeling method available to assess source impacts.

In California, this standard procedure will generally bias concentrations towards over-prediction in most cases when the source is a continuous release. However, in the case when a source is not continuous, these screening factors may not be biased towards over prediction. In this case, we recommend an alternative procedure for estimating screening value concentrations for longer averaging periods than one-hour for intermittent releases.

H.2 Current Procedures

The current screening factors used to estimate longer term averages (i.e., 3-hour, 8-hour, 24-hour, 30-day, and annual averages) from maximum one-hour concentrations in California are shown in Table H.1. The factors are U.S. EPA recommended values with the exception of the 30-day factor. The 30-day factor is an ARB recommended value (ARB, 1994). The maximum and minimum values are recommended limits to which one may diverge from the general case, (U.S. EPA, 1992). Diverging from the general case should only be done on a case by case basis with prior approval from the reviewing agency.

TABLE H.1 RECOMMENDED FACTORS TO CONVERT MAXIMUM 1-HOUR AVG. CONCENTRATIONS TO OTHER AVERAGING PERIODS (U.S. EPA, 2011, 1992; ARB, 1994).

Averaging Time	Range	Typical SCREEN3 Recommended	AERSCREEN Recommended
3 hours	0.8 - 1.0	0.9	1.0
8 hours	0.5 - 0.9	0.7	0.9
24 hours	0.2 - 0.6	0.4	0.6
30 days	0.2 - 0.3	0.3	
Annual	0.06 - 0.1	0.08	0.1

AERSCREEN automatically provides the converted concentration for longer than 1-hour averaging periods. For area sources, the AERSCREEN 3, 8, and 24-hour average concentrations are equal to the 1-hour concentration. No annual average concentration is calculated. SCREEN3 values are shown for comparison purposes.

H.3 Definitions

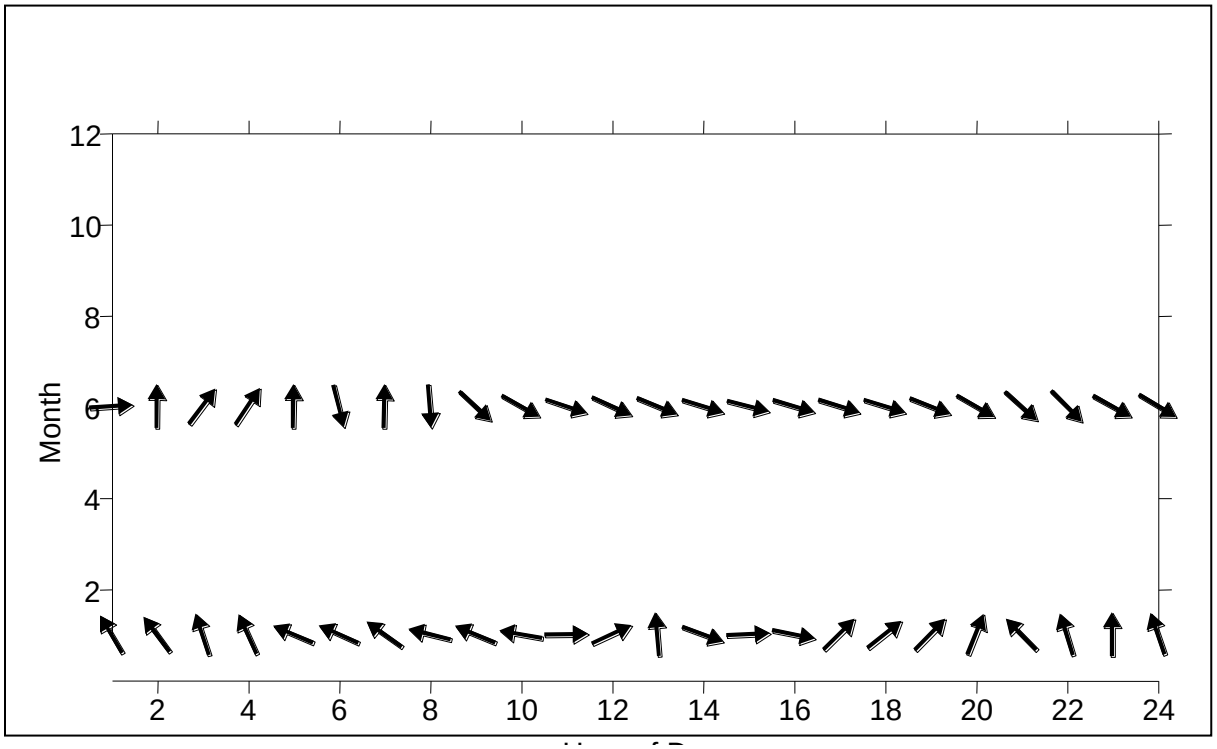
It is convenient to define the following terms relating to sources with respect to the duration of the release.

- Continuous Release – This is a release that is continuous over the duration of a year. An example of this type of release would be fugitive emissions from a 24-hour per day, 7-day per week operation or an operation that is nearly continuous.
- Intermittent Release – Many emissions fall under this category. These are emission types that are not continuous over the year. Any operation that has normal business hours (e.g., 8 am to 6 pm) would fall into this category.
- Systematic Release – These are intermittent releases that occur at a specific time of the day. As an example, these type of releases can occur when a process requires clean out at the end of the work day. Thereby releasing emissions only at the end of the workday systematically. Systematic releases are similar to intermittent releases with a shorter duration during the normal operating schedule.
- Random Release – These are intermittent releases that can occur any time during the operating schedule. An example of this type of release would be of the type that depends on batch processing. For example, a brake shop may emit pollutants only when the brakes are cleaned which happens randomly throughout the normal business hours.

H.4 Screening Factors

The U.S. EPA screening factors, as shown in Table H.1, compensate for the effects of varying conditions of wind speed, wind direction, ambient temperature, atmospheric stability, and mixing height over longer averaging periods, even though it is not explicitly indicated in the U.S. EPA Guidance (U.S. EPA, 1992). Figure H.1 shows the variability in wind direction over a 24-hour period. The data are averaged for two seven-day periods from data collected at Los Angeles International Airport (LAX). Figure H.1 was compiled for data collected in 1989 for January 1 to January 7 and June1 through June 7, 1989. The ordinate in Figure H.1 shows the months of the year. Only two months are plotted. The abscissa shows the hour of the day.

FIGURE H.1: HOURLY WIND DIRECTION - LOS ANGELES, JANUARY (BOTTOM – 1) AND JUNE (TOP - 6)



As seen in Figure H.1, the wind direction changes throughout all hours of the day. In addition, the wind direction for LAX, in the overnight and early morning hours, can vary from January to June. During the afternoon hours of 1400 – 1600, the wind direction is similar in both months of January and June.

The standard U.S. EPA screening factor to estimate the maximum 24-hour concentration from the maximum 1-hour concentration is 0.4, as seen in Table H.1. Figure H.2 shows that for 15 of 24 hours the wind blows from the west-northwest during June. A 24-hour screening factor could be 0.6 (0.6 ≈ 15hrs/24hrs) based on wind direction alone. This is consistent with the upper bound of the adjustment factors shown in Table H.1. Including the variability for wind speed, ambient temperature, and

atmospheric stability could further reduce the estimated scaling factor of 0.6 closer towards the U.S. EPA recommended value of 0.4.

H.5 Intermittent Release

Support for the U.S. EPA screening factor is demonstrated for a continuous release (i.e., 24 hours per day) in the description above. It is important to be cautious when applying the U.S. EPA screening factors to an intermittent source for the purposes of estimating an annual average concentration (e.g., a business that may only emit during normal operating hours of 8 am to 6 pm).

Intermittent emissions, such as those from burning barrels, testing a standby diesel generator, or any normal business hour operation (e.g., 8am to 6pm Monday through Friday), could have the effect of eliminating some of the annual variability of meteorological conditions. For example, emissions only during the daytime could eliminate the variability of a drainage flow pattern in mountainous terrain. Guidance for estimating long-term averages for a screening approach and intermittent emissions is not available.

For a source located in the LAX meteorological domain, an emission pattern confined to the hours of 1400 to 1600 would eliminate any variability associated with the wind direction. In this case, estimating a 24-hour average with the U.S. EPA scaling factor of 0.4 would be incorrect.

In the event the emissions are intermittent but randomly distributed throughout the day, the scaling factor of 0.4 may be appropriate because the natural diurnal variability of meteorological conditions are concurrent with emissions. An additional pro-rating of the concentration, when estimating a 24-hour concentration, would be required to discount due to the intermittent nature of the emissions.

We recommend the following steps to estimate a screening based estimate of annual average concentrations from intermittent emissions.

1. Estimate the maximum one-hour concentration ($\chi_{1\text{-hr}}$) based on the AERSCREEN model approach (or similar, e.g., AERMOD with screening meteorological data) for possible meteorological conditions consistent with the operating conditions and the actual hourly emission rate. It is acceptable to estimate downwind concentrations using all meteorological combinations available to AERSCREEN. However, it is possible to be selective for the choices of meteorological conditions and still be conservative. For example, daytime only emissions need not be evaluated for nighttime stable atmospheric conditions.

2. Estimate the concentration for the longest averaging period applicable based on the length of time of the systematic or randomly distributed emissions and the factors in Table H.1. For example, the longest averaging period concentration that may be estimated with the U.S. EPA scaling factors is an 8-hour concentration ($\chi_{8\text{-hr}}$) for emissions that are systematically released for 12 hours.

Scaling factors between 8-hours and 12-hours are not available. In the case of the 8-hour concentration, the U.S. EPA screening factor of 0.7 $\pm$ 0.2 to estimate the maximum 8-hour concentration is appropriate.

The U.S. EPA Screening Guidance allows for deviation from the suggested conversion factor on a case-by-case basis. We recommend the lower end of the range for the conversion factor (i.e., 0.5 for the 8-hour average) when estimating an annual average concentration. This is because variability associated with seasonal differences in wind speed, wind direction, and atmospheric stability would not be addressed otherwise. As seen in Figure H.1, there are seasonal differences in the wind direction.

For example, if X is the length of time of systematic or randomly distributed emissions, the following scalars can apply.

- $X \leq 2$ hrs; Scalar = 1.0 to estimate a 1-hour average
- 3 hrs $\leq X \leq$ 7 hrs; Scalar = 0.8 to estimate a 3-hour average
- 8 hrs $\leq X \leq$ 20 hrs; Scalar = 0.5 to estimate an 8-hour average (the selection of 20 hours is arbitrary)
- 21 hrs $\leq X \leq$ 24 hrs; this may be a continuous release, use standard screening procedures.

3. Estimate the annual average concentration (χ_{annual}) by assuming the longer averaging period estimated above is persistent for the entire year. In the above example the 8-hour concentration is assumed to be persistent for an entire year to estimate an annual average concentration (i.e., the annual average concentration is assumed to be equal to the 8-hour concentration).

   In addition, the annual average concentration should be pro-rated over the final averaging period based on the pro-rated emissions (i.e., the calculation should include the fact that for some hours over the year, the emission rate is zero).

   For example, if Y is the number of operating hours in the year (e.g., Y = X * 365), the following may apply.

   $(\chi_{annual}) = (\chi_{1\text{-}hr})$ (Scalar) (Y/8760hrs/yr)

4. The hourly emission rate should be calculated based on the assumed operating schedule in the steps above. An example for a facility operating Y hours per year follows.

   $(q_{hourly}) = (Q_{yearly})/(Y$ hrs/yr)

5. The annual average concentration (or ground level concentration GLC) can be estimated as follows.

   $GLC = (\chi_{annual})\ (q_{hourly})$

   $= (\chi_{1\text{-}hr})(Scalar)\ (Yhrs/8760hrs)\ (Q_{yearly})/(Y\ hrs/yr)$

   $= (\chi_{1\text{-}hr})(Scalar)\ (Q_{yearly})/(8760\ hrs/yr)$

Practically speaking, the above five steps condense down to determining three values. The first value is the maximum 1-hour concentration. The second value is the Scalar (either 1.0, 0.8, or 0.5). And the third value is the hourly emission rate estimated by emissions uniformly distributed over the entire year (8760 hours). The operating hours per year drops out of the calculations for an annual average concentration provided the emissions are based on an annual inventory (See step 5).

In the event that the acute averaging period is required and the emissions are based on an annual inventory, then the annual operating hours are required.

Below are four examples using the steps as outlined above. In each case, the annual average concentration is the desired value for use in risk assessment calculations.

<u>Example 1 - Fugitive Gasoline Station Emissions</u>

Emissions are **continuous** for 24 hours per day and 365 days per year.

1. Estimate the maximum 1-hour concentration with the AERSCREEN model (or similar screening modeling approach), $\chi_{1\text{-}hr}$.

2. Estimate the annual average concentration, $\chi_{annual,}$ with the U.S. EPA screening factor of 0.08.

3. $(\chi_{annual}) = (\chi_{1\text{-}hr})(0.08)$

4. The hourly emission rate, q_{hourly}, for the annual average concentration is based on 24 hours per day and 365 days per year (8760 hours per year).

5. $(q_{hourly}) = (Q_{yearly})/(8760\ hrs/yr)$

6. The annual average concentration (or ground level concentration GLC) can be estimated as follows.

   $GLC = (\chi_{annual})\ (q_{hourly})$

   $GLC = (\chi_{1\text{-}hr})(0.08)\ (Q_{yearly})/(8760\ hrs/yr)$

Example 2 - Dry Cleaner Emissions

Emissions are **intermittent** over the year but **systematic** for 10 hours per day, 5 days per week and 50 weeks per year.

1. Estimate the maximum 1-hour concentration with the AERSCREEN model (or similar screening modeling approach), $\chi_{1\text{-hr}}$.

2. Estimate the maximum 8-hour average concentration, $\chi_{8\text{-hr,}}$ with the U.S. EPA screening factor of 0.7 $\pm$0.2 as the longest averaging period of continuous release. The averaging period would need to be less than 10 hours. Use the lower range of the screening factor, 0.5, because the annual average is the final product and variability due to seasonal differences are not accounted for otherwise.

   $(\chi_{8\text{-hr}}) = (\chi_{1\text{-hr}})(0.5)$

3. Assume the worst-case 8-hour concentration is persistent throughout the year and pro-rate the concentration based on emissions over the year. For this dry cleaner, there are 2500 hours of operating condition emissions. Therefore the annual average is calculated as follows.

   $(\chi_{annual}) = (\chi_{8\text{-hr}})$ (2500hrs/8760hrs)

   $= (\chi_{1\text{-hr}})(0.5)$ (2500hrs/8760hrs)

4. The hourly emission rate, q_{hourly}, for the annual average concentration is based on 2500 hours per year.

   $(q_{hourly}) = (Q_{yearly})/(2500$ hrs/yr)

5. The annual average concentration (or ground level concentration GLC) can be estimated as follows.

   $GLC = (\chi_{annual})\ (q_{hourly})$

   $= (\chi_{1\text{-hr}})(0.5)$ (2500hrs/8760hrs) $(Q_{yearly})/(2500$ hrs/yr)

   $= (\chi_{1\text{-hr}})(0.5)\ (Q_{yearly})/(8760$ hrs/yr)

Example 3 - Burning Barrel Emissions

Emissions are **intermittent** over the year and **random** during daylight hours for two hours per burn, two burns per week, and 52 weeks per year.

1. Estimate the maximum 1-hour concentration with the AERSCREEN model (or similar screening modeling approach), $\chi_{1\text{-hr}}$. Meteorological combinations may be restricted to daytime conditions for this screening analysis.

2. Estimate the maximum 8-hour average concentration, $\chi_{8\text{-hr}}$, with the U.S. EPA screening factor of 0.7 ±0.2 as the longest averaging period where the emissions have the potential to be randomly distributed. Depending on the day of the year and latitude of the emissions, the daylight hours can vary. For this example, we assume the daylight hours can be as short as 10 hours per day to as long as 14 hours per day. Since the emissions are randomly distributed throughout the daylight hours, the longest averaging period we can scale with U.S. EPA scaling factors is a 10 hour average. In this case, the averaging period becomes the 8-hour average and the scaling factor becomes 0.7±0.2. Again since this is for an annual average, we use the lower end of the range, 0.5.

   $(\chi_{8\text{-hr}}) = (\chi_{1\text{-hr}})(0.5)$

3. Assume the worst-case 8-hour concentration is persistent throughout the year and pro-rate the concentration based on the emissions over the year. For the burning barrels there are 208 hours of operating condition emissions (208 hrs = (2hrs/burn)(2burns/wk)(52wk/yr)). Therefore the annual average concentration is calculated as follows.

   $(\chi_{annual}) = (\chi_{8\text{-hr}})$ (208hrs/8760hrs)

   $= (\chi_{1\text{-hr}})(0.5)$ (208hrs/8760hrs)

4. The hourly emission rate, q_{hourly}, for the annual average concentration is based on 208 hours per year.

   $(q_{hourly}) = (Q_{yearly})/(208 \text{ hrs/yr})$

5. The annual average concentration (or ground level concentration GLC) can be estimated as follows.

   $GLC = (\chi_{annual})\ (q_{hourly})$

   $= (\chi_{1\text{-hr}})(0.5)$ (208hrs/8760hrs) $(Q_{yearly})/(208 \text{ hrs/yr})$

   $= (\chi_{1\text{-hr}})(0.5)\ (Q_{yearly})/(8760 \text{ hrs/yr})$

The above methods were used in a recent modeling evaluation for emissions from a burning barrel (example 3 above) (ARB, 2002). Table H.2, below, shows results from the modeling evaluation. Shown in Table H.2 are the maximum annual average concentrations based on the screening approach outlined above as well as a refined approach with site specific meteorological data from four locations, Alturas, Bishop, San Benito, and Escondido. As seen in Table H.2, the screening evaluation as described in the example overestimates the values calculated based on the refined analysis. This is the desired outcome of a screening approach.

TABLE H.2: MAXIMUM ANNUAL AVERAGE CONCENTRATION (χ/Q) ABOVE AMBIENT CONDITIONS - BURNING BARREL EMISSIONS

Met. City	**Alturas**	**Bishop**	**San Benito**	**Escondido**	Screening
D (m)	**($\mu g/m^3$)/(g/s)**	**($\mu g/m^3$)/(g/s)**	**($\mu g/m^3$)/(g/s)**	**($\mu g/m^3$)/(g/s)**	***($\mu g/m^3$)/(g/s)***
20	44	61	85	110	*590*
50	12	16	22	30	*230*
100	4	5	7	9	*85*

Notes: (a) Annual χ/q is based on 208 hours of emissions at 1 g/s.

(b) χ/q is the concentration in $\mu g/m^3$ based on an hourly emission rate of 1 g/s.

Example 4 - Standby Diesel Engine Testing

Emissions are **intermittent** over the year and **systematic** for two hours per week and 50 weeks per year. The engine testing is conducted at 2 pm on Fridays.

1. Estimate the maximum 1-hour concentration with the AERSCREEN model (or similar screening modeling approach), $\chi_{1\text{-hr}}$. Meteorological combinations may be restricted to daytime conditions in this screening analysis because the engine test is conducted at 2 pm.

2. In this case, the emission schedule is systematically fixed over a two hour period. Therefore, the longest averaging period which is applicable for the U.S. EPA screening factors is one-hour because a two-hour conversion factor is not available. Therefore, we assume the maximum 1-hour concentration is persistent for the entire year. We still prorate the concentration based on the emissions. There are 100 hours of engine testing per year. Therefore the annual average concentration becomes.

   $(\chi_{annual}) = (\chi_{1\text{-hr}})$ (100hrs/8760hrs)

3. The hourly emission rate, q_{hourly}, for the annual average concentration is based on 100 hours per year.

   $(q_{hourly}) = (Q_{yearly})/(100$ hrs/yr)

4. The annual average concentration (or ground level concentration GLC) can be estimated as follows.

$$GLC = (\chi_{annual})\ (q_{hourly})$$

$$= (\chi_{1\text{-}hr})\ (100hrs/8760hrs)\ (Q_{yearly})/(100\ hrs/yr)$$

$$= (\chi_{1\text{-}hr})\ (Q_{yearly})/(8760\ hrs/yr)$$

H.6 Implementation

The approach outlined above has been implemented in the Hot Spots Analysis and Reporting Program (HARP). The HARP software has been developed in consultation with OEHHA, Air Resources Board (ARB), and District representatives. The HARP software is the recommended model for calculating and presenting HRA results for the Hot Spots Program. Information on obtaining the HARP software can be found on the ARB's web site at www.arb.ca.gov. Note, since the HARP software is a tool that uses the methods specified in this document, the software will be available after these guidelines have undergone public and peer review, been endorsed by the state's Scientific Review Panel (SRP) on Toxic Air Contaminants, and adopted by OEHHA.

Appendix I:

Calculation Examples for Estimating Potential Health Impacts

This appendix provides four example calculations to illustrate the procedures for estimating the potential health impacts from a facility. The examples are intended to assist the risk assessor in understanding the steps associated with conducting the final step of risk assessment, risk characterization. The four examples provided in this appendix evaluate the inhalation cancer risk, the noncancer acute hazard quotient (HQ) and hazard index (HI), the noncancer 8-hour HQ and HI, and the multipathway (inhalation and oral) noncancer chronic HQ and HI. Specific requirements for health risk assessment (HRA) under the Hot Spots Program are presented in Chapter 8. The HARP software will perform the calculations that are presented here and required in the guidelines. See the ARB's website at www.arb.ca.gov for more information on HARP.

I.1 Sample Calculation for Inhalation Cancer Health Risk Assessment

The following example illustrates the steps for calculating cancer risk at the maximum exposed individual resident (MEIR) using the high-end point-estimate for the inhalation exposure pathway. For each included substance, the steps involved in this sample calculation include:

- Determine the annual average concentration and look-up the inhalation cancer potency factor for each substance
- For each age range, calculate the inhalation dose
- For each age range, calculate the cancer risk using the OEHHA cancer potency factor and the appropriate Age Sensitivity Factor
- Sum the cancer risks from each age range for the exposure duration of interest, and express the risk in chances per million

In this example, the inhalation dose and risk are calculated for the third trimester, ages 0<2, 2<9, 2<16, 16<30, and 16-70 using the high-end daily breathing rate for each age range.

This example focuses on the 30-year cancer risk calculation and does not cover the steps for completing a noninhalation or multipathway HRA. Algorithms to estimate point-estimate and stochastic multipathway exposure can be found in Chapter 5. For simplicity, it is recommended that the risk assessor use HARP to conduct a multipathway risk assessment or stochastic risk assessment.

Step one - Determine the annual average concentration at the MEIR and look-up the inhalation cancer potency factor for each emitted substance.

The risk assessor would obtain the annual average concentrations from the air dispersion modeling results. This step has been completed for this example. Table I.1 presents the annual average concentrations at a hypothetical facility. In addition,

Table I.1 also presents inhalation cancer potency factors for each substance, which also can be found in Chapter 7 and Appendix L. Note that where no inhalation cancer potency has been developed for a substance, the tables in this example have been annotated with N/A since it will not be possible to conduct a quantitative risk assessment for these substances. As previously stated, this example does not take into account multipathway effects for the substances listed in Table I.1. It is recommended that the risk assessor use HARP for conducting such an analysis.

TABLE I.1 ANNUAL AVERAGE CONCENTRATIONS AT THE MEIR AND INHALATION CANCER POTENCY FACTORS

Substance	Annual Average Concentrations ($\mu g/m^3$)	Inhalation Cancer Potency Factor $(mg/kg\text{-}d)^{-1}$
Ammonia	160	N/A
Arsenic	0.0015	12
Benzene	5	0.10
Chlorine	0.08	N/A
Chlorobenzene	20	N/A
2,3,7,8-TCDD (dioxin)	0.000004	130,000
Nickel	0.02	0.91

Step two - Determine the inhalation dose for each substance.

Once you have determined the annual average concentration for the emitted substance, the equation below is used to calculate the inhalation dose for each age range and each substance. This equation is listed in Section 5.4.1 of this document, and is also described in the *Air Toxics Hot Spots Risk Assessment Guidelines: Technical Support Document for Exposure Assessment and Stochastic Analysis* (OEHHA, 2012)

$$Dose-air = (Cair)\left(\frac{BR}{BW}\right)(A)(EF)\left(1\times10^{-6}\right)$$

Where:

Dose-air	=	Dose through inhalation (mg/kg/d)
Cair	=	Concentration in air ($\mu g/m^3$)
BR/BW	=	Daily breathing rate normalized to body weight (L/kg BW-day). See Table I.2 for the daily breathing rate for each age range.
A	=	Inhalation absorption factor
EF	=	Exposure frequency (unitless, days/365 days)
$1x10^{-6}$	=	Milligrams to micrograms conversion (10^{-3} mg/μg), cubic meters to liters conversion (10^{-3} m^3/l)

A summary of the exposure point-estimates and data distributions for use in risk assessment can be found in Chapter 5 of this document. For more detail on point-estimates and data distributions, see OEHHA (2012). The recommended default values presented in Table I.2 can be used when site-specific information is not available. Note that in this example the mean daily breathing rates listed in the table are for information purposes only. In some cases, the mean value can be used for a Tier-1 risk assessment or applied when multiple noninhalation routes of exposure dominate the risk (See Chapter 8.2.6).

TABLE I.2 RECOMMENDED DEFAULT VALUES FOR INHALATION DOSE EQUATION

Variable	Recommended Default Value		
EF	0.96 (350 days/365 days) Assumes 2-week vacation away from exposure		
Daily Breathing Rates (DBR) (L/kg BW-day) for 9, 30, and 70-year exposures in examples below	**Period**	**Mean**	**95th percentile**
	3rd trimester	225	**361**
	0<2 yrs	658	**1090**
	2<9 yrs	535	**861**
	2<16 yrs	452	**745**
	16<30 yrs	210	**335**
	16-70 yrs	185	**290**
	(For other DBRs see Chapter 5)		
A	1[a]		

[a] OEHHA's Hot Spots inhalation cancer potency factors for the Hot Spots program have already been adjusted where necessary to allow for the inhalation absorption factor, so a value of 1 is used in this equation.

The following equation shows the calculation for the inhalation dose of arsenic for the third trimester by using the annual average concentration for arsenic (Table I.1) and the recommended default values in Table I.2. Note that the high-end (95th percentile) daily breathing rates are used to estimate the third trimester inhalation dose in this example.

$$\text{Arsenic}(\text{dose}-\text{air})_{(\text{third trimester})} = \left(\frac{0.0015\mu g}{m^3}\right)\left(\frac{361 liters}{kg-day}\right)(1)(0.96)\left(\frac{1\text{x}10^{-3}\ mg}{1\mu g}\right)\left(\frac{1\text{x}10^{-3}\ m^3}{liters}\right)$$

$$\text{Arsenic}(\text{dose}-\text{air})_{(\text{third trimester})} = 5.2\times10^{-7} mg/kg-day$$

To estimate the 30-year arsenic inhalation dose, this calculation is repeated using 95th percentile breathing rates for 0<2 years, 2<16 years, and 16<30 years shown in Table I.2:

$$\text{Arsenic}(\text{dose}-\text{air})_{(0<2yrs)} = \left(\frac{0.0015\mu g}{m^3}\right)\left(\frac{1090 liters}{kg-day}\right)(1)(0.96)\left(\frac{1\text{x}10^{-3}\ mg}{1\mu g}\right)\left(\frac{1\text{x}10^{-3}\ m^3}{liters}\right)$$

Arsenic (dose-air) $_{(0<2\ \text{yrs})}$ = 1.6 × 10^{-6} mg/kg-day

$$\text{Arsenic}(\text{dose}-\text{air})_{(2<16yrs)} = \left(\frac{0.0015\mu g}{m^3}\right)\left(\frac{745 liters}{kg-day}\right)(1)(0.96)\left(\frac{1\text{x}10^{-3}\ mg}{1\mu g}\right)\left(\frac{1\text{x}10^{-3}\ m^3}{liters}\right)$$

Arsenic (dose-air) $_{(2<16\ \text{yrs})}$ = 1.1 × 10^{-6} mg/kg-day

$$\text{Arsenic}(\text{dose}-\text{air})_{(16<30yrs)} = \left(\frac{0.0015\mu g}{m^3}\right)\left(\frac{335 liters}{kg-day}\right)(1)(0.96)\left(\frac{1\text{x}10^{-3}\ mg}{1\mu g}\right)\left(\frac{1\text{x}10^{-3}\ m^3}{liters}\right)$$

Arsenic (dose-air) $_{(16<30\ \text{yrs})}$ = 4.8 × 10^{-7} mg/kg-day

To estimate 70-year exposure, the 95th percentile breathing rate for ages16-70 years in Table I.2 is used instead of the breathing rate for 16<30 years. The arsenic dose for the 16<70 year age bin is 4.2 × 10^{-7} mg/kg-day. Therefore, the age bins that are used for the 70-year scenario include the third trimester, ages 0<2 years, 2<16 years, and 16<70 years.

To estimate the 9-year arsenic inhalation dose, the 95th percentile breathing rates are used for the third trimester, ages 0<2 years and 2<9 years.

These calculations are repeated for each substance under evaluation using their respective annual average concentrations. For our hypothetical facility, we have calculated each inhalation dose for each substance by age bin. In reality, you only need to calculate the dose for the age bins that are required for the exposure duration of interest for your assessment (e.g., 30 years, etc.). However, Table I.3 shows the results from our analysis for all age bins so that potential risk for any exposure duration can be calculated.

TABLE I.3 CALCULATED INHALATION DOSES FOR SUBSTANCES

Substance		Calculated Dose (mg/kg-day)*				
	3rd Tri.	0<2 yrs	2<9 yrs	2<16 yrs	16<30 yrs	16-70 yrs
Ammonia	N/A	N/A	N/A	N/A	N/A	N/A
Arsenic	5.2×10^{-7}	1.6×10^{-6}	1.2×10^{-6}	1.1×10^{-6}	4.8×10^{-7}	4.2×10^{-7}
Benzene	1.7×10^{-3}	5.2×10^{-3}	4.1×10^{-3}	3.6×10^{-3}	1.6×10^{-3}	1.4×10^{-3}
Chlorine	N/A	N/A	N/A	N/A	N/A	N/A
Chlorobenzene	N/A	N/A	N/A	N/A	N/A	N/A
2,3,7,8-TCDD (dioxin)	1.4×10^{-9}	4.2×10^{-9}	3.3×10^{-9}	2.9×10^{-9}	1.3×10^{-9}	1.1×10^{-9}
Nickel	6.9×10^{-6}	2.1×10^{-5}	1.7×10^{-5}	1.4×10^{-5}	6.4×10^{-6}	5.6×10^{-6}

* The doses shown in this table are rounded and the rounded numbers are used for risk calculations in this example.

Step three – Determine inhalation cancer risk for the MEIR.

Once you have calculated the inhalation dose, then the cancer risk is calculated for each age bin and the risk estimates are summed for the exposure duration of interest. To complete this step, the dose for each age bin is multiplied by the inhalation cancer potency factor, the Age Sensitivity Factor (ASF), the exposure duration for the specified age bin over the averaging time (i.e., AT is always 70 years), and the fraction of time spent at home, to determine the cancer risk. Studies have shown that infants and children are more sensitive than adults to exposure to many carcinogens (OEHHA, 2009). Therefore, OEHHA applied ASFs to take into account the increased sensitivity to carcinogens during early-in-life exposure. OEHHA and ARB also evaluated information from activity patterns databases to estimate the percentage of the day that people are home (OEHHA, 2012). This information can be used to adjust exposure duration and risk from a specific facility's emissions, based on the assumption that exposure to the facility's emissions are not occurring while the person is away from home. The ASF and FAH variables are only used when estimating residential cancer risk (e.g., the MEIR)

The risk calculation is performed for each age bin and each substance. The total cancer risk for each substance is the sum of the cancer risks from each age bin for the exposure duration of interest.

$$\text{Cancer Risk} = \left(\text{Inhalation Dose}\,\frac{mg}{kg-day}\right)\left(\text{Cancer Potency}\,\frac{kg-day}{mg}\right)(ASF)(FAH)\left(\frac{EDyrs}{ATyrs}\right)$$

Where:

Cancer Risk	=	Unitless expression of risk (see below)
Inhalation Dose	=	In mg/kg-d
Cancer Potency	=	Chemical specific (in $(mg/kg\text{-}d)^{-1}$ or as kg-d/mg)
ASF	=	Age sensitivity factor (unitless)
FAH	=	Fraction of time spent at home (unitless)
ED	=	Exposure duration (years)
AT	=	Averaging time period over which exposure duration is averaged (always 70 years).

The age sensitivity factor, exposure duration, and fraction of time spent at home are shown for each age range in Table I.4. However, if it is determined there is a school located within the cancer risk isopleths of $1x10^{-6}$ (one chance per million) or greater for the duration of interest (e.g., 30-year analysis), then the fraction of time at the residence is assumed to be one (1) for ages 3rd trimester to less than 16. Thus, cancer risks and the associated isopleths must first be determined using one (1) as the fraction of time at the residence before the FAH values between ages 3rd trimester to less than 16 in Table I.4 can be utilized. See Chapter 8 for more information on calculating a zone of impact, isopleths, and population exposure. In this example, we assume there is no school located within the cancer risk isopleth of $1x10^{-6}$ or greater; therefore, the FAH factors in Table I.4 are used.

TABLE I.4 INPUTS FOR AGE SENSITIVITY FACTOR, EXPOSURE DURATION, AND THE FRACTION OF TIME SPENT AT HOME

	3rd Tri.	0<2 yrs	2<9 yrs	2<16 yrs	16<30 yrs	16-70 yrs
Age Sensitivity Factor	10	10	3	3	1	1
Exposure Duration (years)	0.25	2	7	14	14	54
Fraction of Time Spent at Home (FAH)	0.85*	0.85*	0.72*	0.72*	0.73	0.73

* FAH is 1 for ages 3rd trimester to less than 16 unless it is determined there is no school located within the cancer risk isopleth of $1x10^{-6}$ or greater.

The equation below shows the calculation of the cancer risk from arsenic for the third trimester:

$$\text{Arsenic Cancer Risk}_{\text{(third trimester)}} = \left(\frac{5.2\times10^{-7}mg}{kg-d}\right)\left(\frac{12kg-d}{mg}\right)(10)(0.85)\left(\frac{0.25yrs}{70yrs}\right)$$

$$\text{Arsenic Cancer Risk}_{\text{(third trimester)}} = 1.9 \times 10^{-7}$$

To estimate the 30-year cancer risk from arsenic, the cancer risk calculation is repeated for the age bins 0<2, 2<16, and 16<30 years using the appropriate age-related inputs for average daily inhalation dose, ASF, FAH and ED in Tables I.3 and I.4, respectively:

$$\text{Arsenic Cancer Risk}_{(0<2\,\text{yrs})} = \left(\frac{1.6\times10^{-6}\,mg}{kg-d}\right)\left(\frac{12\,kg-d}{mg}\right)(10)(0.85)\left(\frac{2\,yrs}{70\,yrs}\right)$$

Arsenic Cancer Risk $_{(0<2\ \text{yrs})}$ = 4.7×10^{-6}

$$\text{Arsenic Cancer Risk}_{(2<16\,\text{yrs})} = \left(\frac{1.1\times10^{-6}\,mg}{kg-d}\right)\left(\frac{12\,kg-d}{mg}\right)(3)(0.72)\left(\frac{14\,yrs}{70\,yrs}\right)$$

Arsenic Cancer Risk $_{(2<16\ \text{yrs})}$ = 5.7×10^{-6}

$$\text{Arsenic Cancer Risk}_{(16<30\,\text{yrs})} = \left(\frac{4.8\times10^{-7}\,mg}{kg-d}\right)\left(\frac{12\,kg-d}{mg}\right)(1)(0.73)\left(\frac{14\,yrs}{70\,yrs}\right)$$

Arsenic Cancer Risk $_{(16<30\ \text{yrs})}$ = 8.4×10^{-7}

Calculated arsenic cancer risks for each age range are then summed together as shown in the example below to estimate the total 30-year cancer risk from arsenic:

Total Arsenic Cancer Risk $_{(30\text{-year})}$ = Arsenic Cancer Risk $_{(\text{third trimester})}$ +

Arsenic Cancer Risk $_{(0<2\ \text{yrs})}$ +

Arsenic Cancer Risk $_{(2<16\ \text{yrs})}$ +

Arsenic Cancer Risk $_{(16<30\ \text{yrs})}$

$= (1.9 \times 10^{-7}) + (4.7 \times 10^{-6}) + (5.7 \times 10^{-6}) + (8.4 \times 10^{-7}) = 1.1 \times 10^{-5}$

To estimate the 70-year cancer risk from arsenic, the cancer risk calculation is repeated for the last trimester to birth, ages 0<2, 2<16, and 16<70 using the appropriate age-related inputs from Tables I.3 and I.4. The calculated arsenic cancer risks for each

age range from the third trimester to age 70 are then summed together to estimate the total 70-year cancer risk from arsenic.

To estimate the 9-year cancer risk from arsenic, the cancer risk calculation is repeated for the last trimester to birth, ages 0<2 and 2<9 using the appropriate age-related inputs from Tables I.3 and I.4. The calculated arsenic cancer risks for each age range from the third trimester to age 9 are then summed together to estimate the 9-year cancer risk from arsenic.

Step four – Express cancer risk in chances per million.

The final step converts the cancer risk in scientific notation to a whole number that expresses the cancer risk in "chances per million"; to complete this step, multiply the estimated cancer risk by a factor of $1x10^6$ (i.e., 1 million).

(Total Cancer Risk) ($1x10^6$) = Total Cancer Risk in chances per million

For a hypothetical facility, the equation below shows the calculation for the inhalation cancer risk of arsenic as a result of 30-year exposure to arsenic:

$$\left(1.1\times10^{-5}\right)\left(1\times10^{6}\right)=11\,\text{chances per million}$$

Use the substance-specific inhalation dose and inhalation cancer potency factor to determine the cancer risk for each substance by repeating these steps. Sum the individual substance cancer risks to give you the total facility (inhalation) cancer risk. Table I.5 shows the individual substance and total facility inhalation cancer risk. In this example, a hypothetical facility poses a (inhalation) cancer risk of 658 chances per million at the MEIR. Note, although not presented here, a facility emitting arsenic or dioxins should also evaluate cancer risk from noninhalation exposure pathways. *Note that although rounding was utilized for ease throughout this example, rounding should not take place until the final answer.*

TABLE I.5 HYPOTHETICAL FACILITY INHALATION 30-YEAR CANCER RISK

Substance	Cancer risk* (chances per million)
Ammonia	N/A*
Arsenic	11
Benzene	310
Chlorine	N/A**
Chlorobenzene	N/A**
2,3,7,8-TCDD (dioxin)	326
Nickel	11
Total Facility Inhalation Cancer Risk	**658**

* The calculated numbers in each step are rounded and the rounded numbers were used in succeeding calculation steps in this example.

** N/A: Inhalation cancer potency factor is not applicable.

While this example illustrates the steps used to calculate cancer risk using the inhalation dose algorithm, steps one through four can also be used to calculate noninhalation cancer risk and ultimately multipathway (inhalation and noninhalation pathway) cancer risk. To determine noninhalation cancer risk, an assessor should use the appropriate exposure pathway algorithm presented in Chapter 5. For example, equation 5.4.3.1.1 (Chapter 5) would be used to determine dose for the soil ingestion pathway. Once the assessor has determined the ingestion dose by age group, the cancer risk for that pathway is calculated using the substance-specific oral slope factor and the appropriate age-sensitivity factors. Oral slope factors can be found in Appendix L and Chapter 7. To calculate multipathway cancer risk, the cancer risks for all substances and exposure pathways are summed. See Chapter 8 for further discussion.

I.2 Sample Calculation of Noncancer Acute Hazard Indices

Risk characterization for noncancer health impacts are expressed as a hazard quotient (for individual substances) or a hazard index (for multiple substances). In addition, all hazard quotients (HQ) and hazard indices (HI) must be determined by target organ system. The example below illustrates the approach for calculating a noncancer acute HQ and HI at the MEIR. The steps involved in this sample calculation include: 1) determining the 1-hour maximum concentration, the acute reference exposure level (REL), and the target organ systems for each substance; 2) calculating the acute HQ for each substance and applying the calculated HQ to the specified target organs for each substance; and 3) calculating the acute HI by summing each HQ from each substance by target organ system. As discussed in Chapter 8, the following example is provided to assist the risk assessor in understanding how to calculate an acute HQ and HI. Using HARP, both the acute HQ and HI will automatically be calculated at each receptor. No exposure duration adjustment should be made for acute noncancer assessments. Specific requirements for risk assessment under the Hot Spots Program can be found in Chapters 8 and 9.

Step one - Determine the 1-hour maximum concentration at the MEIR, the acute reference exposure level, and the target organ systems for each emitted substance.

The risk assessor would obtain the 1-hour maximum concentrations from the air dispersion modeling results. This step has been completed for this example. Table I.6 presents the maximum 1-hour concentrations, target organ systems, and acute RELs for seven substances. Note that where an acute REL has not been developed for a substance, the tables in this example have been annotated with "N/A".

TABLE I.6 CONCENTRATIONS, ACUTE RELS, AND TARGET ORGAN SYSTEM(S) FOR SUBSTANCES AT THE MEIR

Substance	1-hour Maximum Concentration ($\mu g/m^3$)	Acute REL ($\mu g/m^3$)	Target Organ System(s)
Ammonia	1900	3200	Respiratory System; Eye
Arsenic	0.03	0.20	Reproductive/Development ; Cardiovascular System; Nervous System
Benzene	0.54	27	Reproductive/Development; Immune System; Hematologic System
Chlorine	140	210	Respiratory System; Eye
Chlorobenzene	60	N/A	N/A
2,3,7,8-TCDD (dioxin)	0.00001	N/A	N/A
Nickel	0.08	0.20	Immune System

In this example, chlorobenzene and 2,3,7,8-TCDD (dioxin) do not have acute REL values. The acute RELs and their corresponding target organ system(s) can be found in Table 6.1 (Chapter 6) and also in Appendix L.

Step two - Determine the hazard quotient for each substance.

The hazard quotients for each substance are calculated by taking the acute maximum 1-hour concentration and dividing by the substance-specific acute REL. The following equation shows how to calculate the hazard quotient for ammonia.

$$\text{Acute Hazard Quotient} = \frac{\left(\text{Maximum 1-hr Concentration}\right)}{\left(\text{Acute REL}\right)} \Rightarrow \text{Acute Hazard Quotient}_{(\text{ammonia})} = \frac{\left(1900\ \mu g/m^3\right)}{\left(3200\ \mu g/m^3\right)} = 0.6$$

Step three – Determine the acute HI for all emitted substances.

The acute HQ calculated above for a substance applies to all the target organs listed under that substance. The acute HI is calculated by summing each hazard quotient for each substance by target organ system. For example, add the HQs for all substances that impact the respiratory system, then repeat this step for the next target organ system (e.g., reproductive/development system). This step is repeated until all target organs (for the substances emitted) are individually totaled. See Table 6.1 for target organ system information. Note, do not add together the HQs or HIs for different target organ systems (e.g., do not add the impacts for the respiratory system to that for reproductive/development). Table I.7 shows individual hazard quotients for each substance and total hazard index.

TABLE I.7 INDIVIDUAL HAZARD QUOTIENTS AND TOTAL HAZARD INDEX FOR ACUTE EXPOSURE

Substance	Immune System	Reproductive/ Development	Hematologic System	Nervous System	Cardiovascular System	Respiratory System	Eye
Ammonia						0.6	0.6
Arsenic		0.2		0.2	0.2		
Benzene	0.02	0.02	0.02				
Chlorine						0.7	0.7
Chlorobenzene							
2,3,7,8-TCDD (dioxin)							
Nickel	0.4						
Total Acute Hazard Index*	**0.42**	**0.22**	**0.02**	**0.2**	**0.2**	**1.3**	**1.3**

* The total hazard index is the sum of the rounded individual hazard quotients for each target organ

In this example, an HQ of one was not equaled or exceeded for any individual substance. However, an HI (the sum of the hazard quotients for each target organ) of one was exceeded for the respiratory system and eyes. Exceeding a hazard index of one may indicate that there is the potential for adverse acute health impacts at this receptor location. The District and OEHHA should be consulted when a hazard index exceeds one (see Section 8.3).

I.3 Sample Calculation of Noncancer 8-Hour Hazard Indices

The 8-hour RELs are used to evaluate impacts to offsite workers. The 8-hour RELs also apply to exposure of children and teachers during school hours. Although not required in the HRA, 8-hour exposure modeling could also be performed at the discretion of the District to a residential scenario (i.e., the MEIR) where a facility operates only a portion of the day and exposure to residences are not adequately reflected by averaging concentrations over a 24 hour day.

The example below illustrates the approach for calculating a noncancer 8-hour HQ and HI at the maximum exposed individual worker (MEIW) from a noncontinuously emitting facility. An HQ expresses the noncancer 8-hour health impacts for an individual substance and an HI expresses the cumulative potential impacts for multiple substances. All HQs and hazard indices HIs must be determined by target organ system.

The steps involved in this sample calculation include: 1) estimating the daily 8-hour annual average concentration, determining the 8-hour reference exposure level (REL) and the target organ systems for each substance; 2) calculating the 8-hour HQ for each substance and applying the calculated HQ to the specified target organs for each substance; and 3) calculating the 8-hour HI by summing each HQ from each substance by target organ system. As discussed in Chapter 8, the following example is provided to assist the risk assessor in understanding the calculation of noncancer 8-hour HQ and HI. Using the HARP software, both the 8-hour HQ and HI will be automatically calculated at each receptor. Specific requirements for risk assessment under the Hot Spots Program can be found in Chapters 8 and 9.

In this example, the facility emits for a typical schedule of eight hours per day and five days per week and the offsite worker's shift coincides with the facility's emission schedule.

Step one – Estimate the daily 8-hour annual average concentrations at the MEIW from the annual average using an adjustment factor; determine the 8-hour REL and target organ systems for each emitted substance

The risk assessor would obtain the annual average concentrations from the air dispersion modeling results. See Chapter 4 or Appendix M for information on modeling and approximating 8-hour exposure concentrations. This example uses an adjustment factor to approximate the concentration the worker is breathing. Since this is a noncontinuously emitting facility, the annual average concentration is adjusted to represent daily 8-hour average concentration. These steps have been completed for this example. However for completeness, the following equation shows how to calculate the adjustment factor. See Chapter 4 for more explanation.

$$WAF = \frac{H_{residential}}{H_{source}} \times \frac{D_{residential}}{D_{source}} = \frac{24}{8} \times \frac{7}{5} = 4.2$$

Where:

WAF = the worker adjustment factor
$H_{residential}$ = the number of hours per day the long-term residential concentration is based on (always 24 hours)
H_{source} = the number of hours the source operates per day. In this example, we are assuming 8 hours per day.
$D_{residential}$ = the number of days per week the long-term residential concentration is based on (always 7 days).
D_{source} = the number of days the source operates per week. In this example, we are assuming 5 days per week.

The daily 8-hour annual average inhalation concentration is then estimated by multiplying the WAF with the annual average concentration:

$$\text{Concentration}_{\text{(8-hour average)}} = \text{Concentration}_{\text{(annual average)}} \times (\text{WAF})$$

Table I.8 shows the daily 8-hour annual average inhalation concentrations at a MEIW, target organ systems, and 8-hour RELs for seven substances. Note that where an 8-hour REL has not been developed for a substance, the tables in this example have been annotated with "N/A"; therefore, Table I.8 lists 8-hour RELs for arsenic and nickel. The 8-hour RELs and their corresponding target organ system(s) can be found in Table 6.2 (Chapter 6) and also in Appendix L.

TABLE I.8 ANNUAL AVERAGE CONCENTRATIONS AND ADJUSTED (AVERAGE DAILY) 8-HOUR CONCENTRATIONS FOR A FACILITY OPERATING 8 HRS/DAY, 5 DAYS/WEEK, AND THE 8-HOUR RELS AND TARGET ORGAN SYSTEM(S) FOR SUBSTANCES

Substance	Annual Average Conc. ($\mu g/m^3$)	Adjusted (Average Daily) 8-Hour Conc. ($\mu g/m^3$)	8-Hour REL ($\mu g/m^3$)	Target Organ System(s)
Ammonia	16	67	N/A	N/A
Arsenic	0.0015	0.0063	0.015	Cardiovascular System; Reproductive/Development; Nervous System: Respiratory System; Skin
Benzene	0.05	0.21	3	Hematologic system
Chlorine	0.08	0.3	N/A	N/A
Chlorobenzene	20	84	N/A	N/A
2,3,7,8-TCDD (dioxin)	0.000001	0.000004	N/A	N/A
Nickel	0.01	0.04	0.06	Respiratory System; Immune System

Step two - Determine the 8-hour hazard quotient for each substance.

Similar to the acute hazard quotient (HQ) calculation shown above, the 8-hour HQs are calculated by taking the noncontinuous source concentration, assumed to be based on an 8-hour facility operation from Table I.8, and dividing by the substance-specific 8-hour REL. The following equation shows how to calculate the hazard quotient for arsenic using the values presented in Table I.8:

$$\text{8-Hour Hazard Quotient} = \frac{\left(\text{Average daily concentration}\right)}{\left(\text{8-Hour REL}\right)} \Rightarrow \text{8-Hour Hazard Quotient}_{(\text{arsenic})} = \frac{\left(0.0063\ \mu g/m^3\right)}{\left(0.015\ \mu g/m^3\right)} = 0.4$$

Step three – Determine the HI for all emitted substances.

The 8-hour HQ calculated above for a substance applies to all the target organs listed under that substance. The 8-hour HIs are calculated by summing each HQ for each substance by target organ system. Similar to the example calculation for the acute HI, add the HQs for all substances that impact a specific organ system, then repeat this step for the next target organ system (e.g., respiratory system). This step is repeated until all target organs (for the substances emitted) are individually totaled. See Table 6.2 for target organ system information for 8-hour RELs. Note: do not add together the HQs or HIs for different target organ systems (e.g., do not add the impacts for the respiratory system to the reproductive/developmental system). Table I.9 shows individual hazard quotients for each substance and total hazard index for each organ system using the information presented in Table I.8.

In this example, an HQ of one was not equaled or exceeded for any individual substance. However, an HI (the sum of the hazard quotients for each target organ) of one was exceeded for the respiratory system. Exceeding a hazard index of one may indicate that there is the potential for an adverse health impact at this receptor location with repeated daily 8-hour exposures. The District and OEHHA should be consulted when a hazard index exceeds one (see Section 8.3).

For the MEIW, ideally only an 8-hour noncancer hazard assessment is required. However, development of 8-hour RELs is an ongoing process and many substances that have chronic RELs do not yet have 8-hour RELs. If 8-hour RELs have not been developed yet for all of the emitted chemicals with a chronic REL, as in the example below, then a chronic noncancer hazard assessment is also performed.

TABLE I.9 INDIVIDUAL HAZARD QUOTIENTS AND TOTAL HAZARD INDEX FOR 8-HOUR EXPOSURE

Substance	Respiratory System	Reproductive/ Development	Nervous System	Cardiovascular System	Skin	Immune System	Hematologic
Ammonia							
Arsenic	0.4	0.4	0.4	0.4	0.4		
Benzene							0.07
Chlorine							
Chloro-benzene							
2,3,7,8-TCDD (dioxin)							
Nickel	0.7					0.7	
Total Hazard Index*	**1.1**	**0.4**	**0.4**	**0.4**	**0.4**	**0.7**	**0.07**

* The total hazard index is the sum of the rounded individual hazard quotients for each target organ

I.4 Sample Calculation of Noncancer Chronic Hazard Indices

The example below illustrates the approach for calculating a noncancer chronic HQ and HI at the MEIR. An HQ expresses the noncancer health impacts for an individual substance and an HI expresses the potential impacts for multiple substances. All hazard quotients (HQ) and hazard indices (HI) must be determined by target organ system. The steps involved in this sample calculation include: 1) determining the annual average concentration, the inhalation and oral chronic RELs, and the target organ systems for each substance; 2) calculating the inhalation chronic HQ for each substance and applying the calculated HQ to all target organs for each substance; 3) calculating the noninhalation chronic HQ for each substance and applying the calculated HQ to all target organs for each substance; and 4) calculating the chronic HI by summing each HQ (inhalation and noninhalation) from each substance by target organ system.

As discussed in Chapter 8, the following example is provided to assist the risk assessor in understanding the calculation of a chronic HQ and HI. Using the HARP software, both the chronic HQ and HI will be automatically calculated at each receptor. No exposure adjustments are applied to chronic noncancer assessments. Specific requirements for risk assessment under the Hot Spots Program can be found in Chapters 4, 8 and 9.

Step one - Determine the annual average concentrations at the MEIR and inhalation and oral chronic RELs for each emitted substance.

The risk assessor would obtain the substance-specific annual average concentrations from the air dispersion modeling results. This step has been completed for this example. Table I.10 presents the annual average concentrations, target organ systems, and chronic RELs for seven substances. All of the substances have a chronic REL value associated with them. In addition, arsenic, dioxins, and nickel are multipathway substances; therefore, oral and dermal exposure must be included as potential exposure pathways. The chronic RELs and their corresponding target organ system(s) can be found in Tables 6.3 and 6.4 (Chapter 6) and also in Appendix L.

Step two – Determine the inhalation chronic hazard quotient for each substance.

For inhalation exposure, the individual hazard quotients for each substance are calculated by taking the annual average concentration and dividing by its corresponding chronic inhalation REL. Using the information contained in Table I.10, the equation below is used to calculate the inhalation hazard quotient for arsenic.

$$\text{Chronic Hazard Quotient} = \frac{\left(\begin{matrix}\text{Annual Avg.}\\ \text{Concentration}\end{matrix}\right)}{\left(\begin{matrix}\text{Chronic}\\ \text{REL}\end{matrix}\right)} \quad \Rightarrow \quad \text{Chronic Hazard Quotient}_{(\text{arsenic})} = \frac{\left(0.0015\ \mu g/m^3\right)}{\left(0.015\ \mu g/m^3\right)} = 0.1$$

The inhalation chronic HQ calculated above for a substance applies to all the target organs listed under that substance.

TABLE I.10 ANNUAL AVERAGE CONCENTRATIONS, CHRONIC RELS, AND TARGET ORGAN SYSTEMS FOR SUBSTANCES AT THE MEIR.

Substance	Annual Average Conc. ($\mu g/m^3$)	Chronic Inhalation REL ($\mu g/m^3$)	Target Organ System(s) (inhalation)	Chronic Oral REL (mg/kg-day)	Target Organ System(s) (oral/dermal)
Ammonia	160	200	Respiratory System	-	-
Arsenic	0.0015	0.015	Reproductive/ Development; Cardiovascular System; Nervous System; Respiratory System; Skin	0.0000035	Reproductive/ Development; Cardiovascular system; Nervous System; Respiratory System; Skin
Benzene	0.05	3	Hematologic System	-	-
Chlorine	0.08	0.2	Respiratory System	-	-
Chloro-benzene	20	1000	Alimentary System; Kidney; Reproductive/ Development	-	-
2,3,7,8-TCDD (dioxin)	0.000004	0.00004	Alimentary System (Liver); Reproductive/ Development; Endocrine System; Respiratory System; Hematologic System	0.00000001	Alimentary System (Liver); Reproductive/ Development; Endocrine System; Respiratory System; Hematologic System
Nickel	0.003	0.014	Respiratory System; Hematologic System	0.011	Reproductive/ Development

Step three – Determine the noninhalation hazard quotient for each substance.

For the substances that are subject to deposition, noninhalation (i.e., oral and dermal) exposure pathways need to be considered in the chronic hazard quotient evaluation. The point-estimates and algorithms for calculating the oral dose for all of the applicable exposure pathways and receptors (e.g., workers or residents) are explained in Chapter 5. Note, the HARP software uses the appropriate information and performs all the steps discussed in these examples.

As discussed in Section 8.3.3 for noncancer multipathway assessments, Tier I of the tiered approach to risk assessment states that the high-end point-estimates are used for the two dominant noninhalation exposure pathways and the non-dominant exposure pathways use the mean point-estimates to determine the dose and chronic health impacts at a residential receptor. To determine which exposure pathways are the two dominant ones, high-end point-estimates are used for all applicable noninhalation exposure pathways to see which two pathways provide the highest impacts for each substance. Once the two dominant noninhalation pathways are determined for each substance, the doses for the remaining noninhalation exposure pathway for that substance are recalculated using the average point-estimates. The 70-year dose (i.e., from calculating and adding the exposure contributions from the age 0 through 70 year bins) is used for residential receptors and the dose from the 16 through 70 year age bin is used for the worker evaluation. See Chapters 1, 4, 5, 6, and 8 for more information.

This example shows how to combine the impacts from multiple exposure pathways to obtain an oral (noninhalation) hazard quotient for a single substance. For each substance, the impacts for a specific exposure pathway are assessed by dividing the oral dose (derived from the annual average concentration) in milligrams per kilogram-day (mg/kg-day) by the oral chronic REL, expressed in units of (mg/kg-day) (Table 6.4). The next equation shows the HQ calculation for arsenic through the soil ingestion (SI) exposure pathway.

Note, prior to this point in this calculation, we are assuming several steps have taken place. These steps include: 1) the completion of air dispersion modeling to obtain the ground-level annual-average air concentration; 2) identification of the existing exposure pathways at the receptor location; 3) calculation of the concentration in the exposure media (e.g., for soil - Equation 5.3.2.A); 4) determination of the dominant noninhalation exposure pathway(s) for the substance; and 5) the calculation of the substance-specific dose for that exposure pathway (e.g., Equation 5.4.3.1 is used to calculate the dose from soil ingestion). See Chapter 5 for the algorithms for calculating the oral dose for all of the applicable exposure pathways and receptors.

For this example, the calculated dose for arsenic from soil ingestion is assumed to be 0.000000015 mg/kg-day.

$$\text{Chronic Oral Hazard Quotient} = \frac{SI\ dose}{\left(\frac{Chronic}{Oral\ REL}\right)} \Rightarrow \text{Chronic Oral Hazard Quotient}_{(SI\ arsenic)} = \frac{(0.000000015 mg/kg-day)}{(0.0000035 mg/kg-day)}$$

$$= 0.04$$

For each substance, this step is repeated for each applicable noninhalation exposure pathway. As illustrated below, the (total) oral HQ for a substance is calculated by summing the HQs for all applicable exposure pathways. In this example, the chronic oral HQ is assumed to equal 0.1 from all exposure pathways.

$$\text{Chronic Oral Hazard Quotient*}_{(arsenic)} = [HQ_{(SI)} + HQ_{(D)} + HQ_{(DW)} + HQ_{(MI)} + HQ_{(FI)} + HQ_{(HV)}]$$

$$\text{Chronic Oral Hazard} = 0.1$$

* Noninhalation pathways:

SI = soil ingestion
DW = drinking water
D = dermal absorption
MI = meat, milk & egg
FI = fisher-caught fish
HV = homegrown vegetables
BM = breast milk (not applicable for arsenic exposure)

The oral chronic HQ calculated above for a substance applies to all the target organs listed under that substance for the noninhalation pathway.

Step four – Determine the chronic HI

The chronic HI is calculated by summing each HQ (inhalation and noninhalation) for each substance by the target organ system(s). For example, add the HQs for all substances that impact the respiratory system, then repeat this step for the next target organ system (e.g., cardiovascular system). This step is repeated until all target organs (for the substances emitted) are individually totaled. See Tables 6.3 and 6.4 for target organ system information. Note, do not add together the HQs or HIs for different target organ systems (e.g., do not add the impacts for the respiratory system to the cardiovascular system). Table I.11 shows individual hazard quotients (inhalation and noninhalation) for each substance and the hazard index by target organ system. In this table, arsenic is highlighted in bold to identify how the information calculated above is presented and used.

In this example, an HQ of one was not equaled or exceeded for any individual substance. However, an HI (the sum of the hazard quotients for each target organ) of one was exceeded for the respiratory system. Exceeding a hazard index of one may indicate that there is the potential for adverse chronic health impacts at this receptor location. The District and OEHHA should be consulted when a hazard index exceeds one (see Section 8.3).

TABLE I.11 SUBSTANCE-SPECIFIC INHALATION AND NONINHALATION HAZARD QUOTIENTS AND THE HAZARD INDEX BY TARGET ORGAN SYSTEM

Substance	Respiratory System	Hematologic System	Alimentary System	Endocrine System	Reproductive/ Development	Kidney	Nervous System	Cardiovascular System	Skin
Ammonia	0.8								
Arsenic	***0.1(i)*** ***0.1(ni)***				***0.1(i)*** ***0.1(ni)***		***0.1(i)*** ***0.1(ni)***	***0.1(i)*** ***0.1(ni)***	***0.1(i)*** ***0.1(ni)***
Benzene		0.02							
Chlorine	0.4								
Chloro-benzene			0.02		0.02	0.02			
2,3,7,8-TCDD (dioxin)	0.1(i) 0.2(ni)	0.1(i) 0.2(ni)	0.1(i) 0.2(ni)	0.1(i) 0.2(ni)	0.1(i) 0.2(ni)				
Nickel	0.2(i)	0.2(i)			0.1(ni)				
Chronic Hazard Index*	**1.9**	**0.52**	**0.32**	**0.3**	**0.62**	**0.02**	**0.2**	**0.2**	**0.2**

i = inhalation pathway contribution
ni = noninhalation pathway contribution
* The total hazard index is the sum of the rounded individual hazard quotients for each target organ.

Appendix J:

Glossary of Acronyms and Definition of Selected Terms

Adverse Health Effect: As defined by U.S. EPA, an adverse health effect is a biochemical change, functional impairment, or pathologic lesion that affects the performance of the whole organism, or reduces an organism's ability to respond to an additional environmental challenge. A health effect from exposure to air contaminants may range from relatively mild temporary conditions, such as eye or throat irritation, shortness of breath, or headaches, to permanent and serious conditions, such as birth defects, cancer or damage to lungs, nerves, liver, heart, or other organs.

AERMOD: A steady-state, plume-based air dispersion model (developed by U.S. EPA) for estimating near-field impacts from a variety of industrial source types. This was designed to provide reasonable concentration estimates over a wide range of conditions with minimal discontinuities, to be easily implemented with reasonable input requirements and computer resource needs, to be based on up-to-date science that captures the essential physical processes while remaining simple, and to be easily revised as the science evolves. To the extent practicable, the structure of the input or the control file for AERMOD is the same as that for the previously used ISCST3 model.

Age Sensitivity Factor (ASF): ASFs are default weighting factors to account for potential increased sensitivity to carcinogens during early life stages including prenatal, postnatal and juvenile life stages. ASFs are applied to the cancer risk equation.

Air Dispersion Modeling: Algorithms, usually performed with a computer, that relate a mass emission rate, source configuration, and meteorological information to calculate ambient air concentrations.

Air District: The Air Pollution Control and Air Quality Management Districts are the agencies responsible for managing air quality on a regional or county basis. California is currently divided into 35 air districts.

Air monitoring: The periodic or continuous sampling and analysis of air pollutants in ambient air or from individual pollutant sources.

Air Toxics Hot Spots Act Emission Inventory Reports: Documents that contain information regarding emission sources, emitted substances, emission rates and release parameters, prepared under the Emission Inventory Criteria and Guidelines (also referred to as “Inventory Reports”).

Air Toxics Hot Spots Information and Assessment Act of 1987 (AB 2588): (Health and Safety Code, Section 44300-44394) - A state law which established the "Hot Spots" Program to develop a statewide inventory of site-specific air toxic emissions, to assess the risk to public health from exposure to these emissions, to notify the public of any significant health risks and to reduce emissions below the significant risk levels.

Algorithm: A set of rules for solving a problem in a finite number of steps

California Air Resources Board (ARB): The State's lead air quality management agency consisting of an eleven-member board appointed by the Governor; in addition, the Air Resources Board has an Executive Office and a large staff of scientists and engineers to evaluate air pollution control measures. The ARB is responsible for attainment and maintenance of the state and federal air quality standards, and is fully responsible for motor vehicle pollution control. It oversees county and regional air pollution management programs.

Asthma: A chronic inflammatory disorder of the lungs characterized by wheezing, breathlessness, bronchoconstriction (resulting in chest tightness), and cough.

Atmospheric half-life: The time required for the concentration of a pollutant or reactant to fall to one-half of its initial value.

Benchmark Dose: That dose derived from linear regression, using one or more models of one or more dose-response curves, associated with a specific response rate (such as 1, 5, or 10%) in the test population. This is the starting dose (point of departure) to which uncertainty factors are applied to determine a reference exposure level (REL) using the benchmark dose approach.

Urban Block Groups (BGs): A geographical unit smaller than a census tract used for reporting census data. BGs contain roughly 1,100 persons.

Bioaccumulation: The concentration of a substance in a body or part of a body or other living tissue in a concentration higher than that of the surrounding environment

Bioconcentrate: The process of increasing contaminant concentration in biota up the food chain as contaminants are ingested and concentrated in tissues of organisms higher up in the chain.

Cancer burden: The estimated number of theoretical cancer cases in a defined population resulting from lifetime exposure to pollutants emitted from a facility.

Cancer potency factor (CPF): The theoretical upper bound probability of extra cancer cases occurring in an exposed population assuming a lifetime exposure to the chemical when the chemical dose is expressed in units of milligrams/kilogram body weight-day (mg/kg-d). The CPF is thus expressed in inverse units of mg/kg-d ($(mg/kg\text{-}d)^{-1}$).

California Air Pollution Control Officers Association (CAPCOA): A non-profit association of the air pollution control officers from all 35 air quality districts throughout California. CAPCOA was formed in 1975 to promote clean air and to provide a forum for sharing knowledge, experience, and information among the air quality regulatory agencies around the state.

Cal/EPA: The California Environmental Protection Agency is charged with developing, implementing and enforcing the state's environmental protection laws that ensure clean air, clean water, clean soil, safe pesticides and waste recycling and reduction. Its departments are at the forefront of environmental science, using cutting-edge research to shape the state's environmental laws. The Agency's boards and departments are: the Air Resources Board, the Department of Pesticide Regulation, the Department of Resources Recycling and Recovery (CalRecycle), the Department of Toxics Substances Control, the Office of Environmental Health Hazard Assessment, and the State Water Resources Control Board.

Chemical Abstract Services Registry Number (CAS): The Chemical Abstracts Service Registry Number (CAS) is a numeric designation assigned by the American Chemical Society's Chemical Abstracts Service and uniquely identifies a specific chemical compound. This entry allows one to conclusively identify a material regardless of the name or naming system used.

CCR: California Code of Regulations

CERCLA: Comprehensive Environmental Response, Compensation and Liability Act (Superfund), a federal regulation providing direction and financial support for the clean-up of major hazardous waste sites

Centroid Locations: The location at which calculated ambient concentration is assumed to represent the entire subarea, typically the geometric centroid of an area, but possibly the population-weighted centroid of the area.

Census Tract: A physical area used by the U.S. Census Bureau to compile population and other statistical data.

Criteria Air Pollutant: A pollutant for which the U.S. Environmental Protection Agency or the Air Resources Board has established an Ambient Air Quality Standard (AAQS). Examples include ozone, carbon monoxide, nitrogen dioxide, sulfur dioxide, lead, and PM_{10} and $PM_{2.5}$.

Default: A value used to account for a factor when specific information on that factor that applies to a specific situation is not available.

Developmental toxicity: Adverse effects on the developing organism that may result from exposure prior to conception (either parent), during prenatal development, or postnatally to the time of sexual maturation. Adverse developmental effects may be detected at any point in the life span of the organism. Major manifestations of developmental toxicity include: death of the developing organism; induction of structural birth defects; altered growth; and functional deficiency.

Dilution factor (χ/Q): A site-specific quantity defined as a ratio of the ground level concentration in $\mu g/m^3$ to the mass emission rate in g/s and represented by χ/Q.

Dose: A calculated amount of a substance estimated to be received by the subject, whether human or animal, as a result of exposure. Doses are generally expressed in terms of amount of chemical per unit body weight; typical units are mg/kg-day.

Dose-response assessment: The process of characterizing the relationship between the exposure to an agent and the incidence of an adverse health effect in exposed populations.

DTSC: California Department of Toxic Substances Control—DTSC regulates hazardous waste, cleans-up existing contamination, and looks for ways to reduce the hazardous waste produced in California. Its scientists, engineers, and specialized support staff make sure that companies and individuals handle, transport, store, treat, dispose of, and clean-up hazardous wastes appropriately. Through these measures, DTSC contributes to greater safety for all Californians, and less hazardous waste reaches the environment.

ED: Rural Enumeration District. A geographical unit smaller than a census tract used to report census data. EDs contain roughly 1,100 persons.

Emission Inventory Criteria and Guidelines: Regulation and Report adopted by the California Air Resources Board specifying criteria and procedures for the preparation of Air Toxics Hot Spots Act Emission Inventory Reports (Title 17, California Code or Regulations, Sections 93300-93300.5).

Endpoint: An observable or measurable biological or biochemical event including cancer used as an index of the effect of a chemical on a cell, tissue, organ, organism, etc.

Epidemiology: The study of the occurrence and distribution of a disease or physiological condition in human populations and of the factors that influence this distribution.

Exposure: Contact of an organism with a chemical, physical, or biological agent. Exposure is quantified as the amount of the agent available at the exchange boundaries of the organism (e.g., skin, lungs, digestive tract) and available for absorption.

Exposure Pathway: A route of exposure by which xenobiotics enter the human body, (e.g., inhalation, ingestion, dermal absorption).

Fugitive Dust: Dust particles that are introduced into the air through certain activities such as soil cultivation, or vehicles operating on open fields or dirt roadways. A subset of fugitive emissions.

Fugitive Emissions: Emissions not caught by a capture system which are often due to equipment leaks, evaporative processes, and windblown disturbances.

Gaussian Model: An air dispersion model based on the assumption that the time-averaged concentration of a species emitted from a point source has a Gaussian distribution about the mean centerline.

Genotoxic: Having an adverse effect on the genetic material (DNA) resulting in a mutation or in chromosome damage.

GLC: Estimated ground level concentration, usually for a specified averaging time (e.g., annual average, 1 hour, etc.).

GRAF: The Gastrointestinal Relative Absorption Factor**,** defined as the fraction of contaminant absorbed by the GI tract relative to the fraction of contaminant absorbed from the matrix (feed, water, other) used in the study(ies) that is the basis of either the cancer potency factor (CPF) or the Reference Exposure Level (REL)

Hot Spots Analysis and Reporting Program (HARP): A single integrated software package designed to promote statewide consistency, efficiency, and cost-effective implementation of health risk assessments and the Hot Spots Program. The HARP software package consists of three modules that include: 1) the Emissions Inventory Database Module, 2) the Air Dispersion Modeling Module, and 3) the Risk Analysis and Mapping Module.

Health Risk Assessment (HRA): The name of a computer program developed by the ARB, the OEHHA, and the University of California which was designed to aid in the computation of risk in the Hot Spots program

HSC: Health and Safety Code of the State of California

Haber's Law: The product of the concentration (C) and time of exposure (t) required to produce a specific physiologic effect is equal to a constant level or severity of response (K), or C * t = K.

Hazard Identification: The process of determining whether exposure to an agent can cause an increase in the incidence of an adverse health effect including cancer.

Health Risk Assessment: Health risk assessment is the characterization of the potential adverse health effects of human exposures to environmental hazards. In the Air Toxics Hot Spots program, a health risk assessment (HRA) is an evaluation or report that a risk assessor (e.g., district, consultant, or facility operator) develops to describe the potential a person or population may have of developing adverse health effects from exposure to a facility's emissions. Some health effects that are evaluated could include cancer, developmental effects, or respiratory illness. The pathways that can be included in an HRA depend on the toxic air pollutants that a person (receptor) may be exposed to, and can include breathing, the ingestion of soil, water, crops, fish, meat, milk, and eggs, and dermal exposure.

Health Risk Guidance Value (HRGV): A numerical value with which to compare an exposure level in order to determine the probability of occurrence of an adverse health effect. In the Hot Spots program the toxicity criteria or toxicity values are known as Reference Exposure Levels (RELs) for noncancer effects and as inhalation unit risk factors and cancer potency values for cancer effects.

Hazard Index (HI): The sum of individual acute or chronic hazard quotients (HQs) for each substance affecting a particular toxicological endpoint.

Hazard Quotient (HQ): The estimated ground level concentration divided by the reference exposure level for a single substance and a particular endpoint. For an acute HQ the one hour maximum concentration is divided by the acute Reference Exposure Level (REL) for the substance. For a repeated 8 hr HQ, the 8 hr average concentration is divided by the 8 hr REL. For a chronic HQ, the annual concentration is divided by the chronic REL.

Hot Spot: A location where emissions from specific sources may expose individuals and population groups to elevated risks of adverse health effects, including but not limited to cancer, and contribute to the cumulative health risks of emissions from other sources in the area.

Individual Excess Cancer Risk: The theoretical probability of an individual person developing cancer as a result of lifetime exposure to carcinogenic substances. The Individual Excess Cancer Risk is calculated by summing the potential cancer risks due to both inhalation and noninhalation routes of exposure, generally at the off-site point of maximum impact. This "individual" is the maximally exposed individual (MEI).

Inhalation (Breathing) Rate: The amount of air inhaled in a specified time period (e.g., per minute, per hour, per day, etc.); also called breathing rate and ventilation rate. This is an example of an exposure variate.

Inhalation unit risk factor: The theoretical upper bound probability of extra cancer cases occurring in the exposed population assuming a lifetime exposure to the chemical when the air concentration is expressed in units of microgram/cubic meter ($\mu g/m^3$). The unit risk factor is thus expressed as $(\mu g/m^3)^{-1}$.

Initiator carcinogen: A substance which causes the first stage of carcinogenesis, the conversion of a normal cell to a neoplastic cell. Initiation is considered to be a rapid, irreversible change often involving a change in the DNA caused by the initiator.

Interspecies: Between different species.

Intraspecies: Within the same species.

Industrial Source Complex Dispersion model (ISC3): Air modeling software that was previously used by U.S. EPA and the Hot Spots program. It incorporates three sub-programs into a single program. These are the short-term model (ISCST), the long term model (ISCLT), and the complex terrain model (COMPLEX).

Isopleth: A line on a map connecting points of equal value (e.g., risk, concentration, etc.).

Lowest-observed adverse effect level (LOAEL): The lowest dose or exposure level of a chemical in a study at which there is a statistically or biologically significant increase in the frequency or severity of an adverse effect in the exposed population as compared with an appropriate, unexposed control group.

Margin of safety: The ratio of the no-observed-adverse-effect level (NOAEL) to the estimated human exposure.

Mean: The arithmetic average**.**

MEI: Maximum exposed individual (theoretical)

MEIR: Maximum exposed individual resident (actual)

MEIW: Maximum exposed individual worker (actual)

Meteorology: The science that deals with the phenomena of the atmosphere especially weather and weather conditions. In the area of air dispersion modeling, *meteorology* is used to refer to climatological data needed to run an air dispersion model including: wind speed, wind direction, stability class and ambient temperature.

Milligram: One one-thousandth (10^{-3}) of a gram.

Molecular formula: The formula which identifies the atoms and the number of each kind in the molecules of a compound. Elements in the molecular formula are listed according to the Hill convention (C, H, then other elements in alphabetical order).

Molecular weight: The sum of the atomic weights of the atoms in a molecule. For example, methane (CH_4) is 16.043, the atomic weights are carbon = 12.011, hydrogen = 1.008.

Monte Carlo simulation: Application of random sampling to obtain an approximate value of an expression. Monte Carlo simulation involves computational algorithms that rely on repeated random sampling to obtain numerical results by running simulations many times over in order to calculate probability of a value.

Multipathway substance: A substance or chemical that once airborne from an emission source can, under environmental conditions, be taken into a human receptor by multiple exposure routes, such as inhalation, skin contact with contaminated surfaces, ingestion of soil contaminated by the emission, etc.

No Observed Adverse Effect Level (NOAEL): The highest experimental dose at which there is no statistically or biologically significant increase in frequency or severity of adverse non-cancer health effects in the exposed population compared with an appropriate, unexposed population. Effects may be produced at this level, but they are not considered to be adverse.

Noncarcinogenic Effects: Noncancer health effects which may include birth defects, organ damage, morbidity, and death.

Office of Environmental Health Hazard Assessment (OEHHA): The office within the California Environmental Protection Agency that is responsible for evaluating chemicals for adverse health impacts and establishing safe exposure levels. OEHHA also assists in performing health risk assessments and developing risk assessment procedures for air quality management purposes.

PM_{10}, $PM_{2.5}$: PM_{10} is particulate matter less than 10 μm in diameter; $PM_{2.5}$ is particulate matter less than 2.5 μm in diameter.

PMI: Off-site point of maximum impact. A location, with or without people currently present, at which the total cancer risk, or the total noncancer risk, has the highest numerical value.

Point Estimate: A single value estimate for a given variate.

Potency: The relative effectiveness, or risk, of a standard amount of a substance to cause a toxic response. This term is used particularly to refer to carcinogens.

Potency Slope (also referred to as “Slope Factor” or “ Cancer Potency”)**:** Used to calculate the probability or risk of cancer associated with an estimated exposure, based on the assumption in cancer risk assessments that risk is directly proportional to dose and that there is no threshold for carcinogenesis. It is the slope of the dose-response curve extrapolated to low environmental exposures. It is expressed in per unit dose (usually mg per kg-day): thus cancer potency typically has the units $(mg/kg\text{-}day)^{-1}$.

Proposition 65: Safe Drinking Water and Toxic Enforcement Act of 1986, also known as Proposition 65. This Act is codified in California Health and Safety Code Section 25249.5, et seq. .The Proposition was intended by its authors to protect California citizens and the State's drinking water sources from chemicals known to cause cancer, birth defects or other reproductive harm, and to inform citizens about exposures to such chemicals.

Resource Conservation and Recovery Act (RCRA) of 1976: A federal law regulating disposal of hazardous waste.

Receptor: A location with or without people present at which the ground level concentration of an emitted chemical can be estimated.

Refined Models: Air dispersion models designed to provide more representative concentration estimates than screening models taking into account actual meteorological conditions.

Reference Concentration (RfC): An estimate, derived by the U.S. EPA (with an uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population, (including sensitive subgroups) that is likely to be without appreciable risk of deleterious non-cancer effects during a lifetime of exposure. The RfC is derived from a no or lowest observed adverse effect level from human or animal exposures, to which uncertainty factors are applied, and is expressed in units of mg or µg per m^3.

Reference Dose (RfD): An estimate delivered by the U.S. EPA (with uncertainty spanning perhaps an order of magnitude) of the daily exposure to the human population (including sensitive subpopulations) that is likely to be without deleterious non-cancer effects during a lifetime. The RfD is reported in units of mg of substance/kg body weight/day for oral exposures.

Reference exposure level (REL): The REL is an exposure level at or below which no noncancer adverse health effect is anticipated to occur in a human population, including sensitive subpopulations, exposed for a specific duration. One hour acute RELs are designed to be protective for infrequent one hour maximum exposures. Eight-hour RELs are designed to be protective for repeated 8 hour exposures. Chronic RELs are designed to be protective for continuous long-term exposures. RELs are used to evaluate toxicity endpoints other than cancer. RELs are expressed in units of $\mu g/m^3$ for inhalation exposures and of mg/kg-d for noninhalation exposures.

Reproductive toxicity: Harmful effects on sexual function in males or females, fertility or gestation, caused by exposure of either parent to a substance. Reproductive toxicity also includes developmental effects on the offspring. See also developmental toxicity which refers to adverse effects on the offspring.

Risk: The estimated probability of adverse effects to human health, in this instance from the exposure to environmental hazards.

Risk Assessment: The characterization of the probability of adverse health effects to people from exposure to environmental hazards, in this case of exposure to chemical emissions.

Risk Management: An evaluation of the need for and feasibility of reducing risk. It includes consideration of magnitude of risk, available control technologies, and economic feasibility.

Risk Management and Prevention Program (RMPP): A program administered by the Office of Emergency Services (OES) and local agencies to reduce the frequency and severity of accidental releases of toxic materials.

SB 25 (Children's Environmental Health Protection Act): A state law (Senate Bill 25, Escutia, 1999) that amended the existing Toxic Air Contaminant and Criteria Air Pollutant laws and established requirements for the ARB and the OEHHA to examine the impacts of air pollution more explicitly on children's health. The act required the state to evaluate all ambient air quality standards to determine whether these standards adequately protect human health, particularly that of infants and children; to identify toxic air contaminants that disproportionately impact children, and to ensure that health assessments of toxic chemicals explicitly incorporate considerations of infants and children.

Scientific Review Panel on Toxic Air Contaminants or SRP: A nine-member panel appointed to advise the Air Resources Board, the Office of Environmental Health Hazard Assessment, and the Department of Pesticide Regulation in their evaluation of the adverse health effects and toxicity of substances being evaluated as Toxic Air Contaminants.

Screening Models: Dispersion models used to provide a maximum concentration that is likely to overestimate public exposure.

Sensitive Receptor: A location such as a hospital or daycare center where the human occupants are considered to be more sensitive to pollutants than “average”.

Spatial Averaging: The method used in the Hot Spots Program for determining an average air concentration from a grid of receptors over a specified area.

Stationary source: A non-mobile source of air pollutants which can be either a point or area source.

Stochastic: A process that involves random variation.

Synergism: A pharmacologic or toxicologic interaction in which the combined effect of two or more chemicals is greater than the sum of the effects of each chemical alone.

Subcensus Tract: Smaller population unit within a census tract.

Surrogate: As used in this document refers to a single substance category used to represent a family of related chemical compounds, e.g., benzo(a)pyrene in place of POM (polycyclic organic matter).

Threshold, Nonthreshold: A threshold dose is the minimally effective dose of any chemical that is observed in a population to produce a response (e.g., enzyme change, liver toxicity, death). For most toxic effects, except carcinogenesis, there appear to be threshold doses. (Exceptions include observed cardiovascular mortality in humans from exposure to particulate matter, and the neurotoxic effects of lead). Nonthreshold substances are those substances, including nearly all carcinogens, that are known or assumed to have some risk of response at any dose above zero.

Toxic air contaminant (TAC): As defined by California Health and Safety Code, Section 39655 (a): an air pollutant which may cause or contribute to an increase in mortality or in serious illness, or which may pose a present or potential hazard to human health. Substances, which have been identified by the United States Environmental Protection Agency as hazardous air pollutants (e.g. benzene, asbestos), shall be identified by the Board as toxic air contaminants.

Toxicology: The multidisciplinary study of toxicants, their harmful effects on biological systems, and the conditions under which these harmful effects occur. The mechanisms of action, detection, and treatment of the conditions produced by toxicants are studied.

Uncertainty: True uncertainty is that which is not known about a factor that influences its value.

URF: See inhalation unit risk factor.

UTM Coordinates: Universal Transverse Mercator Coordinates. Coordinates used to define a specific location on earth by means of two values (i.e., easting and northing coordinates).

United States Environmental Protection Agency (U.S. EPA): The mission of EPA is to protect human health and the environment. The agency sets national standards that are enforced by them or that states and tribes enforce through their own regulations. The agency also provide grants to state environmental programs, non-profits, educational institutions, and others for a wide variety of projects, from scientific studies that are used to make decisions to community cleanups. EPA's purpose is to ensure that: 1) All Americans are protected from significant risks to human health and the environment where they live, learn and work; 2) National efforts to reduce environmental risk are based on the best available scientific information; 3) Federal laws protecting human health and the environment are enforced fairly and effectively; 4) Environmental protection is an integral consideration in U.S. policies concerning natural resources, human health, economic growth, energy, transportation, agriculture, industry, and international trade, and these factors are similarly considered in establishing environmental policy; 5) All parts of society -- communities, individuals, businesses, and state, local and tribal governments -- have access to accurate information sufficient to effectively participate in managing human health and environmental risks; 6) Environmental protection contributes to making our communities and ecosystems diverse, sustainable and economically productive; and 7) The United States plays a leadership role in working with other nations to protect the global environment.

Vapor: The gaseous phase of materials at atmospheric temperature and pressure.

Vapor Pressure: The pressure exerted by a chemical vapor in equilibrium with its liquid or solid phase at any given temperature, used to calculate the rate of evaporation of a substance.

Variability: Ability to have different numerical values of a parameter, such as height or weight.

Variate: A variable quantity associated with a probability distribution, in the case of the Hot Spots program, for example, exposure factors (e.g. inhalation rate).

Volatile: Chemicals that rapidly pass off from the liquid state in the form of vapors.

Xenobiotic: A chemical or substance that is foreign to an organism or biological system. A chemical that is foreign to the species in which the chemical is being being studied.

Zone of impact: The area in the vicinity of the facility in which an individual is exposed to a specified cancer risk, usually one in a million or greater.

Table 1: CONSOLIDATED TABLE OF OEHHA/ARB APPROVED RISK ASSESSMENT HEALTH VALUES[a]

Purpose: The purpose of this reference table is to provide a quick list of all health values that have been approved by the Office of Environmental Health Hazard Assessment (OEHHA) and the Air Resources Board (ARB) for use in facility health risk assessments conducted for the AB 2588 Air Toxics Hot Spots Program. The OEHHA has developed and adopted new risk assessment guidelines that update and replace the 2003 version of the OEHHA *Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments*. The OEHHA has adopted three technical support documents for these guidelines, which can be found on their website (http://www.oehha.ca.gov/air/hot_spots/index.html). This table lists the OEHHA adopted inhalation and oral cancer slope factors, noncancer acute Reference Exposure Levels (RELs), and inhalation and oral noncancer chronic RELs. OEHHA is still in the process of adopting new health values. Therefore, new health values will periodically be added to, or deleted from, this table. Users of this table are advised to monitor the OEHHA website (*www.oehha.ca.gov*) for any updates to the health values.

May 2008 update: The Air Resources Board adopted amendments to the AB 2588 Air Toxics "Hot Spots" Emission Inventory Criteria and Guidelines Regulation (Title 17, California Code of Regulations, Section 93300.5) on November 16, 2006. The amendments became effective on September 26, 2007, after approval from the Office of Administrative Law. Under the new amendments, the substances previously listed in Appendix A-I *(Substances For Which Emissions Must Be Quantified*) and Appendix F (*Criteria For Inputs For Risk Assessment Using Screening Air Dispersion Modeling*) of the ARB's *Air Toxics* "*Hot Spots" Emission Inventory Criteria and Guidelines (EICG) (July 1997)* have been removed from this table.

a The *italic* font used in this table clarify applicability of OEHHA adopted health effects values to individual or grouped substances listed in the *Air Toxics* "*Hot Spots" Emission Inventory Criteria and Guidelines*, Appendix A-I list of *"Substances For Which Emissions Must Be Quantified"*.

b Chemical Abstract Service Number (CAS): For chemical groupings and mixtures where a CAS number is not applicable, the 4-digit code used in the *Air Toxics* "*Hot Spots" Emission Inventory Criteria and Guidelines (EICG) Report* is listed. The 4-digit codes enclosed in brackets [ ] are codes that have been phased out, but may still appear on previously reported Hot Spots emissions. For information on the origin and use of the 4-digit code, see the EICG report.

c Date Value Reviewed [Added]: These columns list the date that the health value was last reviewed by OEHHA, and/or the Scientific Review Panel, and/or approved for use in the AB 2588 Air Toxics Hot Spots Program. If the health value is unchanged since it was first approved for use in the Hot Spots Program, then the date that the value was first approved for use by CAPCOA is listed within the brackets [ ].

- April 1999 is listed for the cancer potency values and noncancer acute RELs, which have been adopted by the OEHHA as part of the AB 2588 Hot Spot Risk Assessment Guidelines.
- February 2000, April 2000, January 2001, and December 2001 are listed for the first set of 22, the second set of 16, the third set of 22, and the fourth set of 12 noncancer chronic RELs, respectively. The chronic REL for carbon disulfide was adopted in May 2002. Chronic RELs for phosphine and triethylamine were adopted in September 2002. Chronic RELs for fluorides including hydrogen fluoride were adopted August 2003. Chronic REL for silica [crystalline respirable] was adopted February 2005.
- October 2000 is listed for the oral chronic RELs and oral cancer slope factors.
- Cancer potency value adopted for naphthalene in August 2004. The inhalation and oral cancer potency values for ethyl benzene were adopted in November 2007.
- For the substances identified as Toxic Air Contaminants, the Air Resources Board hearing date is listed. The dates for acetaldehyde, benzo[a]pyrene, and methyl tertiary-butyl ether represent the dates the values were approved by the Scientific Review Panel.
- On December 19, 2008, OEHHA adopted new acute, 8-hour, and chronic RELs for acetaldehyde, acrolein, arsenic, formaldehyde, manganese, and mercury. The most current health values can be found at: http://www.oehha.ca.gov/air/allrels.html.

Note: 1. We present the new oral RELs only in milligrams (mg/kg-d), although OEHHA has presented them in other tables in either micrograms (μg/kg-d) or milligrams.

2. All acute RELs use a 1-hour averaging period (OEHHA, 2008). RELs which were developed using earlier guidelines and specified a different averaging time are unchanged in concentration value, but now refer to the 1-hour averaging period. As of 8/1/2013, the affected chemicals are: benzene, carbon disulfide, carbon tetrachloride, chloroform, ethylene glycol monoethyl ether, ethylene glycol monoethyl ether acetate, and ethylene glycol monomethyl ether: These may be replaced by updated RELs following the OEHHA (2008) guidelines in due course.

3. At OEHHA's direction, the chronic oral REL for arsenic does not apply to arsine because arsine is a gas and not particle associated.

- OEHHA's adoption of the World Health Organization's 2005 Toxicity Equivalency Factors for polychlorinated dibenzo-p-dioxins (PCDDs), dibenzofurans (PCDFs), and dioxin-like polychlorinated biphenyls (PCBs) occurred in January 2011. See Appendix C of OEHHA's *Air Toxics Hot Spots Program Technical Support Document for Cancer Potencies* at http://www.oehha.ca.gov/air/hot_spots/pdf/AppCdioxinTEFs013111.pdf for more information.
- On March 23, 2012, OEHHA adopted revised acute, 8-hour and chronic RELs for nickel and nickel compounds. The values of the RELs are listed in the table at: http://www.oehha.ca.gov/air/chronic_rels/032312CREL.html.
- On July 29, 2013, OEHHA adopted an acute and 8-hour REL, and a revised chronic REL for 1,3-butadiene. The REL values and summary can be found online at: http://www.oehha.ca.gov/air/hot_spots/index.html.
- On October 18, 2013 (February 2014 table update), OEHHA adopted acute, 8-hour, and chronic RELs for caprolactam. The REL values and summary can be found at: http://www.oehha.ca.gov/air/chronic_rels/pdf/Caprolactam2013.pdf. Changes have been made to target organs to the following substances with no change to health factors: Chloroform, Diethanolamine, Fluorides and Hydrogen Fluoride, Methylene Chloride, Styrene, Xylenes. The "date added" in this table reflects the date of the health factor only.
- On June 27, 2014, OEHHA adopted a new 8-hour REL and revised acute and chronic RELs for benzene. The REL values and summary can be found at: http://www.oehha.ca.gov/air/chronic_rels/BenzeneJune2014.html.

d Inhalation cancer potency factor: The "unit risk factor" has been replaced in the new risk assessment algorithms by a factor called the "inhalation cancer potency factor". Inhalation cancer potency factors are expressed as units of inverse dose [i.e., $(mg/kg\text{-}day)^{-1}$]. They were derived from unit risk factors [units = $(ug/m^3)^{-1}$] by assuming that a receptor weighs 70 kilograms and breathes 20 cubic meters of air per day. The inhalation potency factor is used to calculate a potential inhalation cancer risk using the new risk assessment algorithms defined in the OEHHA, *Air Toxics Hot Spots Program; Technical Support Document for Exposure Assessment and Stochastic Analysis (August 2012)*.

Table 1: CONSOLIDATED TABLE OF OEHHA/ARB APPROVED RISK ASSESSMENT HEALTH VALUES[a]

e	Molecular Weight Adjustment Factor: Molecular weight adjustment factors (MWAF) are only to be used when a toxic metal has a cancer potency factor. For most of the Hot Spots toxic metals, the OEHHA cancer potency factor applies to the weight of the toxic metal atom contained in the overall compound. Some of the Hot Spots compounds contain various elements along with the toxic metal atom (e.g., "Nickel hydroxide", CAS number 12054-48-7, has a formula of H_2NiO_2). Therefore, an adjustment to the reported pounds of the overall compound is needed before applying the OEHHA cancer potency factor for "Nickel and compounds" to such a compound. This ensures that the cancer potency factor is applied only to the fraction of the overall weight of the emissions that are associated with health effects of the metal. In other cases, the Hot Spots metals are already reported as the metal atom equivalent (e.g., CAS 7440-02-0, "Nickel"), and these cases do not use any further molecular weight adjustment. (Refer to Note [7] in Appendix A, List of Substances in the EICG Report for further information on how the emissions of various Hot Spots metal compounds are reported.) The appropriate molecular weight adjustment factors (MWAF) to be used along with the OEHHA cancer potency factors for Hot Spots metals can be found in the MWAF column of this table. So, for example, assume 100 pounds of "Nickel hydroxide" emissions are reported under CAS number 12054-48-7. To get the Nickel atom equivalent of these emissions, multiply by the listed MWAF (0.6332) for Nickel hydroxide: a. 100 pounds x 0.6332 = 63.32 pounds of Nickel atom equivalent *This step should be completed prior to applying the OEHHA cancer potency factor for "Nickel and compounds" in a calculation for a prioritization score or risk assessment calculation.* (For more information see Chapter 4, Section 4.2.1.1.1 of OEHHA's 2014 document, *The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments*.) Note: The value listed in the MWAF column for Asbestos is not a molecular weight adjustment. This is a conversion factor for adjusting mass to fibers or structures. See Appendix C of OEHHA's document *The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments (2014)* for more information on Asbestos, or see the EICG report for reporting guidance. Also see the Asbestos footnote (designated by the letter f)
TAC	Toxic Air Contaminant: The Air Resources Board has identified this substance as a Toxic Air Contaminant.
f	Asbestos: The units for the Inhalation Cancer Potency factor for asbestos are $(100 \text{ PCM fibers/m}^3)^{-1}$. A conversion factor of 100 fibers/0.003 µg can be multiplied by a receptor concentration of asbestos expressed in $\mu g/m^3$. Unless other information necessary to estimate the concentration ($fibers/m^3$) of asbestos at receptors of interest is available. A unit risk factor of $1.9 \text{ E } 10^{-4}$ $(\mu g/m^3)^{-1}$ and an inhalation cancer potency factor of $2.2 \text{ E } 10^{+2}$ $(\text{mg/kg BW} * \text{day})^{-1}$ are available. For more information on asbestos quantity conversion factors, see Appendix F of OEHHA's *The Air Toxics Hot Spots Program Risk Assessment Guidelines; Part II; Technical Support Document for Cancer Potency Factors (May 2009)*, and Appendix C of OEHHA's document *The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments (2014)*.
g	Hexavalent Chromium: In July 2011, OEHHA developed the oral cancer slope factor for chromium 6+ and compounds for the California Public Health Goal in drinking water. As of February 2014, OEHHA states it should also be used for the Hot Spots program.
h	Inorganic Lead: Inorganic Lead was identified by the Air Resources Board as a Toxic Air Contaminant in April 1997. Since information on noncancer health effects show no identified threshold, no Reference Exposure Level has been developed. The document, *Risk Management Guidelines for New, Modified, and Existing Sources of Lead, March 2001*, has been developed by ARB and OEHHA staff for assessing noncancer health impacts from sources of lead. See Appendix F of OEHHA's document *The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments* (2014) for an overview of how to evaluate noncancer impacts from exposure to lead using these risk management guidelines.
i	Particulate Emissions from Diesel-Fueled Engines: The inhalation cancer potency factor was derived from whole diesel exhaust and should be used only for impacts from the inhalation pathway (based on diesel PM measurements). The inhalation impacts from speciated emissions from diesel-fueled engines are already accounted for in the inhalation cancer potency factor. However, at the discretion of the risk assessor, speciated emissions from diesel-fueled engines may be used to estimate acute noncancer health impacts or the contribution to cancer risk or chronic noncancer health impacts for the non-inhalation exposure pathway. See Appendix D of OEHHA's document *The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments (2014)* for more information. The noncancer chronic REL for diesel exhaust is based on assumptions of contributions of diesel PM to ambient PM. It should be used with diesel PM measurement.
j	Cancer Potency Factors (CPFs) for unspeciated mixtures of Polychlorinated Biphenyls: High Risk: For use in cases where congeners with more than four chlorines comprise more than one-half percent of total polychlorinated biphenyls. Use as default CPF for Tier 1 assessments. Low Risk: This number would not ordinarily be used in the Hot Spots program. Lowest Risk: For use in cases where congeners with more than four chlorines comprise less than one-half percent of total polychlorinated biphenyls. As of February, 2014, there is no approved method that can be used to assess the noncancer hazard of an unspeciated PCB mixture. Persons preparing HRAs for the Hot Spots Program should consult with OEHHA and the local Air Pollution Control or Air Quality Management District if an assessment of the noncancer hazard for unspeciated PCB mixtures is needed.
k	Polychlorinated Dibenzo-p-dioxins and Polychlorinated Dibenzofurans (also referred to as chlorinated dioxins and dibenzofurans) and dioxin-like PCB congeners: The OEHHA has adopted the World Health Organization 2005 (WHO-05) Toxicity Equivalency Factor scheme for evaluating the risk due to exposure to samples containing mixtures of polychlorinated dibenzo-p-dioxins (PCDD) and polychlorinated dibenzofurans (PCDF) and a number of dioxin-like PCB congeners. See Appendix A of OEHHA's Technical Support Document For Describing Available Cancer Potency Factors for more information about the scheme. See Appendix E of OEHHA's 2014 The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments for the methodology for calculating 2,3,7,8-equivalents, cancer risk, and noncancer Hazard Index for PCDD, PCDFs and a number of dioxin-like PCB congeners. The two numbers (i.e., 1085 and 1086) in the column listing Chemical Abstracts Numbers are used for reporting and risk assessment purposes. Be sure to input emissions under the proper code when using the HARP software. ID code 1085 has no health values associated with it in the HARP software; therefore, no health impacts will be calculated when using ID 1085. See the Emissions Inventory Criteria and Guidelines for more information on reporting emissions.
l	Polycyclic Aromatic Hydrocarbons (PAHs): These substances are PAH or PAH-derivatives that have OEHHA-developed Potency Equivalency Factors (PEFs) which were approved by the Scientific Review Panel in April 1994 (see ARB document entitled *Benzo[a]pyrene as a Toxic Air Contaminant*). PAH inhalation slope factors listed here have been adjusted by the PEFs. See OEHHA's Technical Support Document: Methodologies for Derivation, Listing of Available Values, and Adjustments to Allow for Early Life Exposures (2009) for more information about the scheme. Appendix G of OEHHA's *The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments (2014)* also contains information on PAHs. The two numbers (i.e., 1150 and 1151) in the column listing Chemical Abstracts Numbers are used for reporting and risk assessment purposes. Be sure to input emissions under the proper code when using the HARP software. ID code 1150 has no health values associated with it in the HARP software; therefore, no health impacts will be calculated when using ID 1150. See the Emissions Inventory Criteria and Guidelines for more information on reporting emissions.

Table 1: CONSOLIDATED TABLE OF OEHHA/ARB APPROVED RISK ASSESSMENT HEALTH VALUES[a]

m	SELENIUM AND COMPOUNDS: In February 2014, an oral REL was added to the consolidated table. The REL was adopted in Dec 2001, but could not be used by the Hot Spots Program (or HARP software) until transfer factors for the oral and dermal routes were adopted. Transfer factors are included in the OEHHA's Technical Support Document for Exposure Assessment and Stochastic Analysis (August 2012) and will be added to the HARP software in the future.
N/A	Not Applicable.
Other Changes:	
	• 10/18/2010, removed CHLORODIFLUOROMETHANE, which should have been removed in May 2008.
	February 2014:
	• Removed applicability of oleum to the sulfuric acid chronic inhalation REL because oleum represents only an acute health hazard. • Removed "METHYL MERCURY (see Mercury & Compounds)" entry because methyl mercury has different chemical properties, potency, and toxicity compared to elemental mercury and mercury salts, and it is not emitted directly from any California facilities.

Table 2: OEHHA/ARB APPROVED ACUTE REFERENCE EXPOSURE LEVELS AND TARGET ORGANS[a]

Substance	Chemical[b] Abstract Service Number (CAS)	Acute REL ($\mu g/m^3$)	Date[c] Value Reviewed	Target Organs								
				Alimentary	Cardiovascular	Reproductive/[d] Development	Eye	Hematologic	Immune	Nervous	Respiratory	Skin

Purpose: The purpose of this reference table is to provide a quick list of all health values that have been approved by the Office of Environmental Health Hazard Assessment (OEHHA) and the Air Resources Board (ARB) for use in facility health risk assessments conducted for the AB 2588 Air Toxics "Hot Spots" Program. The OEHHA has developed and adopted new risk assessment guidelines that update and replace the 2003 version of the OEHHA *Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments*. The OEHHA has adopted three technical support documents for these guidelines, which can be found on their website (http://www.oehha.ca.gov/air/hot_spots/index.html). This table lists the OEHHA adopted noncancer acute Reference Exposure Levels (RELs). OEHHA is still in the process of adopting new health values. Therefore, new health values will periodically be added to, or deleted from, this table. Users of this table are advised to monitor the OEHHA website (*www.oehha.ca.gov*) for any updates to the health values.

May 2008 update: The Air Resources Board adopted amendments to the AB 2588 Air Toxics "Hot Spots" Emission Inventory Criteria and Guidelines Regulation (Title 17, California Code of Regulations, Section 93300.5) on November 16, 2006. The amendments became effective on September 26, 2007, after approval from the Office of Administrative Law. Under the new amendments, the substances previously listed in Appendix A-I *(Substances For Which Emissions Must Be Quantified*) and Appendix F (*Criteria For Inputs For Risk Assessment Using Screening Air Dispersion Modeling*) of the ARB's *Air Toxics* "*Hot Spots" Emission Inventory Criteria and Guidelines (EICG) (July 1997)* have been removed from this table.

a The checkmarks included in this table clarify applicability of OEHHA adopted heath effects values to individual or grouped substances listed in the *Air Toxics* "*Hot Spots" Emission Inventory Criteria and Guidelines*, Appendix A-I list of *"Substances For Which Emissions Must Be Quantified"*.

b Chemical Abstract Service Number (CAS): For chemical groupings and mixtures where a CAS number is not applicable, the 4-digit code used in the *Air Toxics* "*Hot Spots" Emission Inventory Criteria and Guidelines (EICG) Report* is listed. The 4-digit codes enclosed in brackets [ ] are codes that have been phased out, but may still appear on previously reported Hot Spots emissions. For information on the origin and use of the 4-digit code, see the EICG report.

Table 2: OEHHA/ARB APPROVED ACUTE REFERENCE EXPOSURE LEVELS AND TARGET ORGANS[a]

c	Date Value Reviewed [Added]: This column lists the date that the health value was last reviewed by OEHHA and the Scientific Review Panel, and/or approved for use in the AB 2588 Air Toxics Hot Spots Program. If the health value is unchanged since it was first approved for use in the "Hot Spots" Program, then the date that the value was first approved for use by CAPCOA is listed within the brackets [ ]. • April 1999 is listed for the noncancer acute RELs which have been adopted by the OEHHA as part of the AB 2588 Hot Spot Risk Assessment Guidelines. • On December 19, 2008, OEHHA adopted new acute RELs for acetaldehyde, acrolein, arsenic, formaldehyde, and mercury. The most current health values can be found at: http://www.oehha.ca.gov/air/allrels.html. Note: All acute RELs use a 1-hour averaging period (OEHHA, 2008). RELs which were developed using earlier guidelines and specified a different averaging time are unchanged in concentration value, but now refer to the 1-hour averaging period. As of 8/1/2013, the affected chemicals are: benzene, carbon disulfide, carbon tetrachloride, chloroform, ethylene glycol monoethyl ether, ethylene glycol monoethyl ether acetate, and ethylene glycol monomethyl ether: These may be replaced by updated RELs following the OEHHA (2008) guidelines in due course. • On March 23, 2012, OEHHA adopted revised acute, 8-hour and chronic RELs for nickel and nickel compounds. The values of the RELs are listed in the table at: http://www.oehha.ca.gov/air/chronic_rels/032312CREL.html. • On July 29, 2013, OEHHA adopted an acute and an 8-hour REL and a revised chronic REL for 1,3-butadiene. The REL value and summary can be found online at: http://www.oehha.ca.gov/air/hot_spots/index.html. • On October 18, 2013 (February 2014 table update), OEHHA adopted acute, 8-hour, and chronic RELs for caprolactam. The REL values and summary can be found at: http://www.oehha.ca.gov/air/chronic_rels/pdf/Caprolactam2013.pdf. Changes have been made to target organs to the following substances with no change to health factors: Chloroform, Methylene Chloride, Styrene, and Xylenes. The "date added" in this table reflects the date of the health factor only. See footnotes below that discuss changes to substance target organs only. • On June 27, 2014, OEHHA adopted a new 8-hour REL and revised acute and chronic RELs for benzene. The REL values and summary can be found at: http://www.oehha.ca.gov/air/chronic_rels/BenzeneJune2014.html
d	February 2014. Per OEHHA's current policy, substances with Reproductive System and/or Development as the hazard Index target organ(s) are represented under the single endpoint "Reproductive/Development"
TAC	Toxic Air Contaminant: The Air Resources Board has identified this substance as a Toxic Air Contaminant.
N/A	Not Applicable.

Other Changes:

February 2014 corrections based on original REL summaries:

- Chloroform – added respiratory system as a target organ.
- Methylene chloride – the cardiovascular system was added as a target organ.
- Entry of SULFURIC ACID AND OLEUM is removed to be consistent with Consolidated Table 1. This entry is removed from Table 1 because oleum represents only an acute health hazard.
- Styrene – added reproductive/development as a target organ.
- Xylenes – add nervous system as a target organ.

Table 3: OEHHA/ARB APPROVED 8-HOUR REFERENCE EXPOSURE LEVELS AND TARGET ORGANS[a]

Purpose:	The purpose of this reference table is to provide a quick list of all health values that have been approved by the Office of Environmental Health Hazard Assessment (OEHHA) and the Air Resources Board (ARB). The OEHHA has developed and adopted new risk assessment guidelines that update and replace the 2003 version of the OEHHA *Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments*. The OEHHA has adopted three technical support documents for these guidelines, which can be found on their website (http://www.oehha.ca.gov/air/hot_spots/index.html). This table lists the OEHHA adopted 8-hour RELs. The methodology for the development and use of 8-hour RELs in Health Risk Assessments can be found in the OEHHA 2008 document *Air Toxics Hot Spots Program Technical Support Document for the Derivation of Noncancer Reference Exposure Levels* online at: http://oehha.ca.gov/air/hot_spots/rels_dec2008.html. OEHHA is still in the process of adopting new health values. Therefore, new health values will periodically be added to, or deleted from, this table. Users of this table are advised to monitor the OEHHA website (*www.oehha.ca.gov*) for any updates to the health values.
a	The checkmarks included in this table clarify applicability of OEHHA adopted health effects values to individual or grouped substances listed in the *Air Toxics "Hot Spots" Emission Inventory Criteria and Guidelines*, Appendix A-I list of *"Substances For Which Emissions Must Be Quantified"*.
b	Chemical Abstract Service Number (CAS): For chemical groupings and mixtures where a CAS number is not applicable, the 4-digit code used in the *Air Toxics "Hot Spots" Emission Inventory Criteria and Guidelines (EICG) Report* is listed. The 4-digit codes enclosed in brackets [ ] are codes that have been phased out, but may still appear on previously reported Hot Spots emissions. For information on the origin and use of the 4-digit code, see the EICG report.
c	Date Value Reviewed [Added]: This column lists the date that the health value was last reviewed by OEHHA and the Scientific Review Panel, and/or approved for use in the AB 2588 Air Toxics Hot Spots Program. If the health value is unchanged since it was first approved for use in the "Hot Spots" Program, then the date that the value was first approved for use by CAPCOA is listed within the brackets [ ]. • On December 19, 2008, OEHHA adopted new 8-hour RELs for acetaldehyde, acrolein, arsenic, formaldehyde, manganese, and mercury. The most current health values can be found at: http://www.oehha.ca.gov/air/allrels.html. • On March 23, 2012, OEHHA adopted revised acute, 8-hour and chronic RELs for nickel and nickel compounds. The values of the RELs are listed in the table at: http://www.oehha.ca.gov/air/chronic_rels/032312CREL.html. • On July 29, 2013, OEHHA adopted an acute and an 8-hour REL and a revised chronic REL for 1,3-butadiene. The REL value and summary can be found online at: http://www.oehha.ca.gov/air/hot_spots/index.html. • On October 18, 2013, OEHHA adopted acute, 8-hour, and chronic RELs for caprolactam. The REL values and summary can be found at: http://www.oehha.ca.gov/air/chronic_rels/pdf/Caprolactam2013.pdf. • On June 27, 2014, OEHHA adopted a new 8-hour REL and revised acute and chronic RELs for benzene. The REL values and summary can be found at: http://www.oehha.ca.gov/air/chronic_rels/BenzeneJune2014.html.
d	February 2014. Per OEHHA's current policy, substances with Reproductive System and/or Development as the hazard Index target organ(s) are represented under the single endpoint "Reproductive/Development".
TAC	Toxic Air Contaminant: The Air Resources Board has identified this substance as a Toxic Air Contaminant.

Table 4: OEHHA/ARB APPROVED CHRONIC REFERENCE EXPOSURE LEVELS AND TARGET ORGANS[a]

Purpose: The purpose of this reference table is to provide a quick list of all health values that have been approved by the Office of Environmental Health Hazard Assessment (OEHHA) and the Air Resources Board (ARB) for use in facility health risk assessments conducted for the AB 2588 Air Toxics "Hot Spots" Program. The OEHHA has developed and adopted new risk assessment guidelines that update and replace the 2003 version of the OEHHA *Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments*. The OEHHA has adopted three technical support documents for these guidelines, which can be found on their website (http://www.oehha.ca.gov/air/hot_spots/index.html). This table lists the OEHHA adopted inhalation and oral noncancer chronic RELs. OEHHA is still in the process of adopting new health values. Therefore, new health values will periodically be added to, or deleted from, this table. Users of this table are advised to monitor the OEHHA website (*www.oehha.ca.gov*) for any updates to the health values.

May 2008 update: The Air Resources Board adopted amendments to the AB 2588 Air Toxics "Hot Spots" Emission Inventory Criteria and Guidelines Regulation (Title 17, California Code of Regulations, Section 93300.5) on November 16, 2006. The amendments became effective on September 26, 2007, after approval from the Office of Administrative Law. Under the new amendments, the substances previously listed in Appendix A-I *(Substances For Which Emissions Must Be Quantified*) and Appendix F (*Criteria For Inputs For Risk Assessment Using Screening Air Dispersion Modeling*) of the ARB's *Air Toxics "Hot Spots" Emission Inventory Criteria and Guidelines (EICG) (July 1997)* have been removed from this table.

a The checkmarks included in this table clarify applicability of OEHHA adopted health effects values to individual or grouped substances listed in the *Air Toxics "Hot Spots" Emission Inventory Criteria and Guidelines*, Appendix A-I list of *"Substances For Which Emissions Must Be Quantified"*.

b Chemical Abstract Service Number (CAS): For chemical groupings and mixtures where a CAS number is not applicable, the 4-digit code used in the *Air Toxics "Hot Spots" Emission Inventory Criteria and Guidelines (EICG) Report* is listed. The 4-digit codes enclosed in brackets [ ] are codes that have been phased out, but may still appear on previously reported Hot Spots emissions. For information on the origin and use of the 4-digit code, see the EICG report.

c Date Value Reviewed [Added]: This column lists the date that the health value was last reviewed by OEHHA and the Scientific Review Panel, and/or approved for use in the AB 2588 Air Toxics Hot Spots Program. If the health value is unchanged since it was first approved for use in the "Hot Spots" Program, then the date that the value was first approved for use by CAPCOA is listed within the brackets [ ].

- February 2000, April 2000, January 2001, and December 2001 are listed for the first set of 22, the second set of 16, the third set of 22, and the fourth set of 12 noncancer chronic RELs, respectively. The chronic REL for carbon disulfide was adopted in May 2002. Chronic RELs for phosphine and triethylamine were adopted in September 2002. Chronic RELs for fluorides including hydrogen fluoride were adopted August 2003. Chronic REL for silica [crystalline respirable] was adopted February 2005.
- October 2000 is listed for the oral chronic RELs.
- For the substances identified as Toxic Air Contaminants, the Air Resources Board hearing date is listed. The date for acetaldehyde represents the date the value was approved by the Scientific Review Panel.
- On December 19, 2008, OEHHA adopted new chronic RELs for acetaldehyde, acrolein, arsenic, formaldehyde, manganese, and mercury. The most current health values can be found at: http://www.oehha.ca.gov/air/allrels.html.

  Note: 1. We present the new oral RELs only in milligrams (mg/kg-d), although OEHHA has presented oral RELs in other tables in either micrograms (μg/kg-d) or mg/kg-d .

  2. At OEHHA's direction, the chronic oral REL for arsenic does not apply to arsine, because arsine is a gas and not particle associated.
- January 2011 is listed to reflect OEHHA's adoption of the World Health Organization's 2005 Toxicity Equivalency Factors for polychlorinated dibenzo-p-dioxins (PCDDs), dibenzofurans (PCDFs), and dioxin-like polychlorinated biphenyls (PCBs). See Appendix C of OEHHA's *Air Toxics Hot Spots Program Technical Support Document for Cancer Potencies* at: http://www.oehha.ca.gov/air/hot_spots/pdf/AppCdioxinTEFs013111.pdf for more information.
- On March 23, 2012, OEHHA adopted revised acute, 8-hour and chronic RELs for nickel and nickel compounds, a separate chronic inhalation REL for nickel oxide, and a revised chronic oral REL for nickel and nickel compounds (including nickel oxide). The values of the RELs are listed in the table at: http://www.oehha.ca.gov/air/chronic_rels/032312CREL.html.
- On July 29, 2013, OEHHA adopted an acute and an 8-hour REL and a revised chronic REL for 1,3-butadiene. The REL value and summary can be found online at: http://www.oehha.ca.gov/air/hot_spots/index.html.
- On October 18, 2013 (February 2014 table update), OEHHA adopted acute, 8-hour, and chronic RELs for caprolactam. The REL values and summary can be found at: http://www.oehha.ca.gov/air/chronic_rels/pdf/Caprolactam2013.pdf. Changes have been made to target organs to the following substances with no change to health factors: Diethanolamine, Fluorides and Hydrogen Fluoride, and Xylenes. The "date added" in this table reflects the date of the health factor only. See footnotes below that discuss changes to substance target organs only.
- On June 27, 2014, OEHHA adopted a new 8-hour REL and revised acute and chronic RELs for benzene. The REL values and summary can be found at: http://www.oehha.ca.gov/air/chronic_rels/BenzeneJune2014.html.

Table 4: OEHHA/ARB APPROVED CHRONIC REFERENCE EXPOSURE LEVELS AND TARGET ORGANS[a]

d	February 2014. Per OEHHA's current policy, substances with Reproductive System and/or Development as the hazard Index target organ(s) are represented under the single endpoint "Reproductive/Development".
TAC	Toxic Air Contaminant: The Air Resources Board has identified this substance as a Toxic Air Contaminant.
e	Particulate Emissions from Diesel-Fueled Engines: The inhalation cancer potency factor was derived from whole diesel exhaust and should be used only for impacts from the inhalation pathway (based on diesel PM measurements). The inhalation impacts from speciated emissions from diesel-fueled engines are already accounted for in the inhalation cancer potency factor and REL. However, at the discretion of the risk assessor, speciated emissions from diesel-fueled engines may be used to estimate acute noncancer health impacts or the contribution to cancer risk or chronic noncancer health impacts for the non-inhalation exposure pathway. The noncancer chronic REL for diesel exhaust is based on assumptions of contributions of diesel PM to ambient PM. It should be used with diesel PM measurement. There is not an oral chronic REL for diesel exhaust. See Appendix D of OEHHA's document *The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments* for more information.
f	Polychlorinated Dibenzo-p-dioxins and Polychlorinated Dibenzofurans (also referred to as chlorinated dioxins and dibenzofurans) and dioxin-like PCB congeners: The OEHHA has adopted the World Health Organization 2005 (WHO-05) Toxicity Equivalency Factor scheme for evaluating the risk due to exposure to samples containing mixtures of polychlorinated dibenzo-p-dioxins (PCDD) and polychlorinated dibenzofurans (PCDF) and a number of dioxin-like PCB congeners. See Appendix A of OEHHA's Technical Support Document For Describing Available Cancer Potency Factors for more information about the scheme. See Appendix E of OEHHA's 2014 The Air Toxics Hot Spots Program Guidance Manual for Preparation of Health Risk Assessments for the methodology for calculating 2,3,7,8-equivalents, cancer risk, and noncancer Hazard Index for PCDD, PCDFs and a number of dioxin-like PCB .
g	Polychlorinated Biphenyls (unspeciated): As of February, 2014, there is no approved method that can be used to assess the noncancer hazard of an unspeciated PCB mixture. Persons preparing HRAs for the Hot Spots Program should consult with OEHHA and the local Air Pollution Control or Air Quality Management District if an assessment of the noncancer hazard for unspeciated PCB mixtures is needed.
h	SELENIUM AND COMPOUNDS: In February 2014, an oral REL was added to the consolidated table. The REL was adopted in Dec 2001, but could not be used by the Hot Spots Program (or HARP software) until transfer factors for the oral and dermal routes were adopted. Transfer factors are included in the OEHHA's Technical Support Document for Exposure Assessment and Stochastic Analysis (August 2012) and will be added to the HARP software in the future.

Other Changes:

February 2014 corrections based on original REL summaries:

- Removed applicability of oleum to the sulfuric acid chronic inhalation REL because oleum represents only an acute health hazard.
- Diethanolamine – deleted cardiovascular and nervous system as target organs, and added hematologic and respiratory systems as target organs.
- Fluorides and Hydrogen Fluoride – target organ for these substances was reconfigured so that "Bone and Teeth" are a combined target organ.
- Xylenes (mixed isomers) – added eye as a target organ.
- Removed "METHYL MERCURY …(see Mercury & Compounds)" entry because methyl mercury has different chemical properties, potency, and toxicity compared to elemental mercury and mercury salts, and it is not emitted directly from any California facilities.

Table 4: OEHHA/ARB APPROVED CHRONIC REFERENCE EXPOSURE LEVELS AND TARGET ORGANS[a]

Appendix M:

How to Post-Process Offsite Worker Concentrations using the Hourly Raw Results from AERMOD

This appendix describes how to calculate refined offsite worker concentrations using the hourly raw results from the AERMOD air dispersion model. In some cases, a better representation of what the offsite worker breathes during their work shift is needed for the health risk analysis. To obtain a better representation, the hourly raw results contain enough information to allow the risk assessor to evaluate the concentrations that occurs during the offsite worker's shift. However, since the hourly raw results include all the concentrations for every hour of meteorological data at each receptor for each source in the air dispersion analysis, the results must be filtered and processed to obtain the refined offsite worker concentrations. The basic steps include: 1) determining the averaging periods needed for the offsite worker analysis; 2) outputting the hourly raw results from the AERMOD air dispersion model; 3) extracting the hourly concentrations based on when the receptor is present; and 4) identifying or calculating the required concentration. The calculation methods described in this appendix can be used for assessing acute, 8-hour non-cancer chronic, and inhalation cancer health impacts.

M.1 Determine the Averaging Periods Required for the Offsite Worker Health Risk Analysis

Before any refined offsite worker concentrations can be calculated, the first step is to determine which type of refined concentrations or averaging periods are needed for the health risk analysis. The refined averaging periods needed for the analysis are based on the pollutant-specific health values emitted by the source or sources. Specifically, refined offsite worker concentrations can only be used for pollutants that have inhalation cancer potency factors, 8-hour RELs, and/or acute RELs. This section describes the refined averaging periods required for assessing acute RELs, 8-hour RELs, and inhalation cancer potency factors.

M.1.1 Averaging Period Required for Acute RELs

The maximum 1-hour concentration is typically required for the acute health hazard index calculation. AERMOD can determine and output the maximum 1-hour concentration at each receptor location for each source in the air dispersion analysis. However, if more refined concentrations for the offsite worker are needed, the maximum1-hour concentration that occurs during the offsite worker's shift may be used.

This type of refinement can be processed using the hourly raw results from the air dispersion analysis.

If there are multiple sources in the analysis, an additional refinement step is to examine the coincident acute health impacts at each receptor from all sources at each hour during the offsite worker's shift and identify the total maximum acute health impacts from all sources. For example, if there are two sources that emit a single pollutant for ten hours per day and the offsite worker's shift is from hour three to hour seven, the risk assessor may evaluate the total acute risk from all sources during the offsite worker's shift. Assuming the acute REL is 50 $\mu g/m^3$, the highest acute health impact occurs at hour three with a Health Hazard Index of 0.3 (see Table M.1). This approach is also known as a refined acute analysis.

TABLE M.1. EXAMPLE OF A REFINED ACUTE CALCULATION

Hour	***1***	***2***	***3***	***4***	***5***	***6***	***7***	***8***	***9***	***10***
Source 1 Concentration ($\mu g/m^3$)	5	7	8	0	9	11	5	1	12	3
Source 2 Concentration($\mu g/m^3$)	4	6	7	0	2	1	3	4	5	2
Total Acute Health Hazard Index from All Sources	0.18	0.26	**0.3**	0	0.22	0.24	0.16	0.1	0.34	0.1

M.1.2 Averaging Period Required for Inhalation Cancer Potency Values

The period average is typically required for cancer risk assessments. AERMOD calculates this average by summing all the hourly concentrations and dividing it by the number of processed hours over the entire time period of the air dispersion analysis. However, the period averages calculated from AERMOD typically represent exposures for receptors (i.e., residential receptors) that are present 24 hours a day and seven days per week. For the offsite worker, the period average should represent what the worker breathes during their work shift when assessing the cancer inhalation pathway.

To estimate the offsite worker's concentration, there are two approaches. The simple approach is to obtain the period average concentration as calculated by AERMOD and approximate the worker's inhalation exposure using an adjustment factor (See Chapter 4.12.2. for more information). For a more representative concentration, the second approach is to calculate a refined period average using the hourly raw results from the air dispersion analysis. This refined period average should reflect only the concentrations that occur during the offsite worker's shift. It is calculated by summing all of the hourly concentrations that occurs during the offsite worker's shift and dividing it by the number of hours that occurs during the offsite worker's shift. The equation for calculating the refined offsite worker concentration is shown in Section 4.3.

M.1.3 Averaging Period Required for 8-Hour RELs

For 8-hour noncancer health impacts, we evaluate if the worker is exposed to a daily (e.g., 8-hour) average concentration that exceeds the 8-hour REL. The daily average concentration is intended to represent the long term average concentration the worker is breathing during their work shift. The long-term 8-hour daily average concentration is required for 8-hour health hazard index calculations. Specifically, this concentration represents the long-term average of repeated 8-hour daily averages that occur when the source's emission schedule and offsite worker's schedule overlap. For example, the 8-hour averages are first calculated for each day in the air dispersion analysis. The 8-hour averages should represent the eight hour sequential concentration for when the source's emission schedule and offsite worker's schedule overlap. All the 8-hour averages are then averaged over the entire time period of the air dispersion analysis.

There are two approaches for calculating the average 8-hour daily concentration. The simple approach is to obtain the long-term concentration (i.e., period average) as calculated by AERMOD and approximate the average 8-hour daily concentration using an adjustment factor. For a more representative concentration, the second approach is to calculate the offsite worker concentration using the hourly raw results from the air dispersion analysis.

Please note that although the duration of work shifts or period of overlap with the source's emission schedule can vary from eight hours, the calculated long-term daily average concentrations can still be applied to the 8-hour RELs. However, the risk assessor may wish to calculate the 8-hour hazard index using the adjustment factor approach as a screening assessment before proceeding with the post-processing approach. Based on the results of the screening assessment, the risk assessor can contact OEHHA for assistance in determining whether further evaluation may be necessary.

M.2 Output the Hourly Raw Results from AERMOD

The hourly raw results from the air dispersion analysis are needed to calculate the refined offsite worker concentrations as described above. AERMOD can output the hourly raw results to a file for post-processing. In order to output a file suitable for post-processing, the AERMOD input file must be modified. The AERMOD input file contains the modeling options, source location and parameter data, receptor locations, meteorological data file specifications, and output options. It is organized into five main sections that include the Control (CO), Source (SO), Receptor (RE), Meteorology (ME), and Output (OU) pathways (U.S. EPA, 2004). This section describes how to modify the pathways in the AERMOD input file to allow the hourly raw results to be saved to a file.

M.2.1 Modify the Control (CO) Pathway to Identify Calm and Missing Hours

By default, AERMOD disregards calm and missing hours when calculating the long-term and short-term averages. When calculating the refined offsite worker concentrations, the calm and missing hours must also be disregarded. However, the hourly raw results from AERMOD do not identify which hours are calm or missing. Since this is the case, an additional file from AERMOD must also be saved in order to post-process the hourly raw results correctly. The AERMOD Detailed Error Listing File will report all calm and missing hours from the air dispersion analysis. The syntax for creating a Detailed Error Listing File in the CO pathway is shown below. This modification in the CO pathway will create a file which will be used to assist with calculating the refined offsite worker concentrations. This process is described in the subsequent sections of this appendix.

Syntax for Creating the Detailed Error Listing File

CO ERRORFIL [Filename]

M.2.2 Modify the Source (SO) Pathway if Unit Emission Rates are used

In an air dispersion analysis, it is typical to use non-substance specific unit emission rates (e.g., 1 g/s) for evaluating multiple pollutants. This precludes modelers from having to run the air dispersion model for each individual pollutant that is emitted from a source. Unit emission rates allow the air dispersion modeling results to be expressed as dilution factors in $(\mu g/m^3)/(g/s)$. When these dilution factors are combined with the pollutant specific emission rate (g/s), it will yield the ground level concentrations ($\mu g/m^3$) for each pollutant in the analysis. When there are multiple sources in the air dispersion analysis and unit emission rates are used, the individual source contributions must be provided in the modeling results so the ground level concentrations can be correctly scaled for each pollutant. To do this, the air dispersion input file must be modified to create individual source groups for each source. The example below shows how individual source groups for two sources (S001 and S002) are specified in the SO pathway of an AERMOD input file. This modification in the SO pathway will allow the individual source contributions to be saved in the hourly raw results.

```
SO STARTING

**S001 and S002 location and source parameters are not shown.**

SRCGROUP SRCGP1 S001

SRCGROUP SRCGP2 S002

SO FINSHED
```

This parameter identifies the sources tied to the source group. Use only one source ID per source group.

This section specifies the name of your source group. The source group name is what is specified when you output the required concentrations files.

Please note that a separate input file is needed for evaluating acute health impacts when unit emission rates are used and the source has a variable emission schedule (e.g., emissions vary by hour-of-day and day-of-week). Acute health impacts are based on maximum hourly emissions whereas cancer and chronic health impacts are based on average hourly emissions. To correctly simulate unit emissions for the acute impacts, a duplicate source with a variable emission rate of "on" (1) or "off" (0) should be used so the maximum hourly inventory is correctly calculated separately from the emission factors placed in the annual file. The example below shows how the variable emission rates should be modified. Alternatively, a source can be duplicated in the same input file instead of rerunning the source using a separate input file.

First Run with Unmodified Emission Rate Factors for Long-Term

```
EMISFACT S002  HROFDY   0.000   0.000   0.000   0.000   0.000
         S002  HROFDY   0.000   2.667   2.667   2.667   2.667
         S002  HROFDY   2.667   2.667   1.333   1.333   1.333
         S002  HROFDY   1.333   1.333   1.333   0.000   0.000
         S002  HROFDY   0.000   0.000   0.000   0.000
```

Second Run with Modified Emission Rates Factors for Acute

```
EMISFACT S002  HROFDY   0.000   0.000   0.000   0.000   0.000
         S002  HROFDY   0.000   1.000   1.000   1.000   1.000
         S002  HROFDY   1.000   1.000   1.000   1.000   1.000
         S002  HROFDY   1.000   1.000   1.000   0.000   0.000
         S002  HROFDY   0.000   0.000   0.000   0.000
```

M.2.3 Modify the Receptor (RE) Pathway to Reduce the Processing Time

AERMOD is capable of outputting the hourly raw results from the air dispersion analysis. However, without taking appropriate precautions, outputting the hourly raw results can produce extremely large file sizes especially when evaluating multiple years of meteorological data, a large number of receptors, and short-term averaging periods (e.g., 1-hour). To minimize the amount of processing time and hard disk space, it is recommended to use only a single discrete receptor representing the off-site worker location. The proper syntax for specifying a discrete receptor is shown below.

Sample Syntax for Creating a Single Discrete Receptor

```
RE DISCCART XcoordYcoord (ZelevZhill) (Zflag)
```

M.2.4 Modify the Output (OU) Pathway to Output the Hourly Raw Results

To create a file containing the hourly raw results, modify the OU pathway to include the POSTFILE keyword and parameters. The sample below shows the syntax for outputting the hourly raw results for a single source. The POSTFILE will list in order the concentration for each receptor and for each hour of meteorological data regardless of the source's emission schedule. Use Table M.2 to help construct the proper syntax for the POSTFILE option. This step must be repeated for each source in the analysis which will result in additional files.

Please note that if the data are outputted as binary file (UNFORM), a separate computer program will be needed to read and parse the data.

Sample Syntax for Outputting the

Hourly Concentrations for a Single Source

```
OU POSTFILE 1 SRCGP1PLOT PSTS001.TXT
```

TABLE M.2. DESCRIPTIONS OF THE POSTFILE PARAMETERS

Keyword	**Parameters**	
POSTFILE	AveperGrpid Format Filnam (Funit)	
where:	Aveper	Specifies averaging period to be output to file. Set this value to 1 to output 1-hour raw results.
	Grpid	Specifies source group to be output to file. If there are multiple sources, you will need to repeat the POSTFILE option for each source. You can combine the different outputs to a single file using the Funit parameter.
	Format	Specifies format of file, either UNFORM for binary files or PLOT for formatted files. Unformatted files offer a smaller file size; however, this file requires programming expertise in order to view and parse the data. Selecting the PLOT option will allow you to view the file in any text editor.
	Filnam	Specifies filename for output file
	Funit (optional)	The file unit is an optional parameter. If the filename and the file unit number are the same, the results for different source groups can be combined into a single file.

M.3 Extract the Hourly Concentrations when the Offsite Worker is Present

To calculate the refined offsite worker concentrations, it is necessary to extract the hourly concentrations based on the offsite worker's schedule. This section provides information on how to extract the hourly concentrations for the offsite worker including the calm and missing hours that may occur during the offsite worker's shift.

At this point, it is recommended the hourly raw results be imported into a spreadsheet or database to assist with the extraction process. Spreadsheets and database contain preprogrammed functions to assist with deciphering data. **Use the information in Section M.3.1 as a guide to help import the hourly raw results into a database or spreadsheet.**

M.3.1 Description of the POSTFILE File Format

AERMOD was created using FORTRAN, a type of programming language. When the AERMOD output files are created, it is based on a specified FORTRAN format. The variables provided on each data record in the POSTFILE include the X and Y coordinates of the receptor location, the concentration value for that location, receptor terrain elevation, hill height scale, flagpole receptor height, the averaging period, the source group ID, and the date for the end of the averaging period (in the form of YYMMDDHH) (U.S. EPA, 2004). Table M.3 shows the equivalent data types based on the POSTFILE format. The POSTFILE will list in order the concentration for each receptor and for each hour of meteorological data regardless of the source's emission schedule (see Figure M.3.1). Use the information in this section as a guide to help import the hourly raw results into a database or spreadsheet.

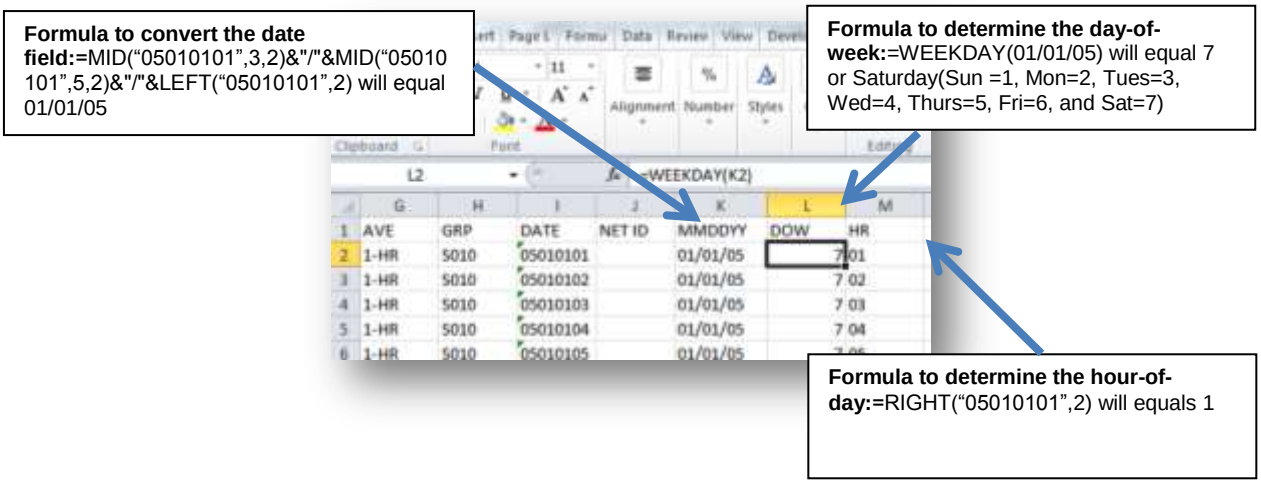
100.00000	0.00000	0.00000	10.00	10.00	1.20	1-HR	S010	05010117	

M.3.2 Determine the Day-of-Week and Hour-of-Day

In order to extract only the hourly concentrations that occur when an offsite worker is present, the risk assessor must first determine the day-of-week and hour-of-day for each hourly record using the date field. Since the date outputted by AERMOD cannot be directly interpreted by the day-of-week function in a database or spreadsheet, the date must be first converted. For example, the date field can be first converted using the LEFT and MID functions in Microsoft Excel (See Column K in Figure M.3.2). After which, the WEEKDAY function in Microsoft Excel can be used to determine the day-of-week (See Column L in Figure M.3.2). The hour-of-day can be extracted using the RIGHT function (See Column M in Figure M.3.2).

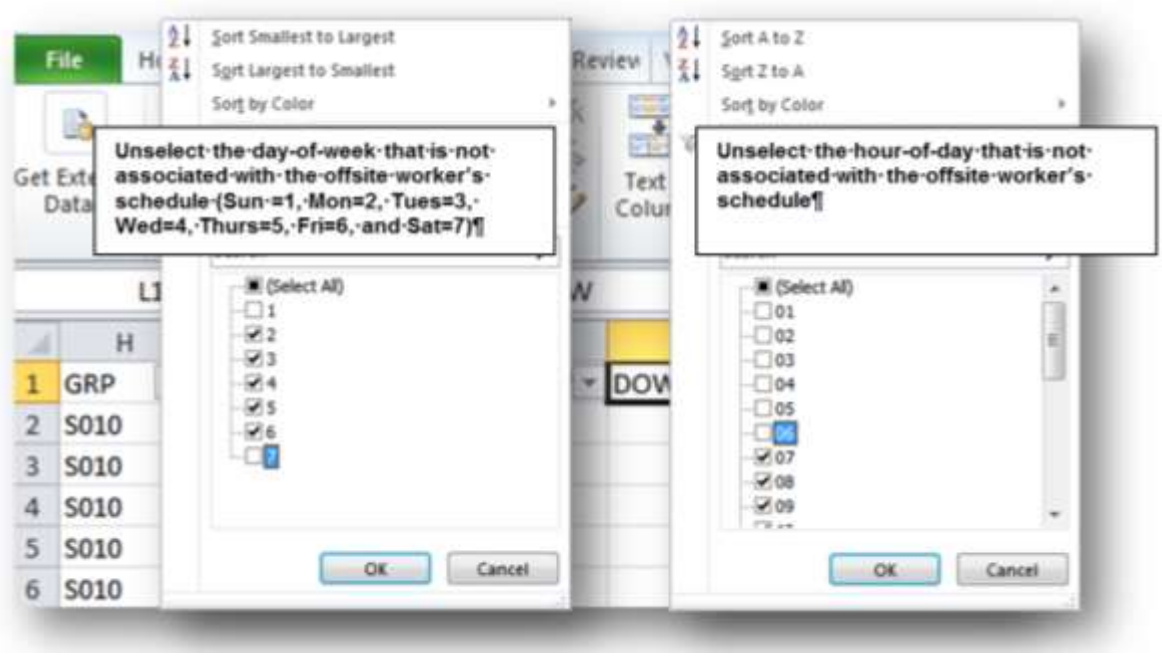
FIGURE M.3.2. HOW TO DETERMINE THE DAY-OF-WEEK AND HOUR-OF-DAY IN MICROSOFT EXCEL



M.3.3 Extract the Hourly Concentrations Based on the Offsite Worker's Schedule

After the day-of-week and hour-of-day have been determined, the concentrations can now be extracted or filtered. Based on the offsite worker's schedule, filter or query the hourly concentrations using a spreadsheet or database. For example, in Microsoft Excel, you can filter the data by selecting the data filter option (see Figure M.3.3). Then unselect the records that are not associated with the offsite worker's schedule using the day-of-week and hour-of-day fields that were created in previous section. If the data contains information for multiple receptors, filter the X and Y coordinates to get the concentrations that are specific to each receptor. The results from the filter will now only show hourly concentrations for times when the offsite worker is present.

FIGURE M.3.3. HOW TO FILTER THE DATA IN MICROSOFT EXCEL



M.3.4 Count the Number of Calm and Missing Hours that Occur During the Offsite Worker's Schedule

If calm hour processing was used in the air dispersion analysis, then calm and missing hours must also be considered when post-processing the long-term and short-term averages for the offsite worker. To assist in this calculation, the Detailed Error Listing File that was created from the air dispersion analysis (Section 2.1) can be used to count the number of calm and missing hours that occurred during the worker's shift.

To identify the calm and missing hours, it is recommended to import the Detailed Error Listing File into a spreadsheet or database. Then follow the instructions from Sections 3.2 and 3.3 to determine the number of calm and missing hours that occur during the offsite worker's schedule. This information is needed to calculate the averaging periods for the offsite worker.

M.4 How to Identify or Calculate the Refined Concentrations for the Offsite Worker Analysis

Depending on which averaging periods are needed (as determined by Section 1.0), use Sections 4.1 through 4.3 below to identify or calculate refined concentrations for estimating the acute, 8-hour, and cancer health impacts. The equations are based on how the long-term and short-term averages are calculated in AERMOD. These equations also account for how calm and missing hours are handled by AERMOD (U.S. EPA, 2005). After calculating the appropriate averaging periods, the refined concentrations can be used to assess the health impacts for the offsite worker's inhalation pathway.

Please note that if unit emission rates were used in the air dispersion analysis, each averaging period calculated using the methods below must be combined with the pollutant specific emission rate (g/s) to yield the actual ground level concentrations (µg/m^3) for each pollutant in the analysis before the health impacts can be assessed.

M.4.1 How to Determine the Maximum 1-Hour Average for a Simple Acute Assessment

The maximum 1-hour average concentration represents the highest concentration that occurs during the offsite worker's schedule. To determine the maximum 1-hour average, sort the extracted hourly concentrations in descending order using a spreadsheet or a database. The maximum hourly concentration will be at the top of the list (Figure M.4.1). This process must be repeated at each receptor for all sources of interest.

FIGURE M.4.1. IDENTIFYING THE MAXIMUM 1-HOUR CONCENTRATION

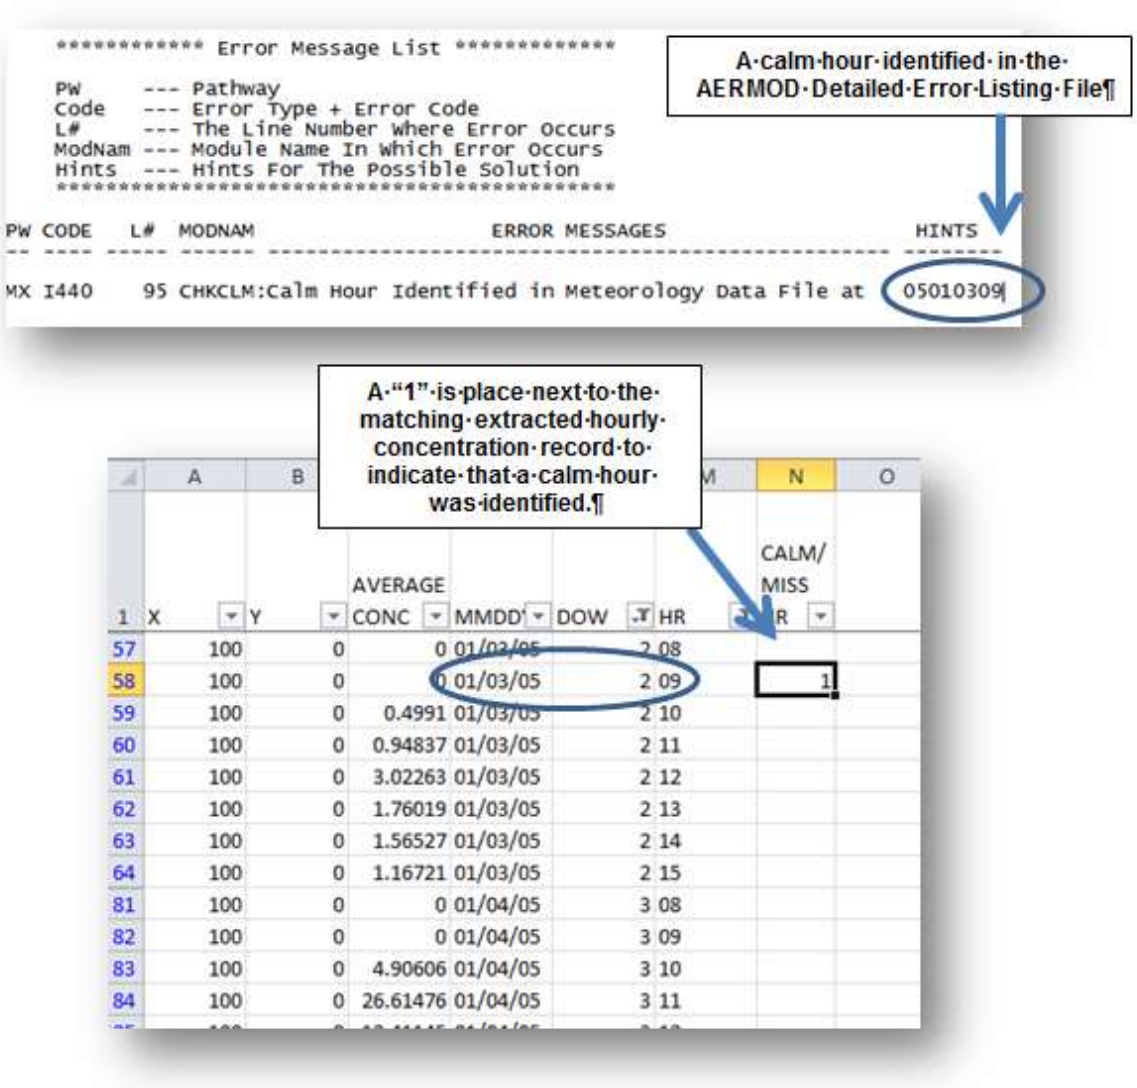
M.4.2 How to Determine the Long-Term Average of 8-Hour Daily Concentrations for an 8-Hour Assessment

To calculate the long-term 8-hour daily average concentration, the 8-hour averages are first calculated for each day in the air dispersion analysis. All the 8-hour averages are then averaged over the entire time period of the air dispersion analysis. However, since the 8-hour daily average is considered a short-term average, the total number of valid hours (i.e., not calm or not missing) must be considered. The total number of valid hours should be 75% of the 8-hour average. If the total number of valid hours in an 8-hour average is less than six (6), the 8-hour total concentration should be divided by six (6) (U.S. EPA, 2005). The following steps below are an example that shows how the average of 8-hour daily concentration is calculated.

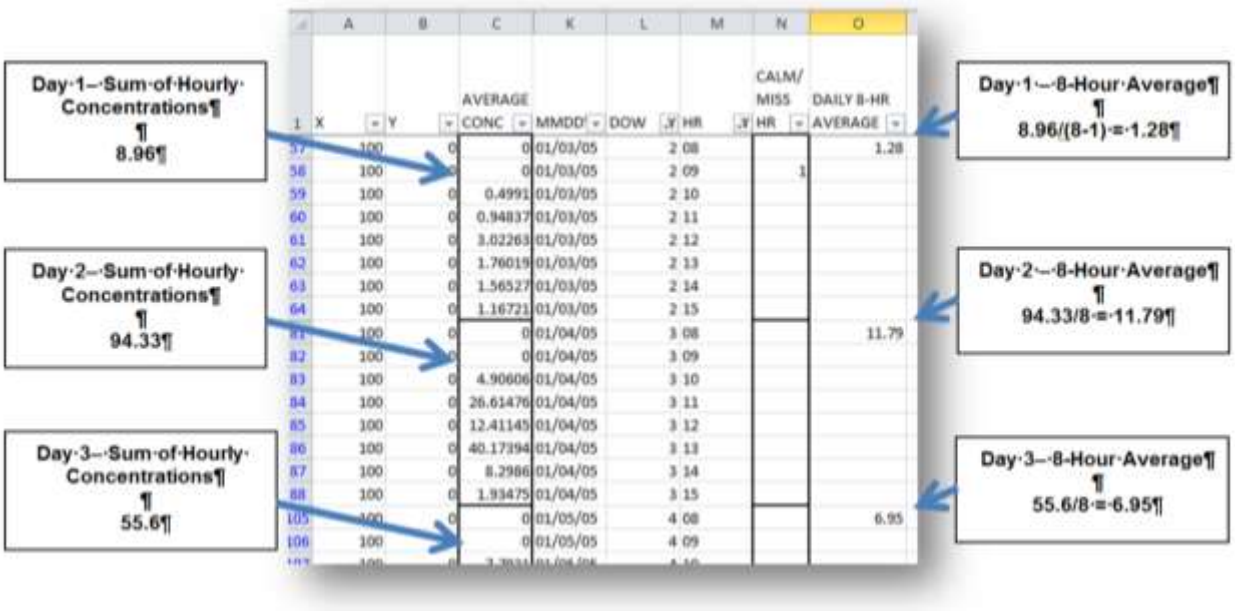
- Using the extracted hourly concentrations based on the steps from Section 3.0, identify any calm and missing hours with a "1". To do this, use the Detailed Error Listing File that was created from the air dispersion analysis (See Section 2.1 for more information).The Detailed Error Listing File will list the calm and missing hours by date. Place a "1" where the dates match up with the extracted hourly concentrations (See Column N in Figure M.4.2.1). Please note that some of the columns are hidden in Figure M.4.2.1 for presentation purposes.

FIGURE M.4.2.1. IDENTIFY CALM AND MISSING HOURS



- Then calculate the 8-hour average for each day throughout the file. The 8-hour average is the sum of the hourly concentrations in a day divided by eight (see Figure M.4.2.2). However, if there are any calm or missing hours in the time period, the sum of hourly concentrations should be divided by total number of valid hours. The total number of valid hours is eight minus the total number of calm and missing hours. If the total number of valid hours is less than six, then the sum of hourly concentrations should be divided by six.

FIGURE M.4.2.2. 8-HOUR DAILY AVERAGE CALCULATION



- Assuming that there were only three days in the entire time period of the air dispersion analysis, the average of 8-hour daily concentrations is (1.28 11.79 + 6.95) /3 = 6.78.

M.4.3 Equation for Calculating the Average Concentration for the Inhalation Cancer Pathway

Below is the equation for calculating the period average for the inhalation cancer pathway. This calculation must be repeated at each receptor for each source of interest.

$$C_{worker\_period\_average} = \frac{\sum C_{hourly}}{N_{total\_hrs} - N_{calm\_hrs} - N_{missing\_hrs}}$$

Where:

C_{hourly} = the concentration that occurs during the worker's shift. To obtain the sum of the hourly concentrations for the offsite worker, sum the extracted worker concentrations from Section 3.0.

N_{total_hrs} = the number of processed hours that occur during worker's shift. To obtain the number of processed hours, use the COUNT function to return the total number of extracted worker concentrations from Section 3.0.

N_{calm_hrs} = the number of calm hours that occur during the worker's shift. To obtain the number of calm and missing hours, use the COUNT function to return the total number of missing and calm hours from Section 3.0. Since the total will include missing hours, it is not necessary to repeat this step for the variable below.

$N_{missing\_hrs}$ = the number of missing hours that occur during worker's shift.

Appendix N:

Sensitivity Study of the Worker Adjustment Factor using AERMOD

N.1. Introduction

The offsite worker health risk analysis begins with estimating the pollutant concentration at a receptor location. To estimate this concentration, the typical approach is to use the residential annual concentration that is modeled based on the adjacent facility's emission schedule. However, if the facility emissions are non-continuous, the residential concentration may not represent what the worker breathes during their work shift. In lieu of conducting additional special case modeling which can be time-consuming, the residential annual concentration is adjusted upwards using a worker adjustment factor based on the facility's emission schedule with respect to the worker's schedule. For an 8-hour work shift that coincides with an adjacent facility that emits eight hours per day, a worker adjustment factor of 4.2 (24 hours / 8 hours * 7 days / 5 days) is typically used for cancer risk assessment.

A possible problem with using this approach is that wind direction, wind speed, and atmospheric stability can vary throughout the day and night and straight scaling as above may skew the results. If the diurnal variation is considerable, the 4.2 adjustment could be an under- or overestimate depending on the time of day that the offsite worker shift begins and ends. The goal of this study is to test the validity of the 4.2 adjustment using five meteorological data sets from five different locations in California and with three different size point sources. The modeling is performed with 8-hour emissions coinciding with the offsite workers' schedule. The 8-hour shifts are modeled as starting every hour around the clock.

To perform this study, the AERMOD air dispersion model, meteorological data from five locations (i.e., Kearny Mesa, Palomar, Pomona, Redlands, and San Bernardino), and three different size point sources (small, medium, and large) are used. The AERMOD-ready meteorological datasets are selected to represent a range of meteorological conditions around the state. To mirror the assumptions used in the 4.2 worker adjustment factor, the emission rate of each source is simulated for eight continuous hours with 24 different start times for five days a week (Monday through Friday). This will simulate the conditions that result during an 8-hour work schedule starting any hour of the day. In addition, the emitting source and offsite worker are assumed to have coincident schedules.

Using the AERMOD air dispersion modeling results, the Point of Maximum Impact (PMI) is identified and the hourly raw concentrations are post-processed to calculate the long-term offsite worker concentration for each scenario. To test the validity of the worker adjustment factor, the calculated long-term offsite worker concentration is divided by the long term residential average to obtain a quotient that is unique to each

meteorological data location. The quotient is then compared to the 4.2 worker adjustment factor to see which is higher or more health protective.

Although this study is primarily based on an 8-hour work schedule, the actual duration that an offsite worker is present near the emitting source may vary when considering a lunch break or a longer work shift. Thus, 10-hour scenarios are also evaluated. The worker adjustment factor for ten hours is 3.4 (24 hours / 10 hours * 7 days / 5 days).

N.2. Background on the Worker Adjustment Factor for Inhalation Cancer Assessments

There are basically two approaches that can be used to calculate the offsite worker inhalation exposure for cancer assessments. One approach is to post-process the hourly dispersion modeling results and examine the coincident hours between the source's emission schedule and the worker's schedule. The second, and more commonly used approach, is to apply a worker adjustment factor to the modeled long-term residential concentration. While post-processing the hourly modeling output will offer a more representative worker concentration, it is very time consuming and requires the management of large amounts of data. Thus, the simplistic approach of applying a worker adjustment factor to estimate the worker inhalation exposure is typically used.

The worker adjustment factor is used together with the long-term residential concentration to estimate the offsite worker's inhalation exposure. This calculation is summarized below.

a. Obtain the long-term concentrations from air dispersion modeling as is typical for residential receptors (all hours of a year or multi-year analysis are used).

b. Determine the coincident hours per day and days per week between the source's emission schedule and the offsite worker's schedule.

c. Calculate the worker adjustment factor using Equation N.1. When assessing inhalation cancer health impacts, a discount factor (*DF*) may also be applied if the offsite worker's schedule partially overlaps with the source's emission schedule. The discount factor is based on the number of coincident hours per day and days per week between the source's emission schedule and the offsite worker's schedule (see Equation N.2).

Please note that worker adjustment factor does not apply if the source's emission schedule and the offsite worker's schedule do not overlap. Since the worker is not around during the time that the source is emitting, the worker is not exposed to the source's emission (i.e., the DF in Equation N.2 becomes 0).

$$WAF = \frac{H_{residentid}}{H_{source}} \times \frac{D_{residentid}}{D_{source}} \times DF \qquad \textbf{Eq. N.1}$$

Where:

WAF = the worker adjustment factor

$H_{residential}$ = the number of hours per day the long-term residential concentration is based on (24)

H_{source} = the number of hours the source operates per day

$D_{residential}$ = the number of days per week the long-term residential concentration is based on (7).

D_{source} = the number of days the source operates per week.

DF = a discount factor for when the offsite worker's schedule partially overlaps the source's emission schedule. Use 1 if the offsite worker's schedule occurs within the source's emission schedule. If the offsite worker's schedule partially overlaps with the source's emission schedule, then calculate the discount factor using Equation N.2 below.

$$DF = \frac{H_{coincident}}{H_{worker}} \times \frac{D_{coincident}}{D_{worker}} \qquad \textbf{Eq. N.2}$$

Where:

DF = *the discount factor for assessing cancer impacts*

$H_{coincident}$ = *the number of hours per day the offsite worker's schedule and the source's emission schedule overlap*

$D_{coincident}$ = *the number of days per week the offsite worker's schedule and the source's emission schedule overlap.*

H_{worker} = *the number of hours the offsite worker works per day*

D_{worker} = *the number of days the offsite worker works per week.*

d. The final step is to estimate the offsite worker inhalation exposure by multiplying the worker adjustment factor with the long-term residential concentration.

N.3. Method and Modeling Parameters

For this study, all scenarios are simulated using the AERMOD (Version 09292) air dispersion model. The modeling parameters input to AERMOD and methods used to process the model outputs are discussed below.

N.3.1. Point Source Release Parameters

This study uses three different size point sources representing small, medium, and large. The point source release parameters are shown in Table N.1.

TABLE N.1. POINT SOURCE MODELING PARAMETERS

Source Size	Emission Rate (g/s)	Release Ht (m)	Diameter (m)	Exit Temp (K)	Exit Vel (m/s)	Building Dimensions L (m) x W (m) x H (m)	XBADJ YBADJ [1]
Large	1	30	3	400	10	15 x 15 x 6	7.5
Medium	1	10	1	400	10	12 x 12 x 6	6
Small	1	2.15	0.1	400	10	6 x 6 x 2	3

1 – The XBADJ and YBADJ are keywords defining the along-flow and across-flow distances from the stack to the center of the upwind face of the projected building, respectively (U.S. EPA, 2004).

N.3.2. Temporal Emission Rate

Each point source (i.e., small, medium, and large) is simulated with continuous emissions for eight hours a day from Monday through Friday. In addition, all starting hour combinations (24 scenarios) are evaluated by duplicating each source 24 times with unique start times. Table N.2 shows the 8-hour operating schedule for each scenario. All emissions for Saturday and Sunday are set at zero. This process will also be repeated for the 10-hour evaluation. Table N.3 shows the 10-hour operating schedule for each scenario.

N.3.3. Receptor Grid Parameters

A 1000 meter by 1000 meter receptor grid is centered over each source. The receptors are spaced in 50 meter increments resulting in 441 receptor points. All receptor flagpole heights are set at 1.2 meters above ground.

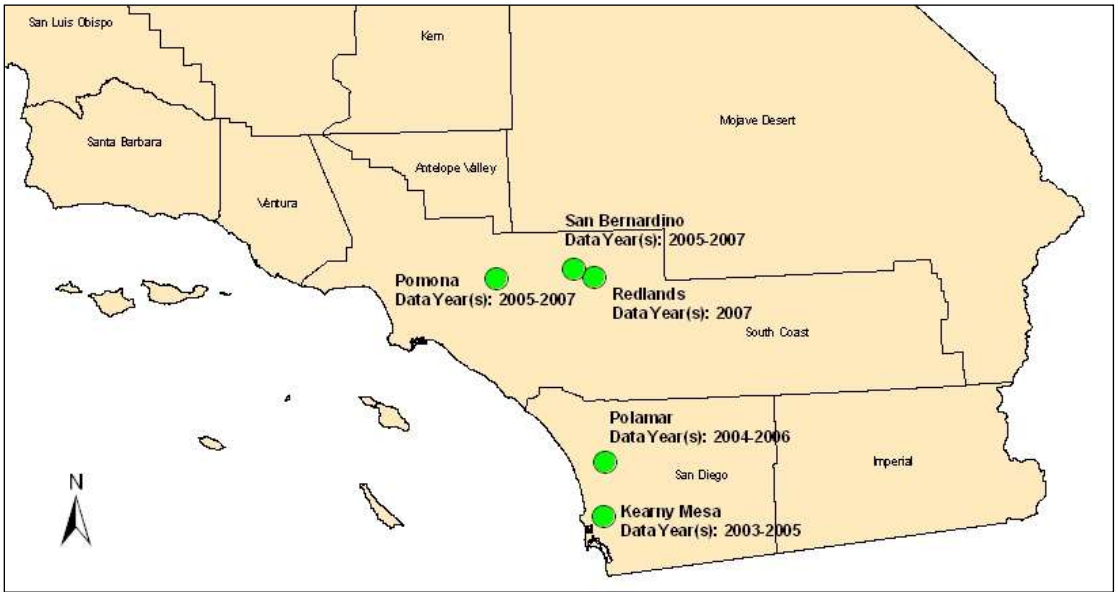
N.3.4. Meteorological Data

The meteorological data input to AERMOD were requested from two local air districts in California (ARB 2009a and ARB 2009b). The meteorological data that were provided by the Districts are, based on the Districts' observations and expertise, datasets that were likely to result in higher than average long-term impacts. The data includes four multi-year files and one single year file. Table N.4 shows the meteorological datasets used in this study. Figure N.1 shows the location of the meteorological station. The AERMOD profile base is defaulted to 10 meters above mean sea level for each meteorological file.

TABLE N.4. METEOROLOGICAL DATASETS

Data Provider	Area	Data Year(s)	Total Hours	Percent of Calm and Missing Hours	Avg. Wind Speed (m/s)
San Diego Air Pollution Control District	Kearny Mesa	2003-2005	26304	6.9	1.36
	Palomar	2004-2006	26304	8.7	1.36
South Coast Air Quality Management District	Pomona	2005-2007	26280	1.6	1.18
	Redlands	2007	8760	5.5	0.94
	San Bernardino	2005-2007	26280	4.9	1.44

FIGURE N.1. METEOROLOGICAL DATA SET LOCATIONS



N.3.5. Post-Processing the Period Average Concentrations for the Offsite Worker

The period average concentration represents the average concentration of all hours processed within the meteorological set. Equation N.3 shows how the period average is calculated in AERMOD including how calm and missing hours are processed (U.S. EPA, 2005).

$$C_{period\_average} = \frac{\sum C_{hourly}}{N_{total\_hrs} - N_{calm\_hrs} - N_{missing\_hrs}} \qquad \textbf{Eq. N.3}$$

Where:

C_{hourly} = the concentration that occurs at a given hour

N_{total_hrs} = the number of processed hours reported by AERMOD (e.g., 1 yr = 8760 hours)

N_{calm_hrs} = the number of calm hours reported by AERMOD

$N_{missing\_hrs}$ = the number of missing hours reported by AERMOD

Normally to post-process hourly data, the off-site worker hours are extracted from the hourly model output files and then averaged. However, this sensitivity study assumes the hourly emissions are coincident with the off-site worker schedule. Since this is the case, the 8-hour period average for the offsite worker can simply be scaled from the period average reported by AERMOD (see Equation N.4). To make sure this calculation is accurate, a check was performed by processing the hourly concentrations

for one receptor with the Pomona data. If the emission schedule was not 100% coincident with the offsite worker, then all post-processing would have to be completed on an hourly basis. See Appendix M for more information on how to post-process worker concentrations using hourly raw results.

$$C_{worker\_period\_average} = C_{period\_average} \times \frac{N_{total\_hrs} - N_{calm\_hrs} - N_{missing\_hrs}}{N_{worker\_hrs} - N_{worker\_calm\_hrs} - N_{worker\_missing\_hrs}} \quad \textbf{Eq. N.4}$$

Where:

$C_{period\_average}$ = the period concentration reported by AERMOD

N_{total_hrs} = the total number of processed hours reported by AERMOD

N_{calm_hrs} = the total number of calm hours reported by AERMOD

$N_{missing\_hrs}$ = the total number of missing hours reported by AERMOD

N_{worker_hrs}[a] = the total number of hours that occurred during the worker's shift

$N_{worker\_calm\_\_hrs}$[b] = the number of calm hours that occurs during the worker's shift

$N_{worker\_missing\_hrs}$[b] = the number of missing hours that occurred during the worker's shift

a. The worker hours are determined by multiplying the number of weekdays (Monday through Friday) that occurs in the meteorological data set by the work shift duration (8 hours). For example, a meteorological data set ranging from 1/1/2003 to 12/31/2005 contains 783 weekdays. If you multiply the number weekdays by the work shift duration (8 hour/day), this will equal 6264 worker hours. The number of weekdays varies depending on the day of the week January 1st starts on.

b. Calm and missing hours are reported in the AERMOD Detailed Message Listing File. To determine the number of worker calm and missing hours, the calm and missing hours that occur during the worker shift are isolated and summed.

N.4. Results

To test the validity of the worker adjustment factor, the post-processed period average concentration for the offsite worker was divided by the modeled period residential average to obtain a quotient. This calculation was performed at the PMI of each scenario. If the quotient is smaller or equal to the worker adjustment factor, the worker adjustment factor is considered a suitable health protective approximation. If the quotient is greater, the worker adjustment factor will underestimate the long-term average concentration and would not be the most conservative estimation of what the worker breathes. For these scenarios, the 8-hour and 10-hour worker adjustment factors are 4.2 and 3.4, respectively. The results for this study are summarized in the figures and tables below. To view the details for every scenario, see Appendix N-1.

Figure N.2 shows how the post-processed period averages changes over 8-hour rolling work shifts. The value at each 8-hour work shift represents the quotient average across the five meteorological data sets. Values that fall on or below the thick dashed line (i.e., the 4.2 worker adjustment factor) indicate that the worker adjustment factor would be a health protective value. Based on the five metrological data sets, the worker adjustment factor is health protective for work shifts that start approximately between 8 am and 3 pm (i.e., 8-hour work shifts starting at 8 am and ending by 11 pm).

FIGURE N.2. SUMMARY OF THE 8-HOUR SCENARIOS

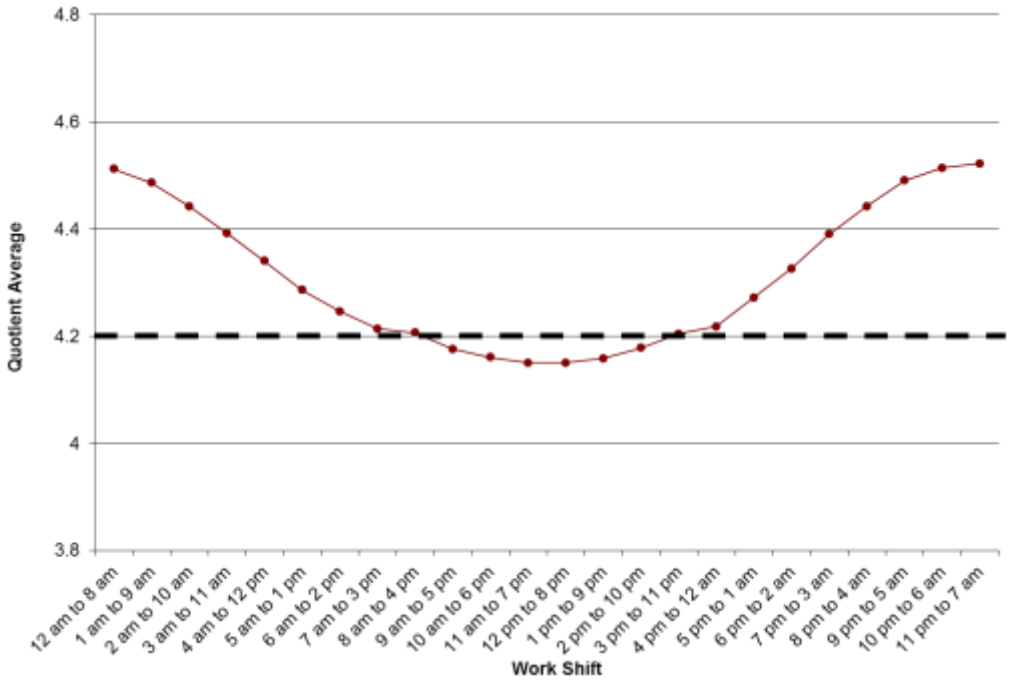


Figure N.3 shows relationship between the worker schedule and the percent of calm and missing hours that occurred during 8-hr work shifts. The figure shows the percent of calm and missing hours are higher during the early morning and evening hour start hours.

FIGURE N.3. AVERAGE PERCENT OF CALM AND MISSING HOURS FOR 8-HOUR WORK SHIFTS

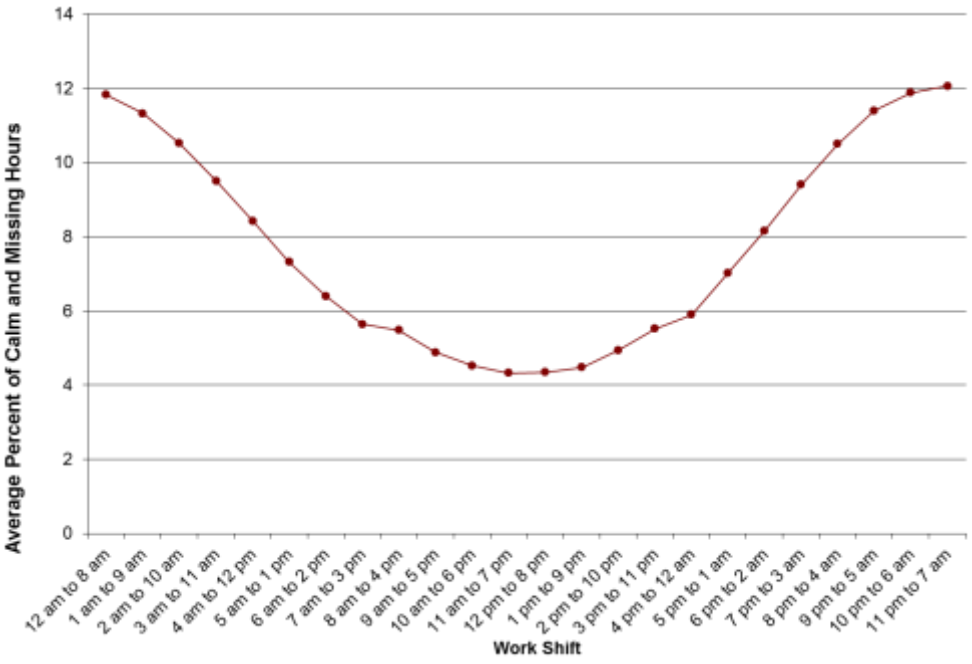

Figure N.4 shows how the post-processed period averages change over 10-hour rolling work shifts. The value at each 10-hour work shift represents the quotient average across the five meteorological data sets. Values that fall on or below the thick dashed line (i.e., the 3.4 worker adjustment factor) indicate that the worker adjustment factor would be a health protective value. Based on the five metrological data sets, the worker adjustment factor is health protective for work shifts that start approximately between 5 am and 4 pm (i.e., 10-hour work shifts starting at 5 am and ending by 2 am).

FIGURE N.4. SUMMARY OF THE 10-HOUR SCENARIOS

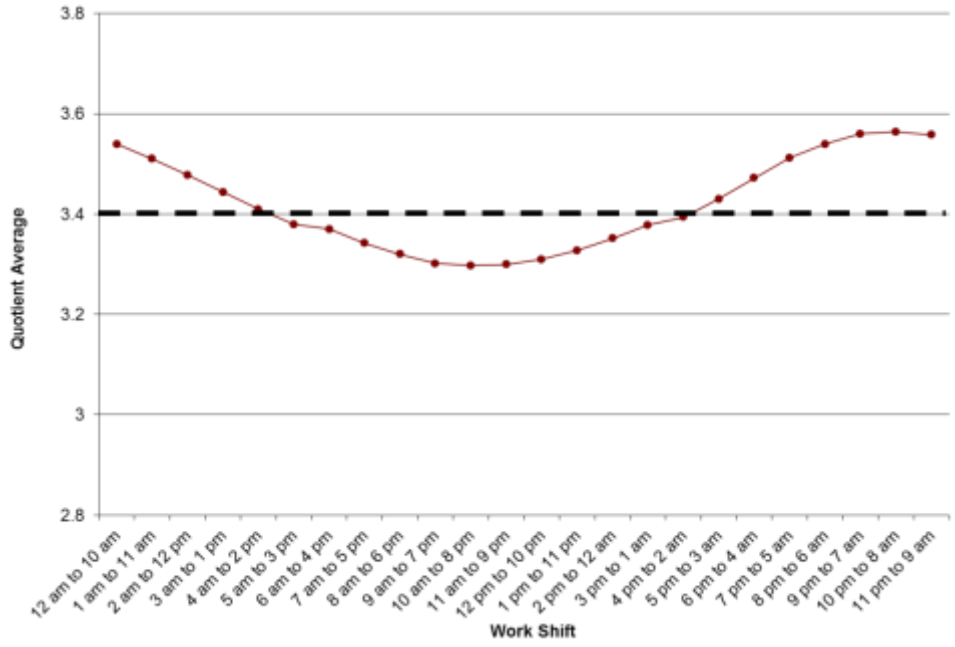

Figure N.5 shows relationship between the worker schedule and the percent of calm and missing hours that occurred during 10-hr work shifts. The figure shows the percent of calm and missing hours are higher during the early morning and evening hour start hours.

FIGURE N.5. AVERAGE PERCENT OF CALM AND MISSING HOURS FOR 10-HOUR WORK SHIFTS

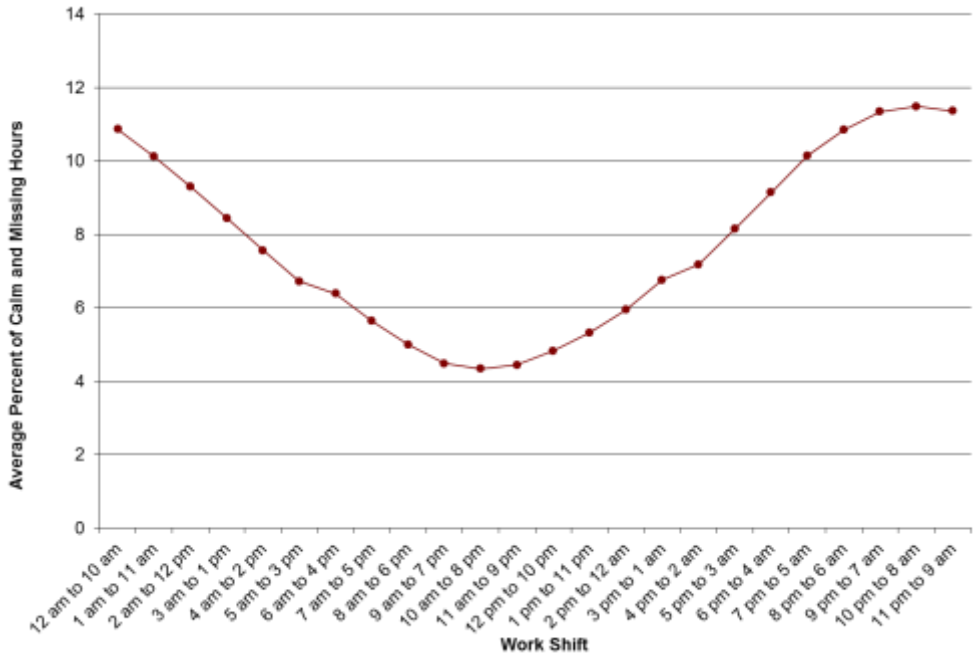

Table N.5 shows the average, minimum, and maximum quotients across all 24 8-hour work shifts for each point source size (i.e., small, medium, and large). The values in the parentheses are the range across the 24 work shifts for each meteorological data set.

TABLE N.5. SUMMARY OF THE AVERAGE 8-HOUR SCENARIOS BY POINT SOURCE SIZE

Meteorological Set	Point Source Size			% Calm/Missing Hours During the Worker's Shift
	Small	Medium	Large	
Kearny Mesa	4.33 (4.19 to 4.43)	4.33 (4.19 to 4.43)	4.33 (4.19 to 4.43)	9.6 (6.8 to 11.8)
Palomar	4.38 (4.18 to 4.65)	4.38 (4.18 to 4.65)	4.38 (4.18 to 4.65)	12.2 (8.2 to 17.5)
Pomona	4.24 (4.23 to 4.25)	4.24 (4.23 to 4.25)	4.24 (4.23 to 4.25)	2.3 (2.1 to 2.5)
Redlands	4.31 (4.00 to 4.75)	4.31 (4.00 to 4.75)	4.31 (4.00 to 4.75)	7.6 (1.0 to 16.5)
San Bernardino	4.31 (4.06 to 4.65)	4.31 (4.06 to 4.65)	4.31 (4.06 to 4.65)	6.9 (1.4 to 14.1)

Table N.6 shows the average, minimum, and maximum quotients across all 24 10-hour work shifts for each point source size (i.e., small, medium, and large). The values in the parentheses are the range across the 24 work shifts for each meteorological data set.

TABLE N.6. SUMMARY OF THE AVERAGE 10-HOUR SCENARIOS BY POINT SOURCE SIZE

Meteorological Set	Point Source Size			% Calm/Missing Hours During the Worker's Shift
	Small	Medium	Large	
Kearny Mesa	3.46 (3.38 to 3.54)	3.46 (3.38 to 3.54)	3.46 (3.38 to 3.54)	9.6 (7.5 to 11.6)
Palomar	3.50 (3.34 to 3.70)	3.50 (3.34 to 3.70)	3.50 (3.34 to 3.70)	12.2 (8.0 to 17.1)
Pomona	3.39 (3.38 to 3.39)	3.39 (3.38 to 3.39)	3.39 (3.38 to 3.39)	2.3 (2.2 to 2.5)
Redlands	3.45 (3.21 to 3.74)	3.45 (3.21 to 3.74)	3.45 (3.21 to 3.74)	7.6 (1.1 to 15.2)
San Bernardino	3.31 (3.12 to 3.54)	3.31 (3.12 to 3.54)	3.31 (3.12 to 3.54)	6.9 (1.5 to 13.1)

N.5. Conclusions

The goal of this study was to determine if the worker adjustment factor of 4.2 (8 hours/day, 5 days/week) or 3.4 (10 hours/day, 5 days/week) would always yield a more conservative or health protective approximation using five meteorological data sets. This study demonstrated that the worker adjustment factor does not always represent the most health protective approximation of long-term hourly model predictions. This is primarily observed during night conditions. Air Districts may wish to evaluate their meteorological data to determine an appropriate worker adjustment factor for their area using the methods described in this appendix.

Although the meteorological data used in this study are site-specific, several general conclusions and recommendations can be made. These conclusions and recommendations are summarized below.

- ***The worker adjustment factor is generally a suitable health protective approximation for daytime work shifts.***

  For the meteorological data used in this study, the results show that the worker adjustment factor is a suitable health protective approximation for work shifts that occur during the daytime hours. When comparing the 8-hour and 10-hour scenarios, the results show that the range of work shifts that were considered a more health protective approximation increased with the longer work shift duration.

- ***The size of the emitting source did not affect the long-term concentration approximated with the worker adjustment factor.***

  The size of the source was inconsequential in determining whether the worker adjustment factor is health protective. This is because the worker adjustment factor is applied to the modeling results after the air dispersion analysis has been completed. However, it should be noted that the size of the source does affect the location of the PMI during a specific time of day. This is shown in the scenario details in Appendix N-1.

- ***The worker adjustment factor may not represent the most conservative estimation of the worker's inhalation exposure for nighttime work shifts.***

  In most cases, the worker adjustment factor will represent a health protective approximation for work shifts that occur during the daytime. However, the worker adjustment factor may not represent the most conservative estimation when the source's emission schedule and offsite worker's schedules are 100% coincident at night. It is recommended that the offsite worker long-term average concentrations be post-processed using the hourly dispersion modeling results when examining work shifts occurring at night. Alternatively, a more conservative worker adjustment factor can be used to account for the calm hours (see the next bullet point below).

- ***Recommended worker adjustment factor for 8 and 10-hour work shifts***

  Based on the five meteorological data sets used in this study, the range of worker adjustment factors (WAF) was between 4.2 and 4.8. We recommend using the 4.2 WAF for most cases. In the event of predominant night time emissions and worker schedule or if only one year of meteorological data are available, then we recommend using 4.8 for the 8-hour WAF.

Abstract

Heavy duty on-road vehicles represent one of the largest sources of NO_x emissions and fuel consumption in North America. Heavy duty vehicles are predominantly diesels, with the recent interest in natural gas (NG) systems. As emissions and greenhouse gas regulations continue to tighten new opportunities for advanced fleet specific heavy duty vehicles are becoming available with improved fuel economy. NO_x emissions have dropped 90% for heavy duty vehicles with the recent 2010 certification limit. Additional NO_x reductions of another 90% are desired for the South Coast Air basin to meet its 2023 NOx inventory requirements.

Although the 2010 certification standards were designed to reduce NO_x emissions, the in-use NO_x emissions are actually much higher than certification standards. The main reason is a result of the poor performance of aftertreatment systems for diesel vehicles during low duty cycle operation. Recent studies by UCR suggest 99% of the operation within 10 miles of the ports represented by up to 1 g/bhp-hr. Thus, a real NO_x success will not only be providing a solution that is independent of duty cycle, but one that also reduces the emissions an additional 90% from the current 2010 standard.

The ISL G NZ 8.9 liter NG engine met and exceeded the target NOx emissions of 0.02 g/bhp-hr and maintained those emissions during a full ration of duty cycles found in the South Coast Air Basin. The other gaseous, particulate matter, particle number and selected non regulated emissions were similar to previous levels. It is expected NG vehicles could play a role in the reduction of the south coast NOx inventory problem given their near zero emission factors demonstrated.

Acronyms and Abbreviations

ARB	Air Resources Board
bs	brake specific
CE-CERT	College of Engineering-Center for Environmental Research and Technology (University of California, Riverside)
CFR	Code of Federal Regulations
CO	carbon monoxide
CO_2	carbon dioxide
CNG	compressed natural gas
CWI	Cummins Westport Inc.
FID	flame ionization detector
NH_3	ammonia
g/bhp-hr	grams per brake horsepower hour
lpm	liters per minute
MEL	mobile emission laboratory
NO_x	nitrogen oxides
N_2O	nitrous oxides
OEM	original equipment manufacturer
PM	particulate matter
$PM_{2.5}$	ultra-fine particulate matter less than 2.5 µm (certification gravimetric reference method)
PN	particle number
PSD	particle size distribution
RPM	revolutions per minute
scfm	standard cubic feet per minute
THC	total hydrocarbons
UCR	University of California at Riverside
FE	Fuel economy
GDE	gallons diesel equivalent
NG	natural gas
LNG	liquid natural gas

Executive Summary

Heavy duty on-road vehicles represent one of the largest sources of NO_x emissions and fuel consumption in North America. Heavy duty vehicles are predominantly diesels, with the recent penetration of natural gas (NG) engines in refuse collection, transit, and local delivery where vehicles are centrally garaged and fueled. As emissions and greenhouse gas regulations continue to tighten, new opportunities to use advanced fleet specific heavy duty vehicles with improved fuel economy are becoming available. NO_x emissions have dropped 90% for heavy duty vehicles with the recent 2010 certification limit. Additional NO_x reductions of another 90% are desired for the South Coast Air basin to meet its 2023 NO_x inventory requirements.

Although the 2010 certification standards were designed to reduce NO_x emissions, the in-use NO_x emissions are actually much higher than certification standards. The main reason is a result of the poor performance of aftertreatment systems for diesel vehicles during low duty cycle operation. Recent studies by UCR suggest 99% of the operation within 10 miles of the ports are up to 1 g/bhp-hr NO_x. Stoichiometric natural gas engines with three-way catalysts tend to have better low duty cycle NO_x emissions than diesel engines with SCR aftertreatment systems. Thus, a real NO_x success will not only be providing a solution that is independent of duty cycle, but one that also reduces the emissions an additional 90% from the current 2010 standard.

Goals: The goals of project are to evaluate the ISL G NZ (near zero) 8.9 liter ultra-low NO_x NG vehicle emissions, global warming potential, and fuel economy during in-use conditions. This report presents a summary of the results and conclusions of ultra-low NO_x NG vehicle evaluation.

Approach: The testing was performed on UC Riverside's chassis dynamometer integrated with its mobile emissions laboratory (MEL) located in Riverside CA just east of the South Coast Air Quality Management District (AQMD). The cycles selected for this study are representative of operation in the South Coast Air Basin and included the urban dynamometer driving schedule, the near dock, local, and regional port cycles, the AQMD refuse cycle, and the central business district cycle.

One of the difficulties in quantifying NO_x emissions at 90% of the 2010 certification level (~ 0.02 g/bhp-hr), is the measurement method is approaching its detection limit. Three upgraded NO_x measurement methods were considered which include a raw NO_x measurement integrated with real time exhaust flow, a real-time ambient correction approach, and a trace level ambient analyzer for accurate bag analysis. In summary the improved methods varied in their success where the raw sampling approach showed to be the most accurate and precise over the range of conditions tested.

In addition to the regulated emissions, the laboratory was equipped to measure particle size distribution, particle number, soot PM mass, ammonia, and nitrous oxide emissions to investigate any dis-benefit resulting from the ISL G NZ engine and aftertreatment system.

Results: The ISL G NZ 8.9 liter NG engine showed NO_x emissions below the proposed 0.02 g/bhp-hr emission target and averaged between 0.014 and 0.002 g/bhp-hr for the various hot start tests, see Figure ES-1. The NO_x emissions (g/bhp-hr) decreased as the duty cycle was decreased

which was the opposite trend for the diesel vehicles (where emissions increased as duty cycle decreased). The large error bars (represented by 1 standard deviation) may suggest measurement variability, but when the real-time data was investigated, one can see the variability was a result of test-to-test differences from a few isolated NO_x events during rapid throttle tip-in at idle, see Figure ES-2. This suggests possible driver behavior may impact the overall NO_x in-use performance of the vehicle where more gradual accelerations are desired. This is also evident with the more gradual accelerations of the near dock and local port cycles which showed smaller error bars and lower average emission factors, see Figure ES-1.

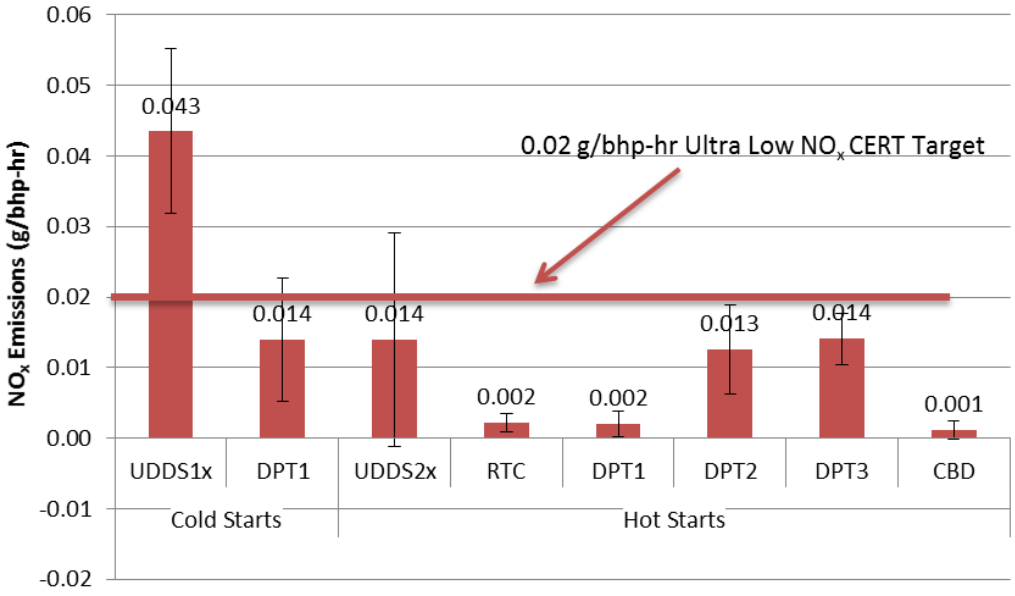

Figure ES-1 Cycle averaged NO_x emissions for the ISL G NZ 8.9 liter equipped vehicle

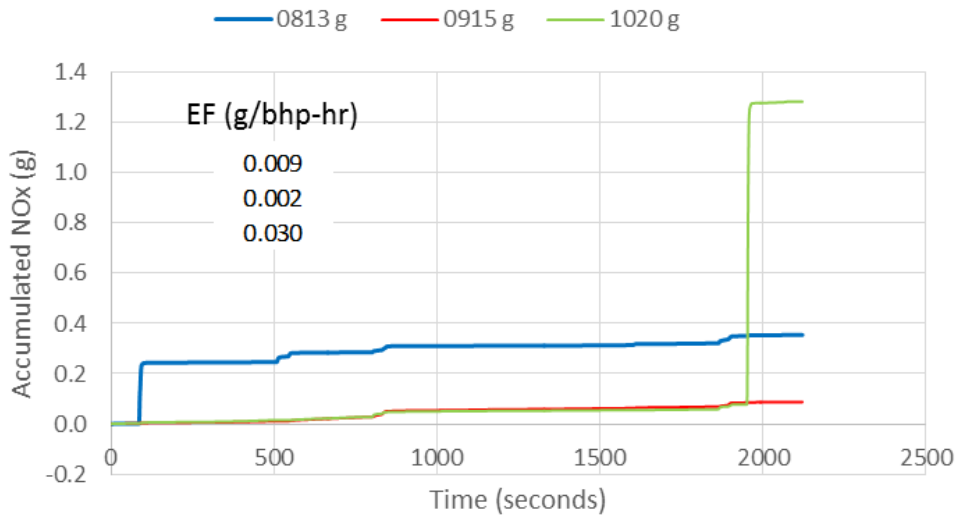

Figure ES-2 Real-time NO_x accumulated mass for the three UDDS hot cycles

[1] Individual accumulated and integrated EF for the UDDS cycle is shown in the figure above. The average of these tests is represented in Figure ES-1, UDDS cycle (0.14 g/bhp-hr).

Cold start emissions represented a significant part of the total NO_x emissions where 90% of the NO_x emissions occurred in the first 200 seconds of the cold UDDS test. Once the catalyst was warmed up, the remaining portions of the cold UDDS test showed low NO_x emissions similar to the hot UDDS test. The hot/cold UDDS weighted emission was 0.0181 g/bhp-hr (weighted as $1/7^{th}$ of the hot cycle) which is below the 0.02 g/bhp-hr standard. Once the TWC catalyst lights off, its NO_x reduction potential remains at a high performance unlike diesel SCR equipped engines where low duty cycles (associated with SCR temperatures below 250C) will cause the SCR performance to decline.

The other emission such as carbon monoxide, particulate matter, particle number, particle size distribution, nitrous oxide, and ammonia were similar to previous versions of the same stoichiometric 8.9 liter engine certified to 0.2 g/bhp-hr NO_x. For example PM was typically below 0.001 g/bhp-h (90% below the standard), ammonia was typically above 200 ppm. This suggests the reduced NO_x emissions did not come at the expense of an increase in other species. The methane emissions were notably lower than the 0.2 g/bhp-hr NOx version of the same engine. The lower methane emissions may be a result of the closed crankcase ventilation system. The fuel economy also appeared to be similar to previous versions of the same engine displacement where the UDDS showed the lowest CO_2 emissions and were below the current FTP standard of 555 g/bhp-hr for both the cold start and hot start tests during in-use chassis testing.

Summary: In general the ISL G NZ 8.9 liter engine hot/cold emissions were within the 0.02 g/bhp-hr certification standard for all the cycles tested. Ironically these emissions factors were maintained for the full range of hot-start duty cycles found in the South Coast Air Basin unlike other heavy duty diesel fueled technologies and certification standards. The other gaseous and PM emissions were similar to previous levels. It is expected NG vehicles with the ISL G NZ could play a role in the reduction of the south coast NO_x inventory in future years given the near zero emission factors demonstrated on each test cycle. Additional research is needed to see if the on-road behavior is similar to test cycles and if there are any deviations as the vehicles age.

1 Background

1.1 Introduction

Heavy duty on-road vehicles represent one of the largest sources of NO_x emissions and fuel consumption in North America. Heavy duty vehicles are predominantly diesels, although there is increasing interest in natural gas (NG) systems. As emissions and greenhouse gas regulations continue to tighten new opportunities for advanced fleet specific heavy duty vehicles are becoming available with improved fuel economy. At the same time NO_x emissions have dropped 90% for heavy duty vehicles with the recent 2010 certification limit. Additional NO_x reductions of another 90% are desired for the South Coast Air basin to meet its 2023 NO_x inventory requirements. Thus, an approach to reduce emissions also needs lower fuel consumption to the extent possible.

1.2 NO_x Emissions

Although the 2010 certification standards were designed to reduce NO_x emissions, the in-use NO_x emissions are actually much higher than certification standards for certain fleets. The magnitude is largely dependent on the duty cycle. Since engines are certified at moderate to high engine loads, low load duty cycle can show different emission rates. For diesel engines low load duty cycles have a significant impact in the NO_x emissions. The NO_x cold start emissions for the first 100 seconds were over 2.2 g/hp-h where for the same time frame with the hot cycle it was 0.006 g/hp-h[1], see Figure 1-1. The cold start emissions were ten times higher than the certification standard and much higher than the corresponding hot start emissions. Additionally the stabilized emission of the two systems over the same time period was very similar at 0.05 g/hp-h (about 75% below the standard). The main cause for the high NO_x emissions is low selective catalytic reduction (SCR) inlet temperatures resulting from low power operation.

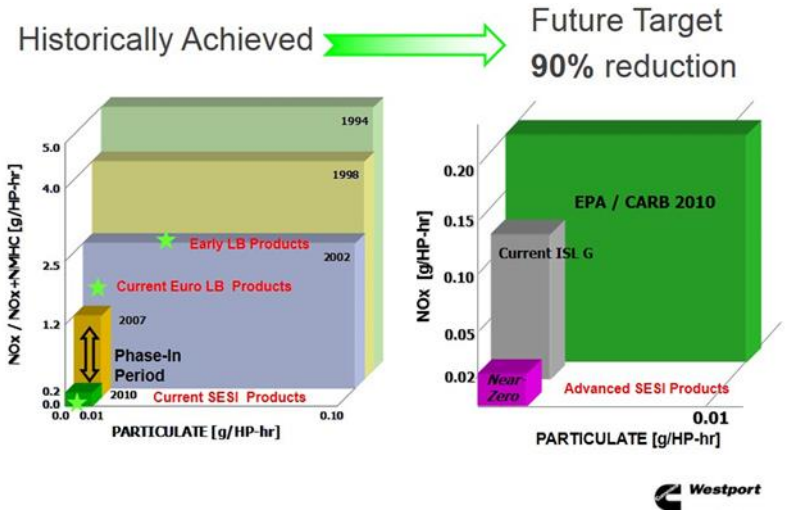

Figure 1-1 Engine dynamometer NO_x and PM certification emissions standards (source CWI)

[1] Wayne Miller, Kent C. Johnson, Thomas Durbin, and Ms. Poornima Dixit 2013, In-Use Emissions Testing and Demonstration of Retrofit Technology, Final Report Contract #11612 to SCAQMD September 2013.

These same trucks were tested on cycles designed to simulate port activity[2]. The port driving schedule represents near dock (2-6 miles), local (6-20 miles), and regional (20+ miles) drayage port operation. The SCR was inactive for 100% of the near dock cycle, 95% of the local cycle, and 60% of the regional cycle, see Figure 1-2. The NO_x emissions were on the order of 0.3 to 2 g/hp-h (1 to 9 g/mi) as much as 10 times higher than the 2010 standards. It has been show that the SCR system also becomes inactive even after hours of operation due to low loads and lean compression ignition combustion. Thus, the current diesel 2010 solution for low duty cycle activity (like at ports) is very poor where a NG solution can make significant improvements for NO_x emissions, and a reduction in carbon emissions (carbon dioxide), but at a slight penalty in equivalent gallon diesel fuel economy.

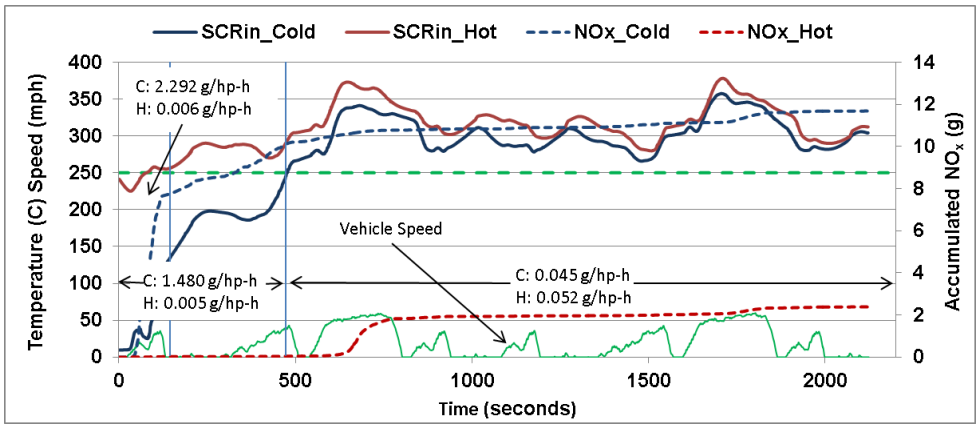

Figure 1-2 In-use emissions from a heavy duty truck tested on UCR's chassis dyno

1.3 Fuel economy

Fuel consumption and emissions are a tradeoff due to the science of combustion. Figure 1-3 shows the NO_x emissions change with changes in fuel consumption for a typical spark ignited engine. As NO_x is reduced from 0.14 to 0.02 g/hp-h fuel consumption increases a known amount. This is a result of the stoichiometric combustion of fuels. Advanced catalysts can be used to reduce NO_x from its baseline levels, but trying to reduce NO_x within a fixed SI combustion system will come at a penalty of increased fuel consumption.

1.4 Objectives

The goals of project are to evaluate the ISL G NZ 8.9 liter ultra-low NO_x NG vehicle emissions, global warming potential, and fuel economy during in-use conditions. Given the low NO_x concentrations expected, additional measures were implemented to quantify NO_x emissions at and below 0.02 g/bhp-hr emissions levels. This report is a summary of the approach, results, and conclusions of ultra-low NO_x NG vehicle evaluation.

2 Approach

The approach for this demonstration vehicle evaluation includes in-use testing on a chassis dynamometer, emissions measurements with UCRs mobile emission laboratory (MEL), improvements to the NO_x measurement method and a representative selection of in-use test cycles. One of the difficulties in quantifying NO_x emissions at the levels proposed in this project (90% lower than the 2010 certification level ~ 0.02 g/bhp-hr) is the measurement methods are approaching their detection limit to accurately quantify NO_x emissions. This section describes the test article, laboratories and the upgrades performed to quantify NO_x emissions at and below 90% of the 2010 emission standard.

2.1 Test article

2.1.1 Engine

The test article is the ISL G NZ 320 Cummins Westport Inc. (CWI) Natural Gas engine (SN = 73779339), see Table 2-1 for specifics and Appendix F for additional details. The engine was initially certified as a 0.2 g/bhp-hr NO_x and 0.01 g/bhp-hr PM based on the family number ECEXH0540LBH found on the engine label and the executive order (EO) published on the ARB website, see Figure F-1 Appendix F. CWI developed this engine as a ultra-low NO_x demonstration engine where the NO_x emissions have been further reduced to 0.02 g/bhp-hr (90% below the 2010 NO_x emissions standard). A second, recently released EO for the near zero configuration with engine family GCEXH0540BH, also on the CARB website and provided from CWI shows the lower NO_x standard is 0.02 g/bhp-hr and the actual certified value was 0.01 g/bhp-hr, see Figure F4 Appendix F. This evaluation is to quantify the in-use NO_x emissions in relationship to the 0.02 g/bhp-hr demonstration level.

Table 2-1 Summary of selected main engine specifications

Mfg	Model	Year	Eng. Family	Rated Power (hp @ rpm)	Disp. (liters)	Adv NO_x Std g/bhp-h [1]	PM Std. g/bhp-h
CWI	ISL G NZ	2014	ECEXH0540LBH	320 @ 2100	8.9	0.02	0.01

[1] The family ECEXH0540LBH is on the engine label given its year of manufacture. The engine tested was produced under the ECEX… label but was later certified and upgraded to the GCEX… label. The engine tested is thus, based on the GCEX label and represents a 0.02 g/bhp-hr NO_x standard, see Appendix F Figure 4 for details.

2.1.2 Test Fuel

California pipeline fuel was used for this study which represents typical Natural Gas available in Southern California. The fuel properties were measured during the emissions testing and are presented in Table 2-2. Fuel samples were collected from the vehicle prior to testing. Three vehicle refuelings (Agua Mansa Station, Riverside CA) were required to complete the work and three fuel samples were collected. Due to sample container issues, only the November 20th sample collected was analyzed as presented in Table 2-2. It is expected the pump NG fuel was consistent over the five days of testing.

Table 2-2 Fuel properties for the local NG test fuels utilized

Property	Molar %	Property	Molar %
Methane	94.65	Pentane	0.01
Ethane	3.87	Carbon dioxide	0.35
Propane	0.41	Oxygen	0.00
Butane	0.08	Nitrogen	0.63

1 Based on these fuel properties the HHV is 1-42.5 BTU/ft3 and the LHV is 939.9 BTU/ft3 with a H/C ratio of 3.905, a MON of 132.39 and a carbon weight fraction of 0.745 and a SG = 0.58, see Appendix E for laboratory results. Note these results meets the US EPA 40 CFR Part 1065.715fuel specification for NG fueled vehicles.

2.1.3 Vehicle inspection

Prior to testing, the vehicle was inspected for proper tire inflation and condition, vehicle condition, vehicle securing, and the absence of any engine code emission faults. The vehicle inspection and securing met UCR's specifications. Cummins Westport Inc. had a service person on site to make sure fault codes were absent prior to and during emissions testing. All tests were performed with-in specification and without any engine code faults. Thus, the results presented in this report are representative of a properly operating vehicle, engine, and aftertreatment system.

2.1.4 Test cycles

The test vehicle utilized an 8.9 liter NG engine which is available for three typical vocations in the South Coast Air Basin, 1) goods movement, 2) bus, and 3) refuse[3]. The engine was provided to UCR in its refuse hauler application which is one of the more common uses for the 8.9 liter engine, see Figure 2-4. In order to characterize emissions from this engine over the rage of in-use applications, goods movement and bus cycles were also tested. UCR tested the vehicle following the three port cycles (Near Dock, Local, and Regional), the Urban Dynamometer Driving Schedule (UDDS), the Central Business District (CBD) bus cycle, and the AQMD Refuse cycle, see Appendix B for details. These cycles are representative of Sothern California driving. Some cycles are short (less than 15 minutes) where double or triple cycles (2x or 3x) cycles are recommended in order capture enough PM mass to quantify emissions near 1 mg/bhp-hr. The UDDS was performed twice (UDDSx2) and the CBD was performed three times (CBDx3) where the emissions represent the average of the cycle.

Table 4 Summary of statistics for the various proposed driving cycles

Day	Distance (mi)	Average Speed (mph)	Duration (sec)
Near Dock	5.61	6.6	3046
Local	8.71	9.3	3362
Regional	27.3	23.2	3661
UDDSx2	11.1	18.8	2122
CBDx3	3.22	20.2	560
AQMD Refuse	4.30	7.31	2997

[1] Hot UDDS was performed as a double cycle (2x) and a single (1x) for the cold tests. The CBD was performed as a triple (3x) test. The refuse cycle includes a compaction element where no distance is accumulated, but emissions are counted with a simulated compaction cycle, see Appendix B for details.

2.1.5 Work calculation

The reported emission factors presented are based on a g/bhp-hr and g/mi basis (g/mi are provided in Appendix E). The engine work is calculated utilizing actual torque, friction torque, and reference torque from broadcast J1939 ECM signals. The following two formulas show the calculation used to determine engine brake horse power (bhp) and work (bhp-hr) for the tested vehicle. Distance is measured by the chassis dynamometer and the vehicle broadcast J1939 vehicle speed signal. A representative ISL G NZ 320 engine lug curve is provided in Figure 2-1.

$$Hp_{\_i} = \frac{RPM_{\_i}\left(Torque_{actual\_i} - Torque_{friction\_i}\right)}{5252} * Torque_{reference}$$

Where:

Hp_i	instantaneous power from the engine. Negative values set to zero
RPM_i	instantaneous engine speed as reported by the ECM (J1939)
Torque_actual_i	instantaneous engine actual torque (%): ECM (J1939)
Torque_friction_i	instantaneous engine friction torque (%): ECM (J1939)
Torque_reference	reference torque (ft-lb) as reported by the ECM (J1939)

$$Work = \sum_{i=0}^{n} \frac{Hp_{\_i}}{3600}$$

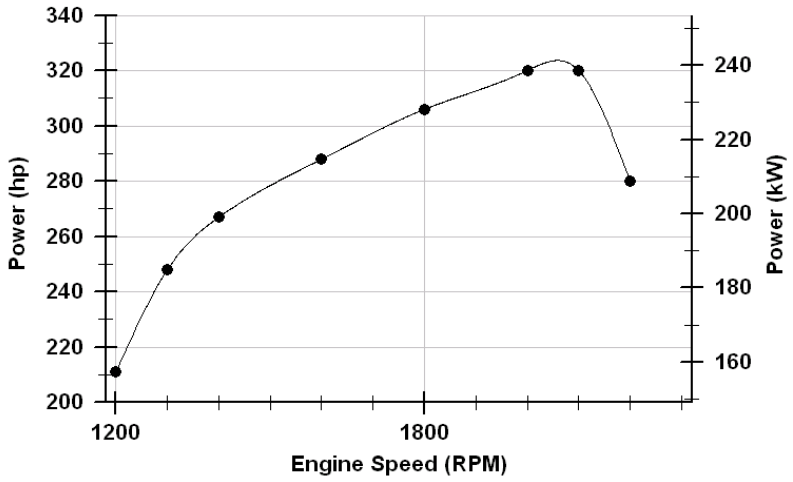

Figure 2-1 Published ISLG 8.9 Natural Gas engine power curve

Figure 2-2 and Figure 2-3 show the measured power and work for each of the tests performed on the refuse vehicle. The engine is certified on the FTP type of cycle where the average power is around 82 Hp and estimated at 24.7 bhp-h, also shown in Figure 2-2 and Figure 2-3. The UDDS, regional (DPT3) and the CBD test cycles represent power near (but lower) than the FTP certification cycle. The near dock (DPT1), local (DPT2), and refuse (RTC) cycles showed much lower power with the DPT1 being the lowest (as shown by previous studies). Previous testing of the low power from the DPT1 cycle resulted in high diesel NO_x emissions because the SCR operating temperatures were never obtained.

The measured work for the all the cycles (except the CBD (lower), RTC, and the regional (DPT3 much higher)) were close to the certification FTP estimated work (Note the hot-UDDS was higher because a double cycle was performed where the cold-UDDS was performed as a single UDDS test). In general the cycles selected are representative of in-use conditions and certification testing. It is expected the results from this study will be very representative for real world emission factors for the test article.

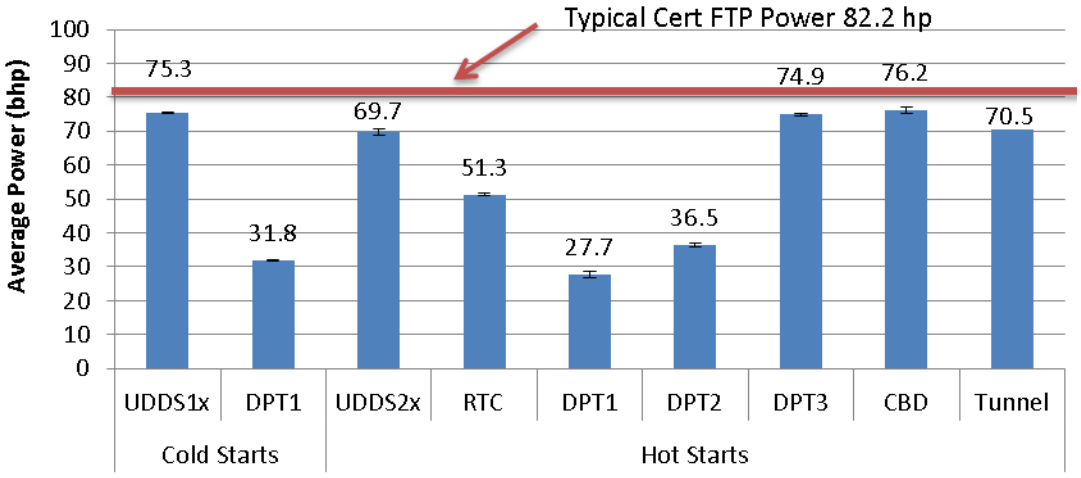

Figure 2-2 Power from the various tests with 1 stdev error bars

[1] The tunnel blank (TB) was performed without the vehicle operating. To calculate a work specific TB comparison, the TB test utilized the power and work value of a single hot-UDDS test to provide context of the measurement detection limits.

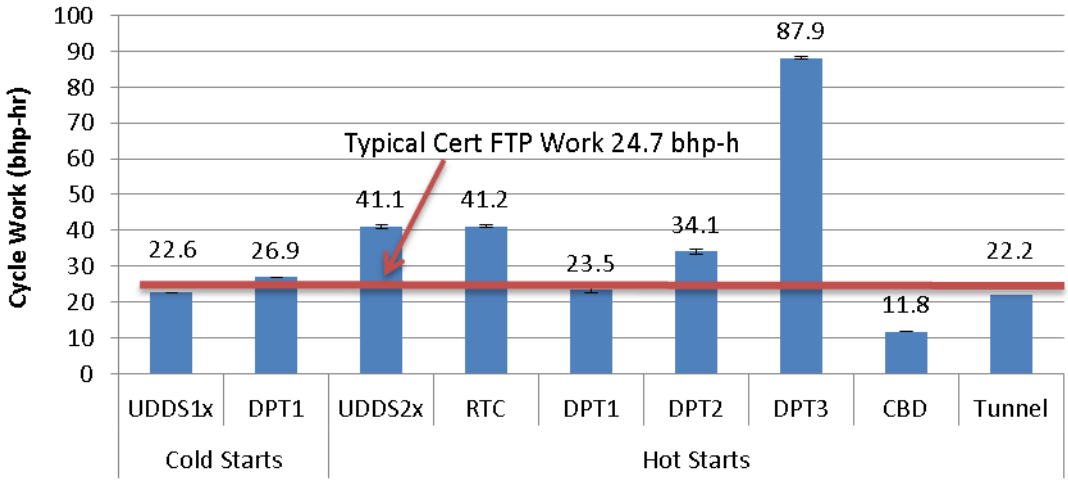

Figure 2-3 Work from the various tests with 1 stdev error bars

[1] The TB was performed without the vehicle operating. To calculate a work specific TB comparison, the TB test utilized the power and work value of a single hot-UDDS test to provide context of the measurement detection limits.

2.2 Laboratories

The testing was performed on UC Riverside's chassis dynamometer integrated with its mobile emissions laboratory (MEL) located in Riverside CA just east of the South Coast Air Quality

Management District (AQMD). This section describes the chassis dynamometer and emissions measurement laboratories used for evaluating the in-use emissions from the demonstration vehicle. Due to challenges of NO_x measurement at 0.02 g/bhp-hr, additional sections are provided to introduce the measurement improvements.

2.2.1 Chassis dynamometer

UCR's chassis dynamometer is an electric AC type design that can simulate inertia loads from 10,000 lb to 80,000 lb which covers a broad range of in-use medium and heavy duty vehicles, see Figure 2-4. The design incorporates 48" rolls, vehicle tie down to prevent tire slippage, 45,000 lb base inertial plus two large AC drive motors for achieving a range of inertias. The dyno has the capability to absorb accelerations and decelerations up to 6 mph/sec and handle wheel loads up to 600 horse power at 70 mph. This facility was also specially geared to handle slow speed vehicles such as yard trucks where 200 hp at 15 mph is common. See Appendix D for more details.

2.2.1.1 Test weight

The ISL G NZ 320 engine is installed in a refuse hauler chassis with a GVW of 62,000 lb, VIN 3BPZX20X6FF100173. The representative test weight for refuse haulers operating in the south coast air basin is 56,000 lb[4]. The testing weight of 56,000 lb was also utilized during previous testing of refuse haulers with diesel and NG engines by UC Riverside and WVU [4 and 5]. For this testing program UCR utilized a testing weight of 56,000 lb for all test cycles (refuse, CBD, UDDS, and port cycles).

Figure 2-4 UCR's heavy duty chassis eddy current transient dynamometer

[5] Daniel K Carder, Mridul Gautam, Arvind Thiruvengada,m Marc C. Besch (2013) In-Use Emissions Testing and Demonstration of Retrofit Technology for Control of On-Road Heavy-Duty Engines, Final Report Contract #11611 to SCAQMD July 2014.

2.2.1.2 Coast down

UCR utilizes a calculation approach for the coast down settings of the chassis dynamometer. This approach is also used by other testing facilities and has been shown to be representative of in-use operation, see Appendix G for a more detailed discussion. The test weight of 56,000 lb resulted in a power of 117.42 Hp at 50 mph with the calculated dynamometer loading coefficients of A = 397.73642, B = -2.43E-14 and C = 0.193166. See calculation methods in Appendix G for more details.

2.2.2 Emissions measurements

The proposed NO_x measurement (at 0.02 g/bhp-hr) are approaching the detection limits for the traditional dilute CVS measurement method. This section discussed the traditional and upgraded methods recommended for the ultra-low NO_x evaluation. This section also provides a section on the calculations utilized, additional measurements needed (ie. Trace analyzers and exhaust flow) and an evaluation of the upgraded methods in comparison to the tradition methods.

2.2.2.1 Traditional method

The approach used for measuring the emissions from a vehicle or an engine on a dynamometer is to connect UCR's heavy-duty mobile emission lab (MEL) to the total exhaust of the diesel engine, see Appendix C for more details. The details for sampling and measurement methods of mass emission rates from heavy-duty diesel engines are specified in Section 40, Code of Federal Regulations (CFR): Protection of the Environment, Part 1065. UCR's unique heavy-duty diesel MEL is designed and operated to meet those stringent specifications. MEL is a complex laboratory and a schematic of the major operating subsystems for MEL are shown in Figure 2-4. The accuracy of MEL's measurements has been checked/verified against ARB's[6] and Southwest Research Institute's [7, 8] heavy-duty diesel laboratories. MEL routinely measures Total Hydrocarbons (THC), Methane (CH_4), Carbon Monoxide (CO), Carbon Dioxide (CO_2), Nitrogen Oxides (NO_x), and Particulate Matter (PM) emissions from diesel engines. Design capabilities and details of MEL are described in Cocker et al[4,9]. Samples can be collected for more detailed analyses such as hydrocarbon speciation, carbonyl emissions, polynuclear aromatic hydrocarbons, etc.

The traditional NO_x measurements include a 600 heated chemiluminescent detector (HCLD) from California Analytical Inc. (CAI) configured to sample from the CVS tunnel during real time and ambient and dilute bag measurements following automated routines of the MEL laboratory. The samples are collected from the CVS dilute tunnel through an acid treated filter to

prevent measurement interferences from ammonia (NH_3) concentrations. The acid treated filters were replaced daily.

In addition to the regulated emissions, the laboratory was equipped to measure particle size distribution (PSD) with TSI's Engine Exhaust Particle Sizer (EEPS) model 3090, particle number (PN) with a TSI 3776 condensation particle counter (CPC), soot PM mass with AVL's Micro Soot Sensors (MSS 483), NH_3 emissions with an integrated real-time tunable diode laser (TDL) from Unisearch Associates Inc. LasIR S Series, and a batched low level nitrous oxide (N_2O) emissions with a Fourier Transform Infrared Spectrometer (FTIR). The PN measurement system used a low cut point CPC (2.5 nm D50) because of the large PN concentrations reported below the PMP protocol CPC 23 nm measurement system (10, 11, and 12). The EEPS spectrometer displays measurements in 32 channels total (16 channels per decade) and operates over a wide particle concentration range, including down to 200 particles/cm3.

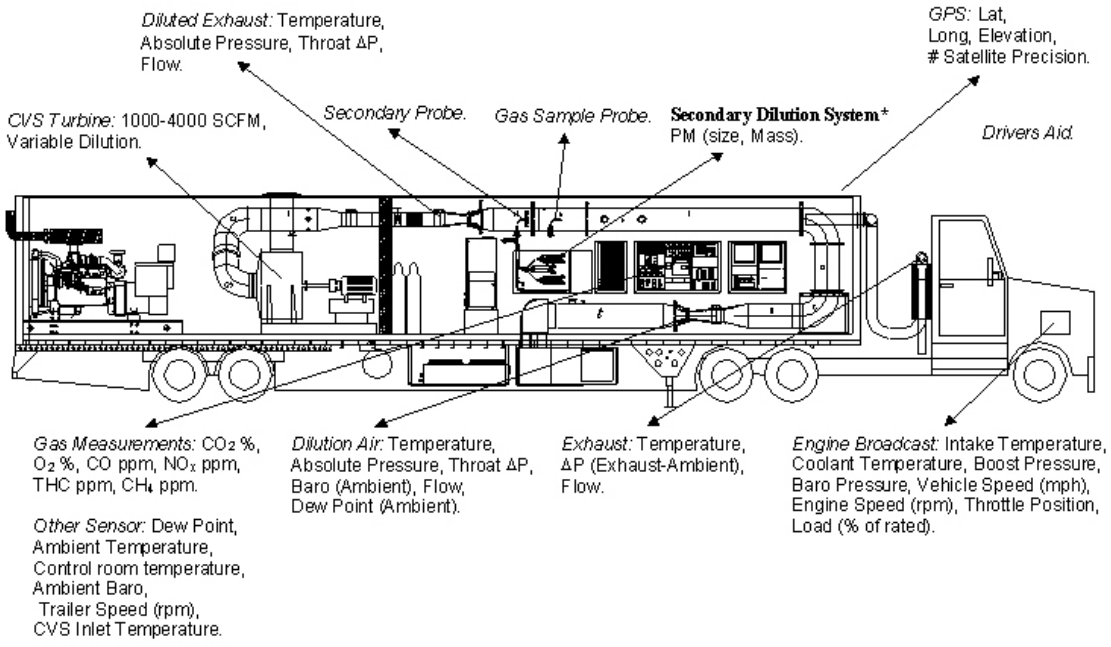

Figure 2-5 Major Systems within UCR's Mobile Emission Lab (MEL)

2.2.2.2 NO_x Method upgrades

Three NO_x upgrade methods were considered for this project. These included 1) real-time raw sampling and exhaust flow measurements, 2) real-time ambient second by second corrections, and 3) advanced trace type analyzer bag measurements. The new measurement methods required instrumentation upgrades which are discussed below.

Raw NOx measurements

The raw NO_x measurements utilized a 300 HCLD CAI analyzer which sampled raw exhaust through a low volume heated filter and heated sample line. The low volume design was considered to improve the response time of the analyzer with the exhaust flow measurement. The heated filter was acid treated to minimize NH_3 interference with the NO_x measurement. A real-time high speed exhaust flow meter (100 Hz model EFM-HS Sensors Inc) was used to align NO_x

concentration with real time exhaust flow measurements. The EFM-HS was correlated with UCR dual CVS system prior to testing to improve the accuracy between the raw and dilute CVS methods and eliminate exhaust flow biases from propagating through the comparison.

Trace level NOx analyzer

A trace level chemiluminescence NO-NO_2-NO_x analyzer model 42C manufactured by Thermo Environmental Instruments Inc (TECO) was used for the real-time ambient measurements and the low level bag analysis. This analyzer has been operating with-in CE-CERT's atmospheric research laboratories for ambient NO_x quantification for several years. This analyzer was calibrated and integrated specially for this ultra-low NO_x project. The span on the instrument was set to 600 ppb and showed a signal to noise ratio about an order in magnitude lower than the traditional (600 HCLD) analyzer. The signal averaging was reduced from 30 seconds to 1 second and showed a $T_{10\text{-}90}$ and a $T_{90\text{-}10}$ just over 10 seconds (slightly higher than the specifications of 40 CFR Part 1065). The slightly slower time constant should not impact the gradual transients expected during real-time ambient measurements or bag concentrations. Although this trace analyzer does not meet the requirements of 1065, it does provide a good assessment of NO_x emissions below 1 ppm with an ambient trace type NO_x analyzer.

2.2.2.3 Calculation upgrades

The calculations for the traditional and improved methods are presented in this section. The calculations are in agreement with 40 CFR Part 1065, but are presented in a condensed version to draw observation differences without the details of working in molar flow rates as per 40 CFR Part 1065.

Table 2-3 NO_x measurement methods traditional and upgraded

Type	Analyzer	Meth. ID	Description
Traditional	600 HCLD dil 600 HCLD amb	M1	Modal NO_x with ambient bag correction
Traditional	600 HCLD dil 600 HCLD amb	M2	Dilute bag NO_x with ambient bag correction
Upgrade	300 HCLD raw	M3	Raw NO_x no ambient bag correction
Upgrade	600 HCLD dil TECO amb	M4	Modal dilute NOx with ambient real time correction
Upgrade	TECO dil TECO amb	M5	Trace analyzer dilute bag with trace ambient bag correction

Traditional Methods:

The traditional NO_x measurement methods are described in the next two equations. The first equation is the real-time modal measurement corrected for the ambient bag concentration and real time dilution factor, Method 1 (M1). The second traditional equation (M2) is based on dilute bag and ambient bag concentrations and an integrated dilution factor over the cycle.

$$NO_{x\_m1} = \sum_{i=1}^{n} (Q_{cvs_i} * \Delta t_{\_i}) * \rho_{NO_x} * \left(C_{m\_i} - C_a * \left(1 - \frac{1}{DF_i}\right)\right)$$

Where:

NO_{x_m1} the Method 1 NO_x measurement method (g/cycle)
Q_{cvs_i} is the instantaneous CVS flow
ρ_{NOx} is the density of NO_x from 40 CFR Part 1065
C_{m_i} is the instantaneous NO_x concentration measured with the dilute NO_x 600 HCLD CAI analyzer
C_a is the ambient bag NO_x concentration measured by the 600 HCLD CAI analyzer
DF_i instantaneous dilution factor

$$NO_{x\_m2} = (Q_{cvs\_ave} * \Delta t) * \rho_{NO_x} * \left(C_d - C_a * \left(1 - \frac{1}{DF_{\_ave}} \right) \right)$$

Where:
NO_{x_m2} the Method 2 NO_x measurement method (g/cycle)
Q_{cvs_ave} is the average CVS flow
ρ_{NOx} is the density of NO_x from 40 CFR Part 1065
C_d is the dilute bag NO_x concentration measured with the dilute NOx 600 HCLD CAI analyzer
C_a is the ambient bag NO_x concentration measured by the 600 HCLD CAI analyzer
DF_{ave} average dilution factor

Upgraded Methods:
The upgraded NOx measurement methods are presented in the next three equations. These upgrades included new analyzers, sample lines, sample filters, and exhaust flow measurement systems. For Method 3 (M3) there is no ambient correction. For Method 4 (M4) the real time dilute NOx is corrected for ambient real time NOx on a second by second basis. For Method 5 (M5) the trace NOx analyzer is used to measure the dilute bag and ambient bags (similar to Method 2).

$$NO_{x\_m3} = \sum_{i=1}^{n} (Q_{exh_i} * \Delta t_{\_i}) * \rho_{NO_x} * \left(C_{m\_i} \right)$$

Where:
NO_{x_m3} the Method 3 NO_x measurement method (g/cycle)
Q_{exh_i} is the instantaneous exhaust flow measured in the tail pipe
ρ_{NOx} is the density of NO_x from 40 CFR Part 1065
C_{m_i} is the dilute bag NO_x concentration measured with the dilute NO_x 300 HCLD CAI analyzer

$$NO_{x\_m4} = \sum_{i=1}^{n} (Q_{cvs_i} * \Delta t_{\_i}) * \rho_{NO_x} * \left(C_{m\_i} - C_{a\_adv\_i} * \left(1 - \frac{1}{DF_i} \right) \right)$$

Where:
NO_{x_m4} the Method 4 NO_x measurement method (g/cycle)
Q_{cvs_i} is the instantaneous CVS flow
ρ_{NOx} is the density of NO_x from 40 CFR Part 1065

C_{m_i} is the dilute bag NO_x concentration measured with the dilute NO_x 600 HCLD CAI analyzer

C_{a_adv} is the trace ambient bag NOx concentration measured by the TECO trace NO_x analyzer

DF_i instantaneous dilution factor

$$NO_{x\_m5} = (Q_{cvs\_ave} * \Delta t) * \rho_{NO_x} * \left(C_{d\_adv} - C_{a\_adv} * \left(1 - \frac{1}{DF_{\_ave}} \right) \right)$$

Where:

NO_{x_m5} the Method 5 NO_x measurement method (g/cycle)

Q_{cvs_ave} is the average CVS flow

ρ_{NOx} is the density of NO_x from 40 CFR Part 1065

C_{d_adv} is the dilute bag NO_x concentration measured by the TECO trace NO_x analyzer

C_{a_adv} is the ambient bag NO_x concentration measured by the TECO trace NO_x analyzer

DF_{ave} average dilution factor

2.2.3 Method evaluation

One of the main contributing factors to the issue with the traditional CVS sampling system is the magnitude of the ambient concentration has on the calculation. Table 2-4 lists the 10th, 50th, and 90th average ambient, dilute modal, and raw tailpipe measured percentile concentrations. The 50th percentile raw, dilute, and ambient NO_x concentration were 0.55 ppm, 0.17 ppm, and 0.07 ppm respectively.

As discussed previously, the ambient concentration is subtracted from the dilute concentration prior to calculating the mass based emissions. This subtraction is typically a larger number minus a small number. At the 0.02 g/bhp-hr emission level, the ambient concentration is now at the same levels as the dilute measured value. The ambient concentration was found to be 54% of the total measured dilute concentration at the 50th percentile measured concentration, see Table 2-4. The ambient corrected NOx concentration (C_{a_cor}) utilized in the dilution measurements is the product of ambient NO_x concentration and an inverse ratio of the dilution factor, see equation below. If we divide the C_{a_cor} by the dilute NOx measured we get a ratio that is representative of the ambient percent of total NOx. Figure 2-6 shows the ratio in a histogram plot and more than half the data is above 0.6 suggest that most of the measurements meeting the 0.02 g/bhp-hr were only twice that of ambient concentrations. This ratio gives the reader a feel for the influence ambient has at and below 0.02 g/bhp-hr NOx emissions.

Table 2-4 Cycle averaged raw, dilute, and ambient measured concentrations (ppm) statistics

Percentile	Amb	Dilute [1]	Raw [1]	C_{a_cor}/Dil %
10th	0.234	0.632	6.533	105%
50th	0.070	0.168	0.554	54%
90th	0.021	0.033	0.070	10%

[1] With the cold starts removed, the dilute and raw 10th, 50th, and 90th would be 0.326, 0.146, and 0.031 ppm for the dilute concentration and 2.115, 0.450, and 0.069 ppm for the raw concentration, respectively.

The results show a 10th, 50th and 90th percentile (C_{a_cor}/C_d) ratio of 10%, 54% and 105%, respectively. This suggest more than ½ of the measurements were sampled where the dilute concentration was 50% of the ambient corrected (C_{a_cor}) concentration. The low concentrations measured by dilute methods will impact all the methods except for M3 that utilizes the raw sampling approach where no dilution correction is needed.

$$C_{a\_cor} = C_a * \left(1 - \frac{1}{DF_{\_ave}}\right)$$

Where:

C_{a_cor}	is the ambient NOx concentration factor used in M1
C_a	is the ambient bag NOx concentration
DF_{ave}	cycle average dilution factor (typically 20-30)
$\left(1 - \frac{1}{DF_{\_ave}}\right)$	dilution factor term (varied from 0.95 to 0.98 in this study)

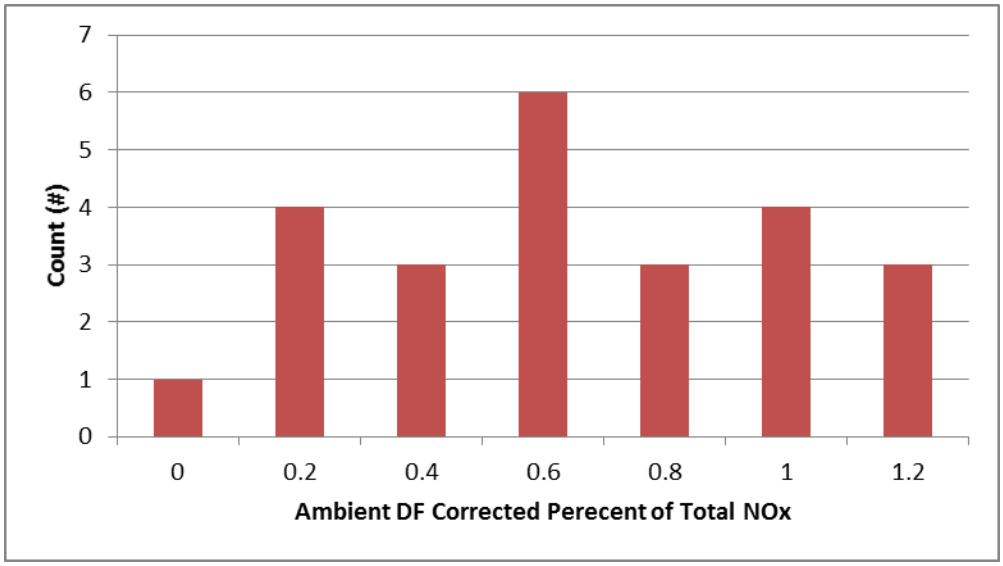

Figure 2-6 Ambient fraction of dilute NO_x concentration distribution

The real-time concentrations for each cycle is also important where observations suggest a few NO_x spikes of 20-30 times the average values were the basis of the cycle average concentrations. Section 4 provides additional discussions on the real-time transient NO_x measurements. It is important to understand that the real-time NO_x spikes will impact the M1, M3, and M4 measurements since these utilize real-time signals where M2 and M5 are integrated bag signals.

The average mean difference in average emissions between the methods is shown in Table 2-5 with M1 as the reference method. For M2 the average NO_x emissions was very similar to M1 (only 5% higher on average, but varied from higher to lower from cycle to cycle). M3 was slightly lower (-18% on average), but was consistently lower except for the CBD tests. Further investigation of the CBD tests shows one of the M1 tests had a negative emission rate due a high ambient bag concentration compared to the modal dilute concentration. This negative value was

not an outlier, but a real measurement difficulty at these emission levels. The M4 average NO_x emission rate was notably higher (and relatively more variable) and for M5 the average was significantly lower for all tests compared to the M1 traditional method.

The M4 utilized real time ambient concentrations for real time correction of the background calculation. The trace analyzer utilized show some short term drift that didn't appear to be related to ambient concentration changes. Additional investigation is needed, but is outside the scope of this effort. The researchers suggest the M4 method will have more variability as a result and could be the cause for the higher mean difference.

The M5 utilized the trace NO_x analyzer for bag measurements. Surprisingly the M5 method showed a much lower mean value. Investigations were carried out to see about analyzer drift or stability and no issues were found during the bag analysis time spans.

Table 2-5 NO_x emission average percent difference from Method 1

Trace	M2	M3	M4	M5
UDDS1x	-17%	-40%	96%	-87%
DPT1	31%	-42%	-8%	-99%
UDDS2x	7%	-13%	21%	-70%
RTC	4%	-21%	111%	-7%
DPT1	-21%	-11%	25%	-14%
DPT2	3%	-20%	25%	-61%
DPT3	12%	-22%	27%	-72%
CBD	19%	23%	32%	16%
Ave	5%	-18%	41%	-49%
Stdev	17%	20%	40%	42%

A comparison of the statistical significance between the traditional M1 and other methods is provided in Table 2-6. The two tailed paired t-test and f-test results suggest the two traditional methods do not have statistically different means or different variances at 95% confidence, see Table 2-6 (M2 p-value >> 0.05 for both). The upgraded methods showed a different result that varies. The M3 (raw exhaust flow approach) mean difference is not statistically significant at 95% confidence (M3 p-value > 0.06) but is at the 90% confidence. The M4 (RT ambient correction) and M5 (trace bag evaluation) upgraded methods both have statistically different means (p-value < 0.05 for both).

Table 2-6 Comparison to traditional Method 1 measurement (modal dilute NO_x)

Method	t-test	f-test
M2	0.521	0.998
M3	0.060	0.152
M4	0.021	0.141
M5	0.001	0.104

Each of the added methods (M3, M4, and M5) may have some possible implementation issues that need to be considered in order to evaluate the comparative results. The M3 measurement showed good alignment between the measured NOx signal and the exhaust flow signal. The majority of the NOx mass emissions resulted from a few large spikes, as discussed in Section 4. These NOx spikes were found to represent more than 80% of the total emission factor. Closer inspection shows that the NOx concentration and exhaust flow spike occurred simultaneously and were usually a result of a rapid acceleration from idle.

For the M4 approach (real-time NOx ambient correction) the analyzer had a slight zero stability issue over the 20-40 minute test cycle not found during the short 3 minute bag analysis. As such, the drift may be the result of the M4 poor method comparison.

The low M5 method may represent the best approach with very accurate bag measurements for both the ambient and dilute bag measurements with a trace type NOx analyzer with a larger sample cell. The drift issue suggested for the M4 measurement didn't appear to be a factor during the short bag analysis, but additional tests should be performed to evaluation. As such, this method may have performed the best, but additional testing is suggested to evaluate this method on future testing opportunities at 0.02 g/bhp-hr.

In summary the M1, M2, and M3 appear to be the most reliable where the M3 results are more consistent at the extremely low concentrations measured. M4 and M5 require further investigation with lower zero drift instrumentation.

3 Results

This section describes the results from the ISL G NZ 8.9 liter ultra-low NO_x NG engine. The results are organized by gaseous emissions followed by PM, particle size distribution, greenhouse gases, and fuel economy. The emission factors presented in g/bhp-hr for comparison to the certification standard. Emissions in g/mile are provided in Appendix E. Error bars are represented by single standard deviations due to the relatively large magnitude of the error bars in relationship to the low emission levels measured for several species (three repeats were performed where the 95% confidence interval multiplier for the single standard deviation is 3.182).

The UDDS cycle is the representative test cycle for comparisons to the engine certification FTP cycle where the other cycles (port, refuse, and bus) provide the reader a feel for the in-use comparability to low duty cycles, cruise conditions, and other vocational specifics of the real world. As such, the results will be presented in each sub-section within the context of the test cycle.

3.1 Gaseous emissions

3.1.1 NOx emissions

The NO_x emissions are presented in Figure 3-1 for each of the methods evaluated and for all the test cycles performed. The NO_x emissions were below the demonstration 0.02 g/bhp-hr emissions targets for the UDDS, DPT1 (hot and cold), and the CBD for all measurement methods. The local and regional port cycles (DPT2 and DPT3) NO_x emissions were below the improved methods but at and below the standard for the traditional methods. The cold start emissions were higher than the hot tests when comparing between like tests (UDDS cold vs hot and DPT1 cold vs hot) and averaged at 0.043 g/bhp-hr for the UDDS test cycle (M3).

In general, the NO_x emissions are below the ISL G NZ 2016 NO_x certification standard of 0.02 g/bhp-hr for all tests and below the in-use NTE standard of 0.03 g/bhp-hr. The reported certification value listed on the ARB EO is 0.01 g/bhp-hr which is slightly lower than the M3 measurements (0.014 g/bhp-hr) shown for the UDDS hot test cycle, Figure 3-1. Deeper investigation shows one of the three hot UDDS tests was statistically higher (M3 = 0.009, 0.002, 0.030 g/bhp-hr). A similar trend was also found for the other four methods where the third point was much higher than the other two points. If the third point was eliminated the average for the hot UDDS would be just under the EO certification value reported by CWI (M3 = 0.005 g/bhp-hr). The test-to-test variability shown by the large error bars in Figure 3-1 was investigated where real-time analysis suggest the variability is not from low measurement issues, but appears to be the results of the vehicle variability. Section 4 provides a discussion on real-time investigation.

	UDDS1x	DPT1	UDDS2x	RTC	DPT1	DPT2	DPT3	CBD	Tunnel
	Cold Starts		Hot Starts						
NOx_M1	0.052	0.022	0.017	0.006	0.004	0.017	0.018	-0.003	0.000
NOx_M2	0.048	0.029	0.018	0.007	0.000	0.017	0.021	0.000	0.003
NOx_M3	0.043	0.014	0.014	0.002	0.002	0.013	0.014	0.001	0.001
NOx_M4	0.071	0.021	0.021	0.029	0.009	0.022	0.024	0.003	0.001

Figure 3-1 Measured NOx emission for the various test cycles

3.1.2 Other gaseous emissions

The hydrocarbon emissions (THC, CH_4, and NMHC) are presented in Figure 3-2. The HC are highest for the cold start tests compared to the hot tests where the regional port cycle (PDT3) showed the highest HC emissions. For all the hot tests the NMHC was below the standard but just above the reported certification value except for the regional port cycle. The NMHC was typically lower than CH_4 emission as one would expect for a NG fueled vehicle. The CH_4 emissions are lower than the certification results presented in Appendix F Figure F-4 (0.04 vs the FEL level of 0.65 g/bhp-hr). Also the CH_4 emissions for the refuse hauler are significantly lower (6.4 g/mi vs 0.26 g/mi) than previously tested NG reuse haulers with the 2010 certified NG 8.9 liter engine. The lower CH_4 emissions may be a result of the closed crankcase ventilation (CCV) improvement over previous versions of this engine, see Appendix F for details.

	UDDS1x	DPT1	UDDS2x	RTC	DPT1	DPT2	DPT3	CBD	Tunnel
	Cold Starts		Hot Starts						
CH4	0.535	0.558	0.043	0.080	0.263	0.155	0.325	0.114	0.004
NMHC	0.323	0.594	0.003	0.010	0.104	0.050	0.168	0.045	-0.019
THC	0.855	1.147	0.046	0.090	0.366	0.205	0.492	0.159	-0.015

Figure 3-2 Hydrocarbon emission factors (g/bhp-hr)

Figure 3-3 shows the CO emissions on a g/bhp-hr basis and Figure 3-4 shows the un-regulated NH_3 emissions on a g/bhp-hr basis. The CO emissions ranged between 1.3 to 5.3 g/bhp-hr for the cold start near dock (PDT1) and regional (DPT3) test cycles, respectively. The distance specific emissions ranged from 4.2 to 24.3 g/mi for the regional (PDT3) and the cold start UDDS test cycles. Previous testing of the ISG vehicle show similar CO emissions ranging from 14.4 to 19.2 g/mi (CBD and UDDS test cycles and same test weights).

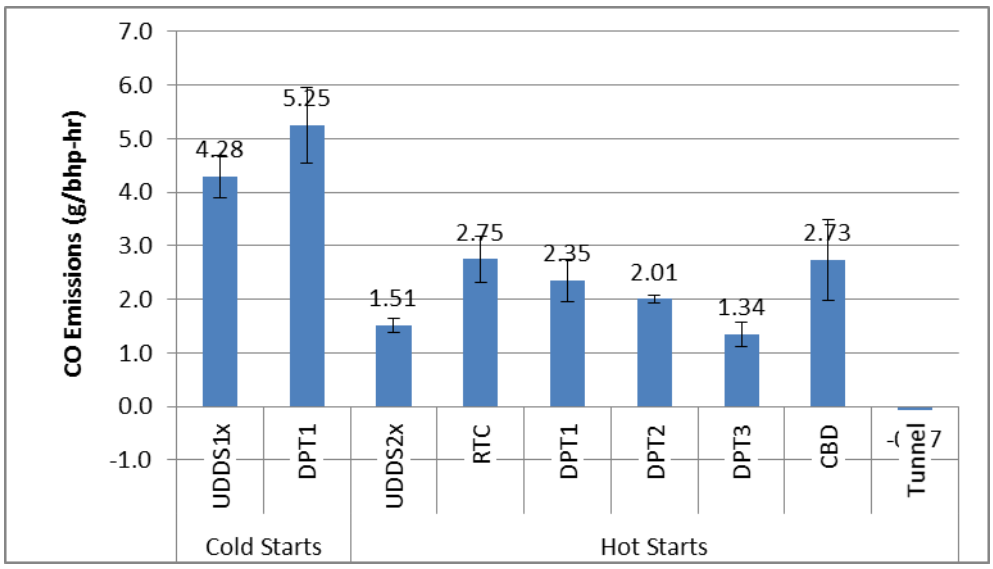

Figure 3-3 CO emission factors (g/bhp-hr)

The NH_3 emissions ranged from 0.43 to 0.94 g/bhp-hr for the hot UDDS and regional (DPT3) cycles. The distance specific emissions varied from 1.16 g/mi to 5.27 g/mi for the regional and CBD test cycles. The NH_3 emissions are slightly higher than previous ISL G vehicle where the NH_3 ranged from 1.17 to 2.8 g/mi for the UDDS and RTC cycle as compared to 1.19 and 4.09 g/mi for the ISL G NZ, respectively. The NH_3 concentration varied from 118 ppm (UDDS) to 305 ppm (CBD), see Figure 3-5.

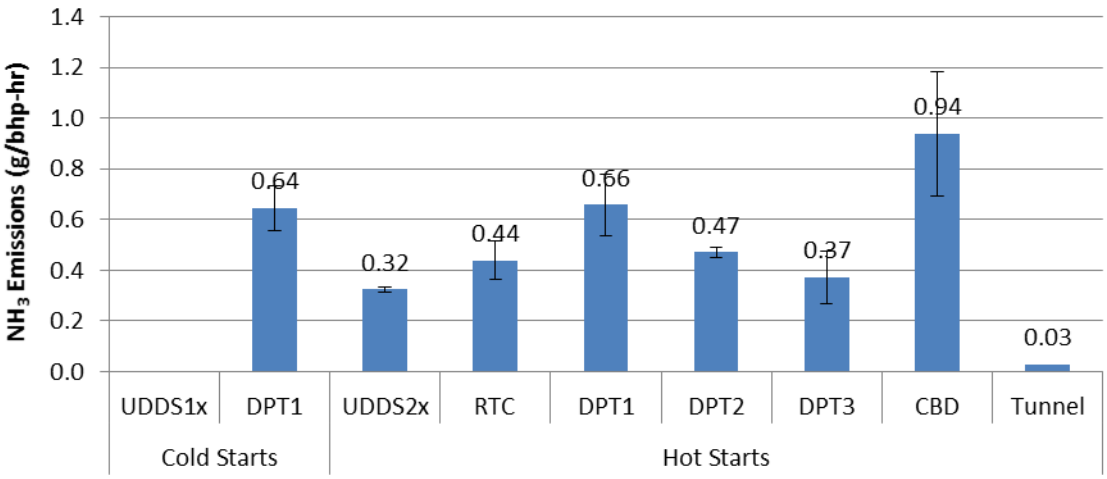

Figure 3-4 Ammonia emission factors (g/bhp-hr)

[1] NH_3 measurements for the cold UDDS test stopped working during the first hill where the system may have over ranged. The cold start UDDS NH_3 results are estimated at 20% higher than the hot-UDDS test.

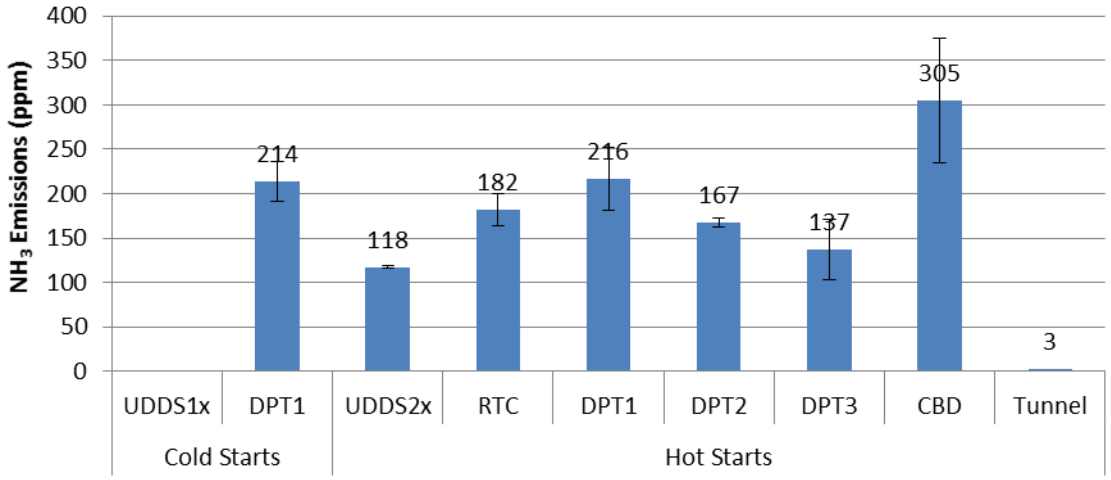

Figure 3-5 Ammonia measured tail pipe concentration (ppm)

[1] NH_3 measurements for the cold UDDS test stopped working during the first hill where the system may have over ranged. The cold start UDDS NH_3 results are estimated at 20% higher than the hot-UDDS test.

3.2 PM emissions

The PM emissions for all the tests including the cold start tests was typically 90% below the certification standard and close to UCR tunnel blank value of 0.42 g/bhp-hr (based on UDDS sample time and work), see Figure 3-6. The first regional PM filter weight was statistically higher than the other three (80, 21, 20 ug) where it is suggested something may have burned off

the exhaust system that test that may be artifact of previous vehicle operation. If the first PM results was eliminated the DPT3 EF would be reduced from 1.01 mg/bhp-hr to 0.5 mg/bhp-hr. In either case all the EF were well below the certification standard of 10 mg/bhp-hr. Low PM results are expected for a NG fueled engine where previous studies showed similar PM emissions well below 10 mg/bhp-hr.

The measured filter weights were 13 ug with a single standard deviation of 3 ug where the tunnel blank was measured at 5 ug (representative of 0.42 g/bhp-hr using the UDDS sample conditions). As such, the PM emission rates are very low and the shown variability may be a result of measurement detection capability more than vehicle performance between cycles.

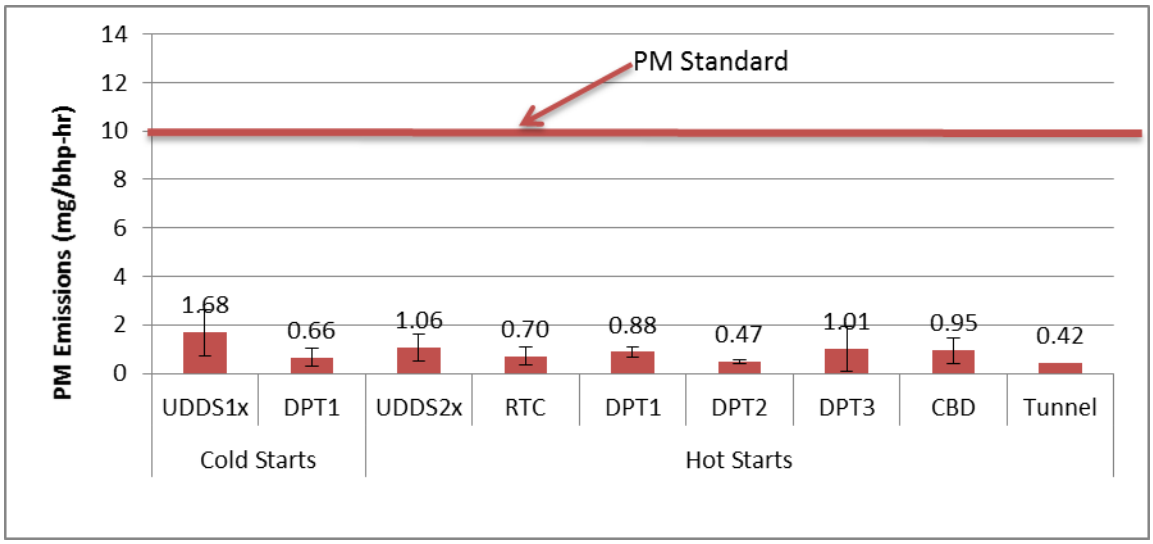

Figure 3-6 PM emission factors (mg/bhp-hr)

[1] Tunnel PM emission factor was based on a tunnel blank and test conditions of the UDDS 2x load conditions for the ISL G NZ test engine.

3.3 PN emissions

The PN emissions (CPC 3772) are shown in Figure 3-7 and Table 3-1 for the test cycles performed. The PN were highest for the high speed regional cycle (DPT3) on a total # basis, but were highest on a #/mi basis for the cold start near dock cycle (PDT1). Since the UDDS cycle is representative of the FTP certification cycle, comparisons to the hot UDDS cycle are presented in Table 3-2 (#/mi basis). The statistical analyses in Table 3-2 were conducted using a 2-tailed, 2 sample equal variance t-test. For the statistical analyses, results are considered to be statistically significant for $p < 0.05$, or marginally statistically significant for $0.05 < p < 0.1$. The near dock port cycle (DPT1) and the UDDS cold start showed statistically significant mean differences where the regional port cycle (DPT 3) showed marginally significant mean difference to the UDDS hot test. The cold start UDDS showed about three times the PN compared to the hot UDDS. The regional cycle showed about 82% more PN compared to the UDDS cycle and the near dock (DPT 1) showed 92% fewer PN. The trash compaction cycle (RTC) and the local port cycle (PDT 2) had similar PN emission rates and did not show statistically different means.

During previous studies with 0.2 g/bhp-hr certified NO_x ISL G engine tested on the near dock and regional port cycles, the PN emissions were $1.9 \times 10^{12} \pm 3.8 \times 10^{11}$ #/mi (11) which was about

92% lower than the ISL G NZ UDDS test cycle results, but about the same as the near dock port cycle. In a second study with the ISL G 8.9 liter engine, the PN emissions were $4x10^{12}$ for the CBD test cycle (10) which agrees well with the results in this study for the near dock and CBD test cycles. During a similar refuse hauler application of the ISL G engine, the PN emissions for the RTC cycle were $2.5x10^{13}$, $5.8x10^{12}$, and $2.0x10^{12}$ #/mi for the curbside, transit, and compaction portions of the RTC test cycle, respectively (12) which compare well with the PN from the ISL G NZ results. Late model diesel engines equipped with DPFs show PN emissions that range from $1.3x10^{11}$ to $0.7x10^{11}$ for on-road UDDS and cruise type of tests (18). In general the PN emissions for the ISL G NZ are mixed in comparison to the ISL G with some higher and some about the same. The ISL G NZ and ISL G both show higher PN emissions compared to diesel vehicles equipped with DPFs.

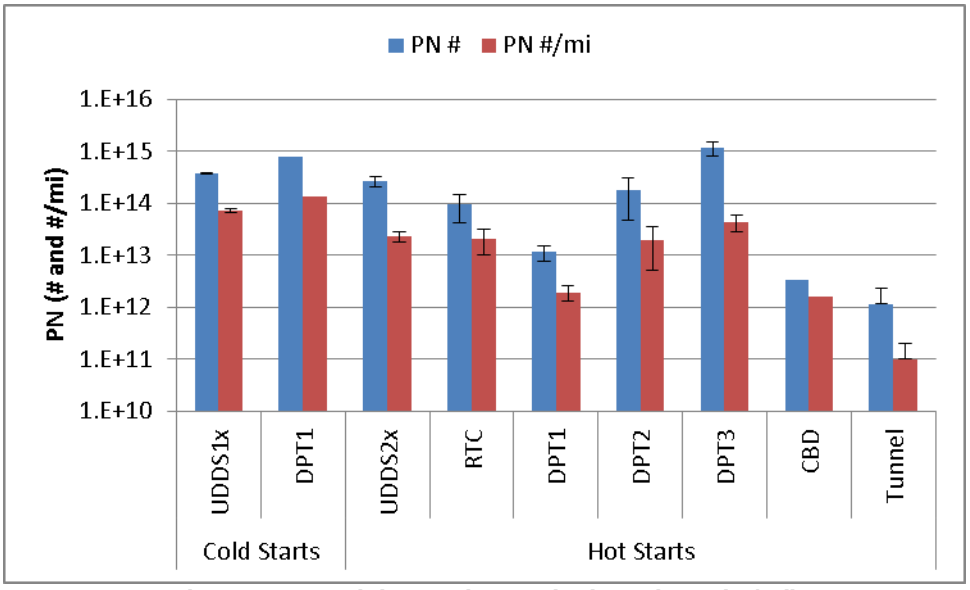

Figure 3-7 Particle number emissions (# and #/mi)

[1] Note the PN presented are based on CVS dilute measurements without sample conditioning (no volatile particle catalytic stripper system) and a D50 of 3 nm (CPC 3776). These PN values will be higher than those presented by the PMP system which uses a 3790A counter (24 nm D50 cut diameter and a volatile particle catalytic stripper system).

Table 3-1 PN Emissions from the ISL-G NZ 8.9 liter engine for various cycles

	PN #		PN #/mi

DPT3	0.104	0.227	82%

[1] Unpaired two tailed sample equal variance t-test and mean % difference from the UDDSx2 test cycle

3.4 Ultrafines

The ultrafine PSD (as measured by the EEPS) are shown in Figure 3-8 on a log-log scale concentration basis as measured in the dilute CVS. The cold start UDDS and the regional (DPT3) cycles showed the highest particle number concentration at 10 nm particle diameter of all the traces. The higher PSD for the cold UDDS and regional cycle are a result of PN spikes under different conditions. The cold start UDDS PSD PN spike occurred during the cold portion and for the hot regional cycle (DPT3) the spike occurred during the cruise. The secondary peak at 105 nm particle diameter was highest for the same two cycles and the CBD. DPT1 showed the lowest PSD and was typically below the tunnel blank concentrations. During previous testing on the ISL G 8.9 liter engine the PSD showed a similar bi-modal PSD at 10 nm and 110 nm (10, 11, and 12). Diesel vehicles equipped with a DPF only show a single mode of operation (when not in a DPF regeneration) for the same UDDS and port cycles tested on the ISL G NZ vehicle (2).

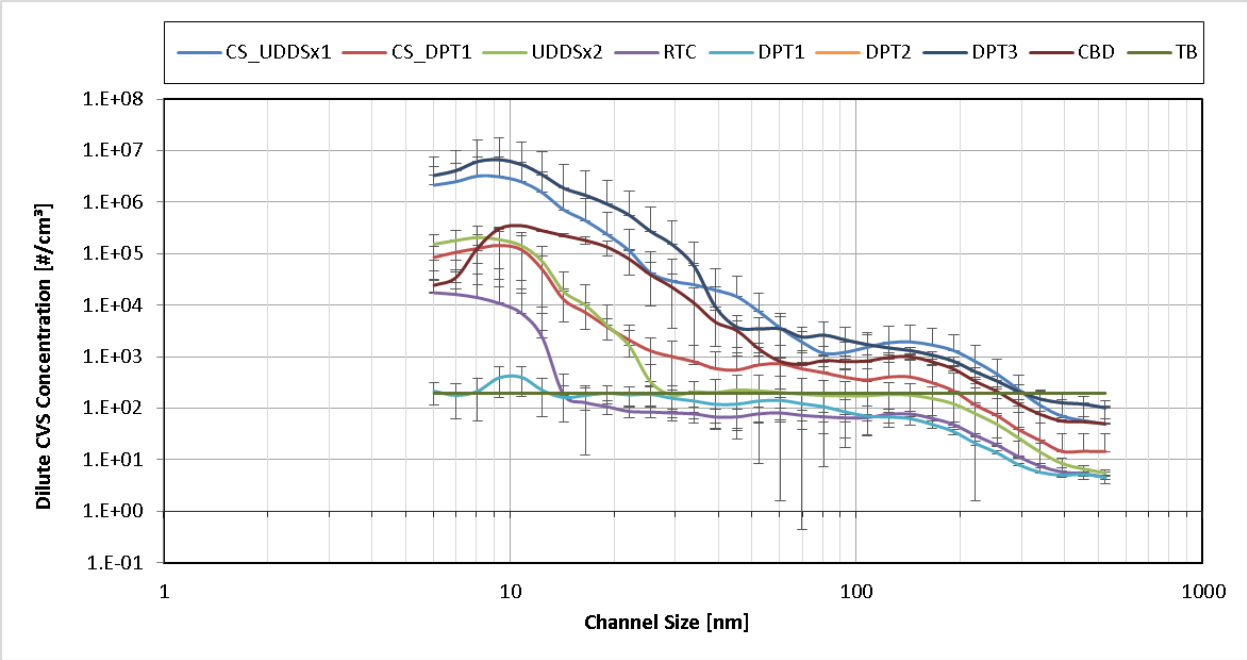

Figure 3-8 EEPS ultrafine PSD measurements for each of the test cycles

3.5 Greenhouse gases

The greenhouse gases include CO_2, CH_4 and N_2O and are reported here to characterize the vehicles global warming potential (GWP). The GWP calculations are based on the

intergovernmental panel on climate change (IPCC) values of 25 times CO_2 equivalent for CH_4 and 298 times CO_2 equivalent for nitrous oxide (N_2O), IPCC fourth assessment report - 2007. The global warming potential is provided in Table 3-3 on a g/bhp-hr basis (see Appendix E for g/mi basis). The CH_4 and N_2O emissions are low and represent 5% for the cold start tests and around 1-2% for the hot start tests.

Greenhouse gases from vehicles are also found in PM emissions for their absorption of solar radiation. The main species of the PM responsible for solar absorption is called black carbon (BC). BC is a short lived climate forcer and is not grouped with the CO_2 equivalent method, and is treated here separately. UCR quantified the BC emissions (referred to as equivalent black carbon eBC) from the vehicle with its AVL micro soot sensor 483 (MSS) which measures the PM soot or eBC. Table 3-3 lists the soot PM for each cycle and the ratio of soot/total PM emissions. The results suggest less than 10% of the PM measured for all the cycles except the regional port cycle are BC and during the regional cycle up to 22% of the total PM measured is BC. Additional analysis showed that the measured average concentration ranged between 2-3 ug/m3 when corrected for water interferences (as reported by manufacturer) the concentration was~ 1ug for all tests. The low concentrations are at the detection limits of the MSS instrument and suggests the measured BC cannot be quantified accurately, but may suggest BC is not significant for the ISL G NZ NG engine.

Table 3-3 Global warming potential for the ISLG NZ vehicle tested (g/bhp-hr)

Trace	CO_2	CH_4	N_2O	GWP ($CO_{2\,eq}$)	CO_2/GWP	Soot	Soot/$PM_{2.5}$
UDDS1x	546.8	0.53	0.062	578.5	0.95	0.05	3%
DPT1	627.0	0.56	0.090	667.7	0.94	0.02	3%
UDDS2x	548.9	0.04	-	555.0	0.99	0.06	5%
RTC	577.0	0.08	-	584.0	0.99	0.01	1%
DPT1	649.8	0.26	-	661.4	0.98	0.07	8%
DPT2	597.0	0.16	0.027	608.9	0.98	0.1	22%
DPT3	549.3	0.33	0.024	564.4	0.97	0.01	1%
CBD	576.1	0.11	0.034	589.0	0.98	0.04	4%

[1] N_20 samples were not collected on the hot UDDS, RTC, and DPT1 due to scheduling details. PM Soot measurements were near the detection limits of the MSS-483 measurement system. The MSS soot signal was corrected for a 1 ug/1% water interference factor as reported by AVL.

3.6 Fuel economy

The fuel economy of the NG vehicle is evaluated by comparing the CO_2 emissions between cycles where the higher the CO_2 the higher the fuel consumption. CO_2 is also regulated by EPA with a standard as performed with the FTP and SET test cycles. The certification like cycle (UDDS) showed the lowest CO_2 emissions and were below 555 g/bhp-hr (FTP standard) for both the cold start and hot start tests. The NG vehicle CO_2 emissions varied slightly between cycles where only the near dock cycle (DPT1) showed a statistically higher CO_2 emission rate. The average CO_2 for all the cycles was 584 g/bhp-hr, and 565 g/bhp-hr with the PDT1 cycle removed. The CO_2 standard and certification value is 555 g/bhp-hr and 465 g/bhp-hr respectively for this displacement engine, see Figure F1 Appendix F. The standard is the target and the certification value is the value measured by the manufacturer. It is suggested the higher in-use CO_2 value (ie in the chassis vs on a test stand) could be a result of additional losses in the chassis where the certification test occurs with the engine on a test stand.

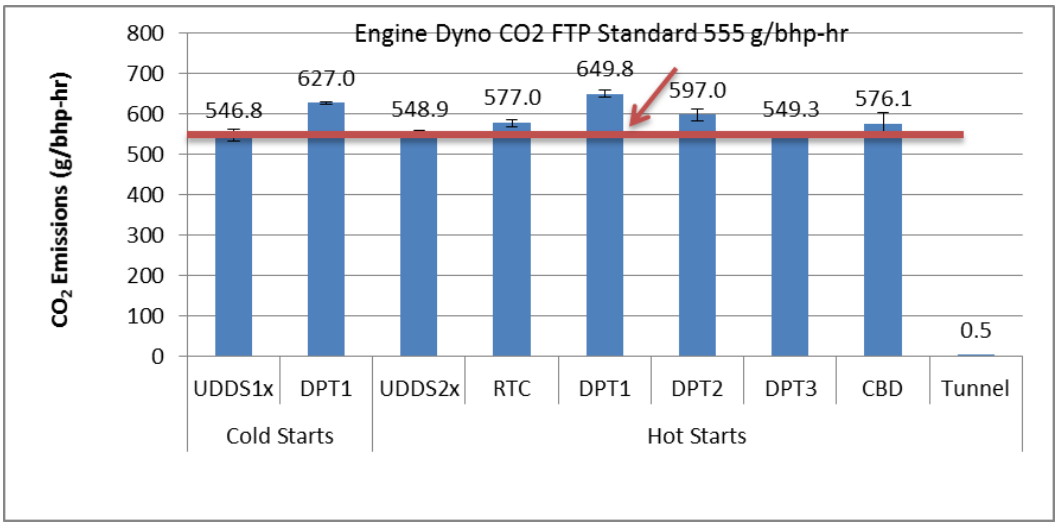

Figure 3-9 CO_2 emission factors (g/bhp-hr)

The ISL G-NZ MPG on a diesel gallon equivalent (MPG_{de}) basis (assuming 2863gNG/gallon diesel (14)) ranges from 4.5 MPG_{de} for the regional port cycle (DPT3) to 2.5 MPG_{de} for the CBD cycle. During previous testing, the previous ISL G 8.9 L fuel economy was found to be 2365 g/mi on a chassis dynamometer at 56,000 GVW following the UDDS test cycle.

4 Discussion

This section discusses investigation into the real-time data to characterize the impact of the cold start and transient NO_x emissions.

4.1 Transient emissions

Figure 4-1 shows the real-time NO_x mass emission rate (g/sec) for the three repeated UDDS cycles. Test 0813 and 1020 had large NO_x spikes, one near the beginning of the test and one near the end of the test where test ID 0915 had only small spikes which are not apparent in Figure 4-1. This indicates that NOx emissions are essentially zero except during sharp accelerations. Figure 4-2 shows the accumulated NO_x emissions as a function of time. The results in Figure 4-2 show the impacts the large and small spikes have on the accumulated NO_x emissions. Test 0915 and 1020 were very similar except for the large spike near the end of the 1020 test.

Figure 4-3 shows the percent of total NOx accumulate as a function of time. The one large spike for test 1020 represented 90% of the total emissions. If the single NOx spike did not occur, the EF for the triplicate cycle would have been close to 0.005 g/bhp-hr instead of the 0.014 g/bhp-hr reported. Figure 4-4 shows the real time NOx emission rate (g/s) exhaust flow, engine RPM, and engine power at the time where the spike occurred. The NOx spike appears to be occurring at the transition from idle to loaded conditions. The figure shows that NOx emission rate and exhaust flow are lined up well suggesting there is not a measurement issue but a real event. In general the transient nature of the emissions suggest the NOx emission are low and are typically below 0.02 g/bhp-hr when good control of the engine stoichiometry is maintained.

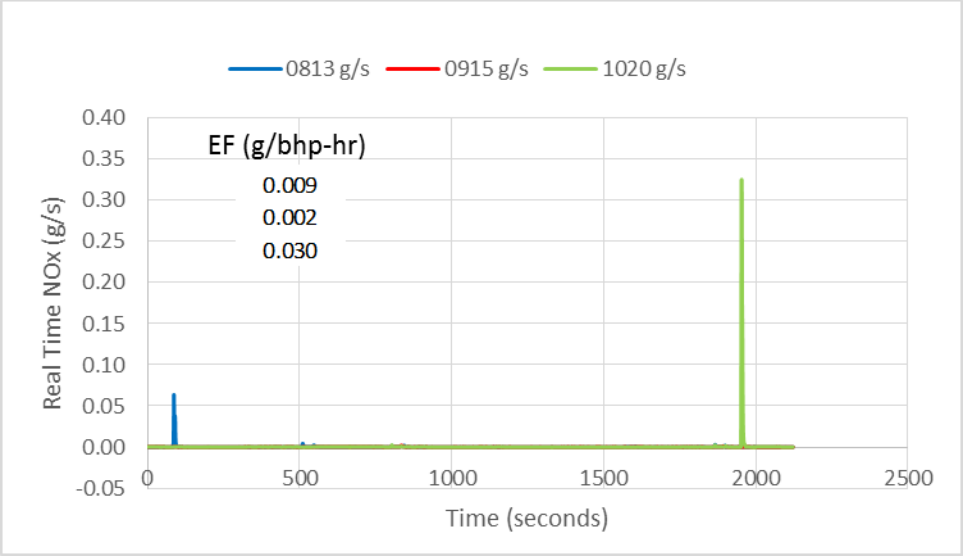

Figure 4-1 Real-time mass rate NOx emissions (g/sec) UDDS cycles

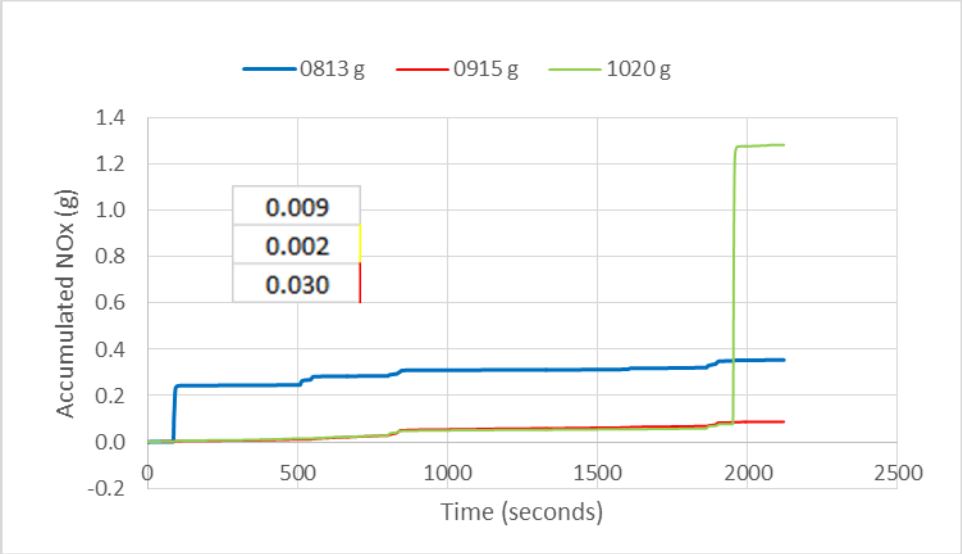

Figure 4-2 Accumulated mass NOx emissions UDDS cycles

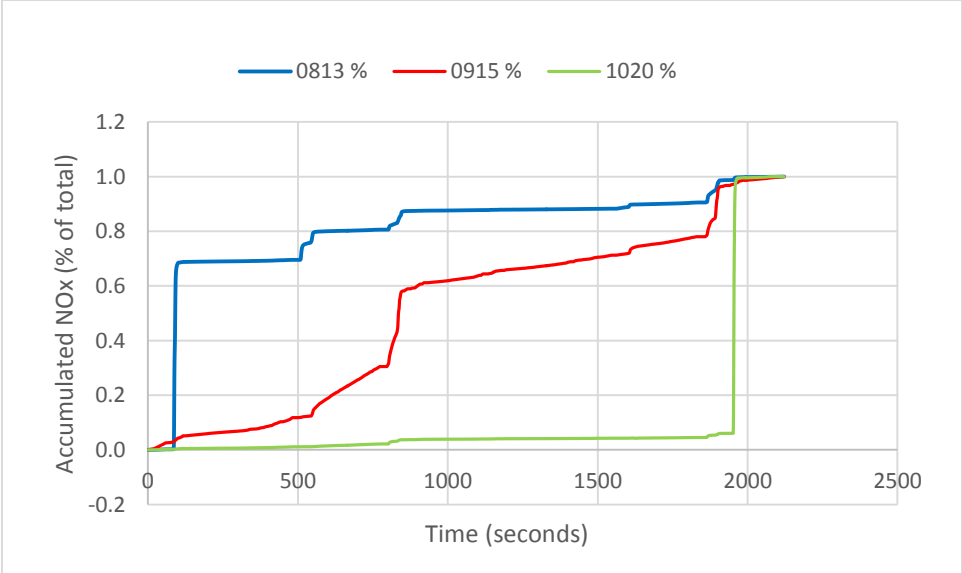

Figure 4-3 Real time NOx emissions (percent of total)

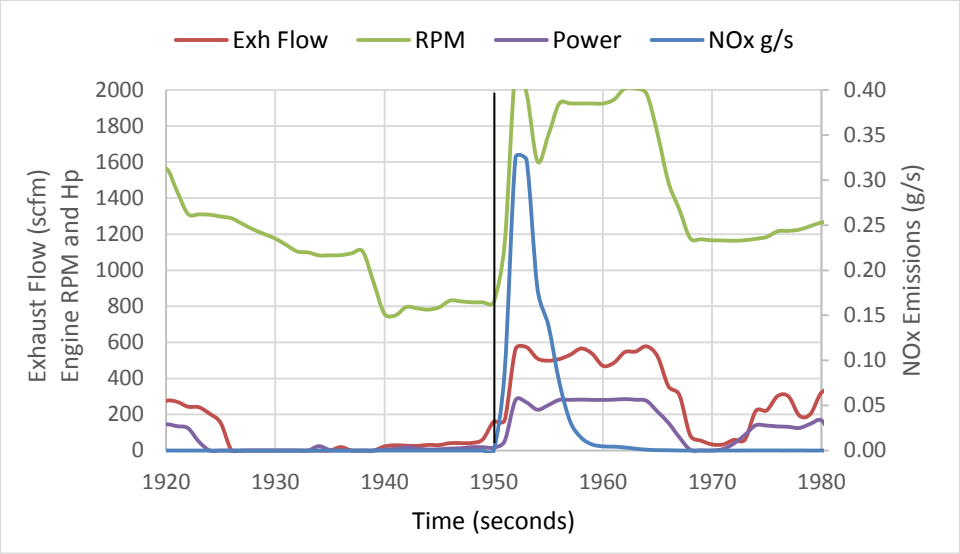

Figure 4-4 Real time NOx emissions large spike evaluation

4.2 Cold start emissions

Cold start emissions represented a significant part of the total emissions as one would expect. Figure 4-5 shows the accumulated NO_x (g) and exhaust temperature as a function of time. 90% of the NO_x emissions occurred in the first 200 seconds of the cold start test. The remaining part of the cold UDDS test was very similar to the hot UDDS test. The UDDS hot/cold weighted emissions is 0.0181 g/bhp-hr (weighted as $1/7^{th}$ of the hot cycle). Given that the cold start lasted 200 seconds out of 1080 seconds (total cycle length) the weighted cold start emissions ($1/7^{th}$ of the hot test) are, thus, based on 200sec/1080sec/7 = 2.6%. This suggests 2.6% of this vehicles in-use emissions are represented by a cold start as defined by how the certification process computes its impact for the regulation process. Also unique to the NG solution, once the catalyst performance is achieved it remains at this high performance unlike the diesel SCR equipped engines where low duty cycle will cause the NOx emissions to increase again.

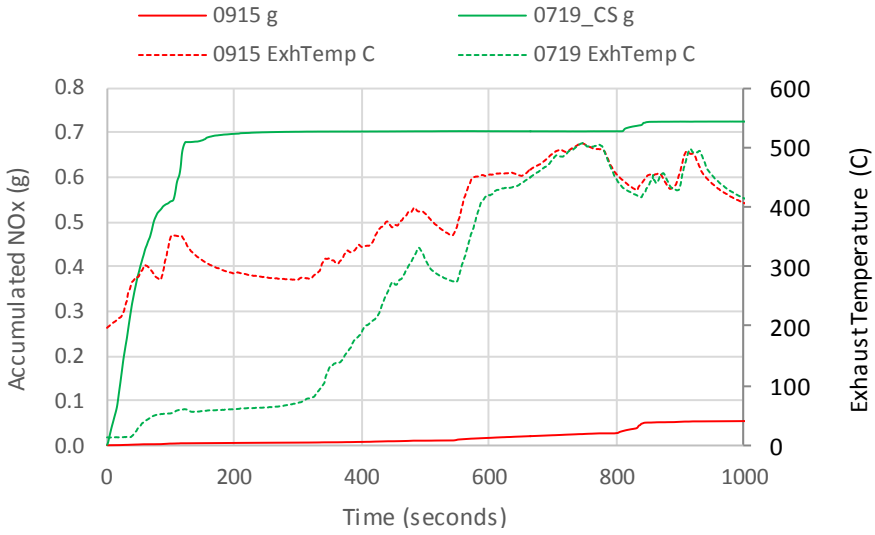

Figure 4-5 Accumulated NOx emissions hot vs cold UDDS comparison

5 Summary and Conclusions

The testing was performed on UC Riverside's chassis dynamometer integrated with its mobile emissions laboratory (MEL) located in Riverside CA just east of the South Coast Air Quality Management District (SCAQMD). The cycles selected for this study are representative of operation in the South Coast Air Basin and included the urban dynamometer driving schedule, the near dock, local, and regional port cycles, the AQMD refuse cycle, and the central business district cycle.

One of the difficulties in quantifying NO_x emissions at the levels proposed in this research (90% below the 2010 certification level ~ 0.02 g/bhp-hr) is the dilute measurement methods are too close to the detection limit to quantify NO_x emissions at the 5% accuracy expected from the emissions industry. Three upgraded NO_x measurement methods were considered which include a raw NO_x measurement integrated with real time exhaust flow, a real-time ambient correction approach, and a trace level ambient analyzer for accurate bag analysis. In summary the improved methods varied in their success; however, the raw sampling approach was the most accurate and precise over the range of conditions tested.

In general the ISL G NZ 8.9 met and exceeded the target NO_x emissions of 0.02 g/bhp-hr and maintained those emissions during a range of duty cycles found in the South Coast Air Basin. It is expected NG vehicles could play a role in the reduction of the south coast NOx inventory problem given their near zero emission factors demonstrated

The main conclusions can be summarized as (conclusions are based on the Method 2 results unless noted otherwise):

1. The ILS G NZ 8.9 liter NG engine showed NO_x emissions below the 0.02 g/bhp-hr emission target and averaged between 0.014 and 0.002 g/bhp-hr for hot start tests.
2. The cold start tests ranged from 0.043 to 0.014 g/bhp-hr for the UDDS and DPT2 cycles. The UDDS hot/cold weighted emissions was 0.0181 g/bhp-hr for all test cycles performed which is below the certified 0.02 g/bhp-hr emission factor.
3. The NO_x emissions did not increase with lower power duty cycles and showed the opposite trend where the lower power duty cycles showed lower NO_x emissions unlike the diesel counterparts
4. The large NO_x error bars suggest measurement variability, but real-time data shows the variability is isolated to a few NO_x events during rapid tip-in events from accelerations from idle. This suggests possible driver behavior may impact the overall NO_x in-use performance of the vehicle and more gradual accelerations are desired for minimum emissions.
5. This suggests possible driver behavior may impact the overall NO_x in-use performance of the vehicle where more gradual accelerations are desired.
6. The other gaseous and PM emissions were similar to previously measured levels from the 0.2 g/bhp-hr ISL G engine and should not add to any unknown impacts for the use of the NZ engine in the heavy duty fleet.

Appendix A. Test Log

This Appendix contains detailed test logs recorded during engine and chassis dynamometer testing. The testing was performed on Vehicle ID 2015_016, Project Low NOx 2015, Vehicle VIN = 3BPZX20X6FF100173 with the test mode in Conventional mode. The chassis and vehicle operators were Eddie and Don for all the testing and the instrument operators were Mark, Jade, Danny and Joey.

Appendix B. Test Cycle Description

The test vehicle utilizes an 8.9 liter NG engine which is available for three typical vocations in the South Coast Air Basin, 1) goods movement, 2) transit bus, and 3) refuse. As such UCR tested the vehicle following the three drayage type port cycles (Near Dock, Local, and Regional), the Urban Dynamometer Driving Schedule (UDDS), the Central Business District (CBD) bus cycle, and the AQMD Refuse cycle. These cycles are representative of Sothern California driving vocations used. Some cycles are very short (less than 30 minutes) where double or triple cycles (2x or 3x) cycles are recommended in order capture enough PM mass to quantify emissions near 1 mg/bhp-hr.

Drayage Truck Port (DTP) cycle

TIAX, the Port of Long Beach and the Port of Los Angeles developed the port cycle. Over 1,000 Class 8 drayage trucks at these ports were data logged for trips over a four-week period in 2010. Five modes were identified based on several driving behaviors: average speed, maximum speed, energy per mile, distance, and number of stops. These behaviors are associated with different driving conditions such as queuing or on-dock movement, near-dock, local or regional movement, and highway movements (see Table B-1 for the phases). The data was compiled and analyzed to generate a best fit trip (combination of phases). The best-fit trip data was then additionally filtered (eliminating accelerations over 6 mph/s) to allow operation on a chassis dynamometer.

The final driving schedule is called the drayage port tuck (DPT) cycle and is represented by 3 modes where each mode has three phases to best represent near dock, local, and regional driving as shown in Table B-1, B-2 and Figure B-1. The near-dock (DTP-1) cycle is composed of phase 1, 2, and 3a from Table B-1. This gives the complete near-dock cycle listed in Table B-2. Similarly, for the Local and Regional cycles (DPT-2 and DPT-3) the main difference is phase 3, which changes to 4 and 5 respectively. Phase 1 and 2 remain the same for all three cycles where creep and low speed transient are considered common for all the port cycles. For this testing it is recommended to perform phase 1 through 5 individually and to calculate the weighted emissions from the combined phases for an overall weighing impact.

Table B-1. Drayage Truck Port cycle by phases

Description	Phase #	Distance mi	Ave Speed mph	Max Speed mph	Cycle length
Creep	1	0.0274	0.295	4.80	335
low speed transient	2	0.592	2.67	16.8	798
short high speed transient	3	4.99	9.39	40.6	1913
Long high speed transient	4	8.09	13.07	46.4	2229
High speed cruise	5	24.6	35.04	59.3	2528

Table B-2. Drayage Truck Port cycle by mode and phases

Description	Distance mi	Ave Speed mph	Max Speed Mph	Mode 1	Mode 2	Mode 3
Near-dock PDT1	5.61	6.6	40.6	Creep	Low Speed Transient	Short High Speed Transient
Local PDT2	8.71	9.3	46.4	Creep	Low Speed Transient	Long High Speed Transient
Regional PDT3	27.3	23.2	59.3	Creep	Low Speed Transient	High Speed Cruise

Figure B-2 Drayage truck port cycle conditioning segments consisting of phase 3 parts

Urban Dynamometer Driving Schedule (UDDS) description

The Federal heavy-duty vehicle Urban Dynamometer Driving Schedule (UDDS) is a cycle commonly used to collect emissions data on engines already in heavy, heavy-duty diesel (HHD) trucks. This cycle covers a distance of 5.55 miles with an average speed of 18.8 mph, sample time of 1061 seconds, and maximum speed of 58 mph. The speed/time trace for the HUDDS is provided below in Figures B-3. This cycle was used for all cold start tests as a single test and was performed in duplicate for all hot tests. Duplicates were used to accumulate sufficient mass for the gravimetric measurement method.

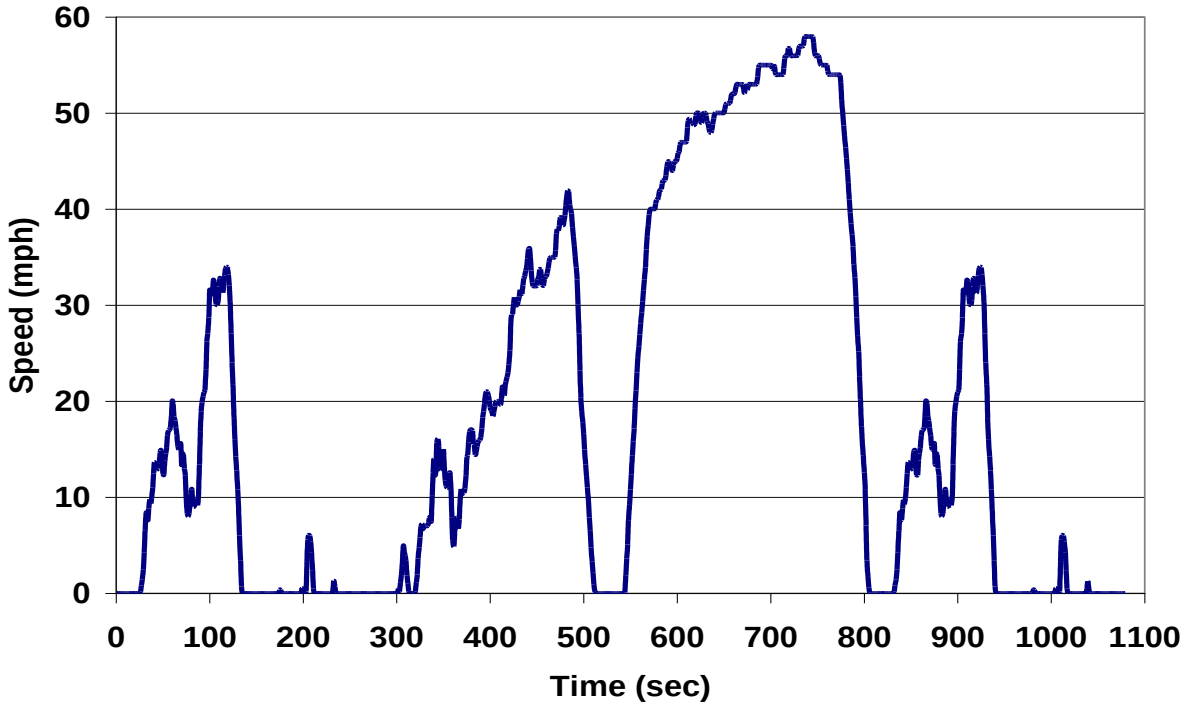

Figure B-3. Speed/Time Trace for a 1xHUDDS cycle for the chassis dynamometer.

The AQMD refuse truck cycle

The AQMD refuse truck cycle (AQMD-RTC) is the same as the WHM-RTC in that the cycle consists of a transport, curbside and compaction operation, with the main difference being the length of time and arrangement of the individual modes. The duration of the AQMD-RTC transport and curbside is 2127 seconds, representing a distance of 4.56 miles and the compaction adds another 760 seconds for a total of 2887 seconds. Figure A-4 shows the vehicle speed vs. time trace for the cycle preparation, transport (phase 1) and curbside (phase 2) portion of the cycle. The curb side pick-up mode is representative of multiple short idle times with frequent stop-and-go operation. The cycle is characterized by frequent accelerations and decelerations. The frequent stop-and-go operation could lead to lower catalytic activity and higher mass tailpipe emissions rates.

Real-world compaction operation was obtained from ECU engine load. It was observed that the engine load varied from 80 to 20 hp in a cyclical manner. The compaction cycle is simulated with the vehicle operating at steady-state speed of 30 mph with an intermittent engine of 80 hp and 20 hp. The total duration of the compaction cycle (phase 3) is 880 seconds, see Figure A-5 for the vehicle speed vs. time trace and axle power loading of the compaction cycle. The emissions are collected for only the stabilized speed which occurs 80 seconds into the trace and ends 40 seconds before the end of the trace for a total of 760 seconds.

Since, the compaction operation does not accrue any driving miles in real-world, the emissions from the compaction cycle are represented on a time-specific basis. Further, in order to represent the distance-specific emissions of the refuse truck operation as a whole, the total mass of emissions from the compaction cycle is added to the transport and curbside emissions divided by

the distance of the transport and curbside portion. Thus, it is expected the distance specific emissions on the refuse cycle will be higher than the transport plus curbside emissions since the compaction cycle didn't accumulate any distance.

UCR's MEL was configured with the conditioning and transport plus triple curbside into a signal cycle where the sampling was started at second 526 (Start of Transport Phase 1). After completing Phase 2 (Curbside), the compaction cycle was loaded and the driver brought the vehicle speed up to 30 mph and then the dyno was put in a load cycle mode that oscillated from 20 to 80 hp as shown in Figure B-5.

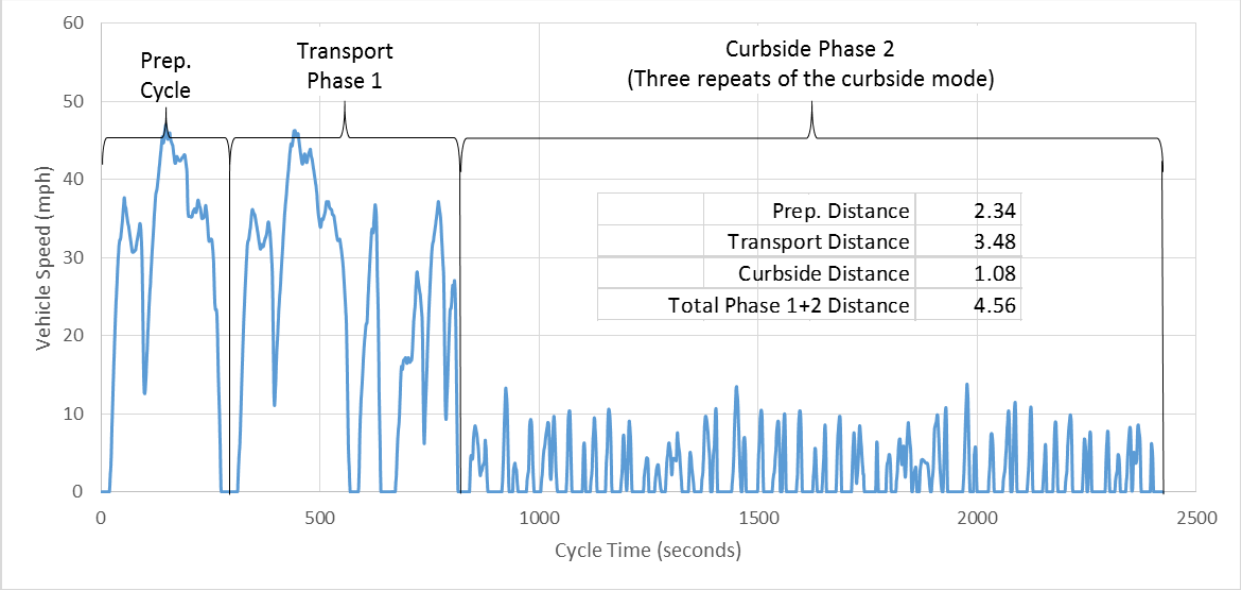

Figure B-4 Speed trace for AQMD refuse truck driving cycle

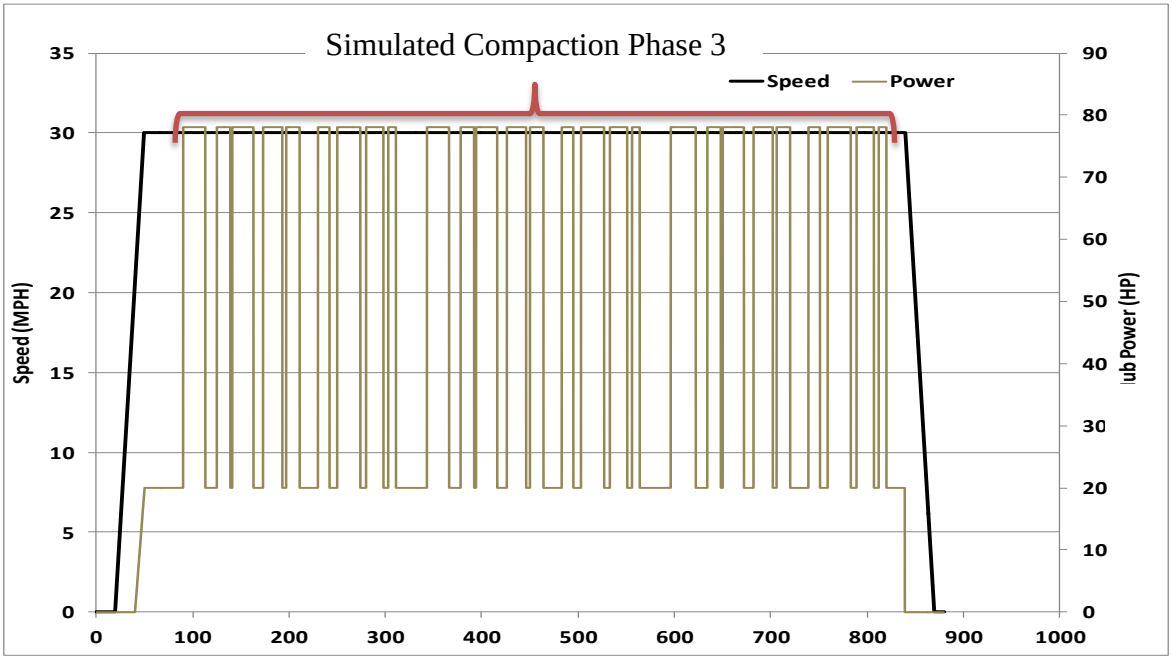

Figure B-5 Speed trace for AQMD refuse truck compaction cycle

Central Business District (CBD) Cycle

The Central Business District (CBD) Cycle is a chassis dynamometer testing procedure for heavy-duty vehicles (*SAE J1376*). The CBD cycle represents a "sawtooth" driving pattern, which includes 14 repetitions of a basic cycle composed of idle, acceleration, cruise, and deceleration modes. The following are characteristic parameters of the cycle:

- Duration: 560 s
- Average speed: 20.23 km/h
- Maximum speed: 32.18 km/h (20 mph)
- Driving distance: 3.22 km
- Average acceleration: 0.89 m/s^2
- Maximum acceleration: 1.79 m/s^2

Vehicle speed over the duration of the CBD cycle is shown in Figure A-1.

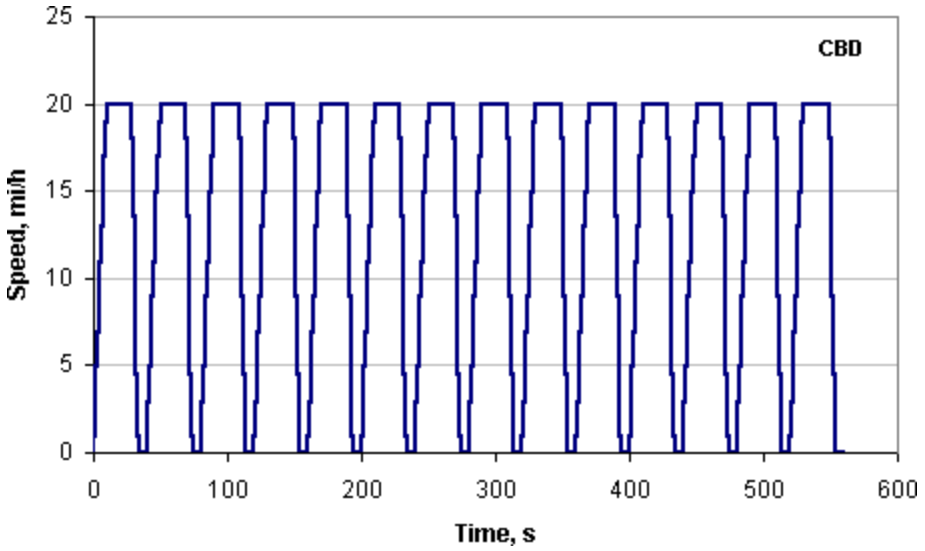

Figure B-6. CBD Driving Cycle

The standard CBD test cycle will be used for bus testing where three cycles will be combined for a triple CBD for a total sample time of 30 minutes. Performing the CBD cycle three times in one test allows for additional sample volumes to be collected for all batched type analysis (filters, DNPH, BETEX and N_2O). Preconditioning is defined as performing a previous triple CBD and a 20 minute soak to improve repeatability between hot repeats. Emissions analyses for gaseous emissions will also be collected over the triple CBD cycles. This cycle is shown in Figure A-2. The triple CBD cycle will be repeated in triplicate for repeatability metrics as described earlier.

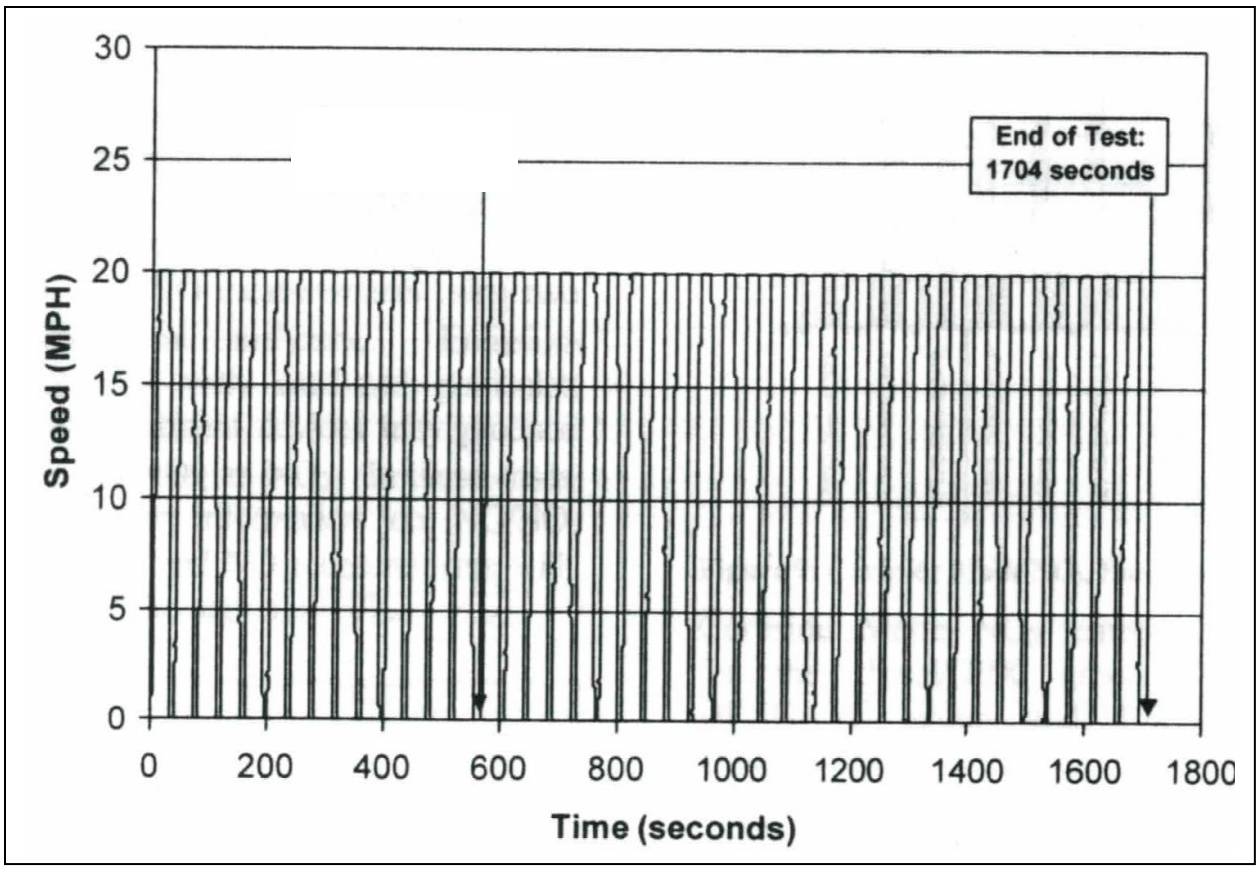

Figure B-7. Triple CBD Cycle

Appendix C. UCR Mobile Emission Laboratory

The approach used for measuring the emissions from a vehicle or an engine on a dynamometer is to connect UCR's heavy-duty mobile emission lab (MEL) to the total exhaust of the diesel engine. The details for sampling and measurement methods of mass emission rates from heavy-duty diesel engines are specified in Code of Federal Regulations (CFR): Protection of the Environment, Section 40, Part 1065. UCR's unique heavy-duty diesel mobile emissions laboratory (MEL) is designed and operated to meet those stringent specifications. MEL is a complex laboratory and a schematic of the major operating subsystems for MEL are shown in Figure C-1. The accuracy of MEL's measurements have been checked/verified against ARB's[10] and Southwest Research Institute's[11,12] heavy-duty diesel laboratories. MEL routinely measures Total Hydrocarbons (THC), Methane, Carbon Monoxide, Carbon Dioxide, Nitrogen Oxides, and Particulate Matter (PM) emissions from diesel engines. Design capabilities and details of MEL are described in Cocker et al[1,13]. Samples can be collected for more detailed analyses such as hydrocarbon speciation, carbonyl emissions, polynuclear aromatic hydrocarbons, etc.

Appendix D. Heavy-Duty Chassis Dynamometer Laboratory

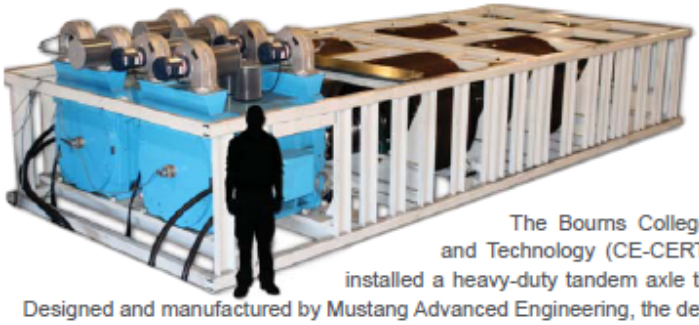
UCR's chassis dynamometer is an electric AC type design that can simulate inertia loads from 10,000 lb to 80,000 lb which covers a broad range of in-use medium and heavy duty vehicles, see Figure D-1. The design incorporates 48" rolls, axial loading to prevent tire slippage, 45,000 lb base inertial plus two large AC drive for achieving a range of inertias. The dyno has the capability to absorb accelerations and decelerations up to 6 mph/sec and handle wheel loads up to 600 horse power at 70 mph. This facility was also specially geared to handle slow speed vehicles such as yard trucks where 200 hp at 15 mph is common.

The chassis dynamometer was designed to accurately perform the new CARB 4 mode cycle, urban dynamometer driving schedule (UDDS), refuse drive schedule (WHM), bus cycles (CBD), as well as any speed vs time trace that do not exceed the acceleration and deceleration rates. The load measurement uses state of the art sensing and is accurate to 0.05% FS and has a response time of less than 100 ms which is necessary for repeatable and accurate transient testing. The speed accuracy of the rolls is ± 0.01 mph and has acceleration accuracy of ± 0.02 mph/sec which are both measured digitally and thus easy to maintain their accuracy. The torque transducer is calibrated as per CFR 1065 and is a standard method used for determining accurate and reliable wheel loads.

Figure D-1. UCR's heavy duty chassis eddy current transient dynamometer

Mustang Publication “Project Spotlights” March 2010

Mustang Advanced Engineering delivers a newly designed 48” Electric AC Heavy-Duty Truck Chassis Dynamometer with dual, direct-connected 300-hp AC motors to The University of California - Riverside, College of Engineering - Center for Environmental Research and Technology (CE-CERT).



The science of measuring emissions from mobile and other sources has evolved significantly over the past several years. The most important changes in the nature of emissions measurement science has been a shift to examining emissions from diesel sources and to understanding emissions under in-use driving conditions.

The Bourns College of Engineering – Center for Environmental Research and Technology (CE-CERT) at The University of California Riverside has recently installed a heavy-duty tandem axle truck chassis dynamometer in the facility’s research area. Designed and manufactured by Mustang Advanced Engineering, the development of this chassis dynamometer design was based on targeting vehicles in the medium to heavy-duty diesel vehicle range. Heavy-duty applications that can be tested at the facility include on-highway trucks, buses, waste haulers, yard tractors, and more - under test conditions representative of their specific in-use operations. The facility couples the new heavy-duty chassis dynamometer from Mustang Advanced Engineering with CE-CERT’s Mobile Emissions Laboratory (MEL), to perform precise vehicle simulation and in-operation emissions measurements.

The first research conducted on the new facility will be a comparison of federally mandated diesel fuel formulas versus the stricter formulation required in California. The program calls for 10 heavy-duty trucks to be tested with several different fuels.

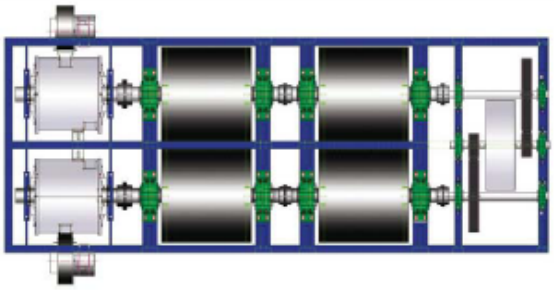
The new dynamometer will simulate on-road driving conditions for any big rig using its 48" precision rollers with dual, direct connected, 300 horsepower motors attached to each roll set. The dynamometer applies the appropriate loading to a vehicle to simulate factors such as the friction of the roadway and wind resistance that it would experience under typical driving conditions. An additional large inertia weight was incorporated into the dynamometer to increase the base mechanical inertia and enable the dynamometer to provide precise on-road simulation for a wide range of vehicle weights. The driver accelerates and decelerates according to a driving trace which specifies the speed and time over a wide range of vehicle simulation cycles. As the on-road driving conditions are being simulated on the dynamometer, emissions measurements will be collected with CE-CERT’s Mobile Emissions Laboratory (MEL).

“This adds new capabilities in California that are only available at a limited number of facilities around the country," said Tom Durbin, who with J. Wayne Miller, are the principle investigators for the project. At both the state and federal levels, scientific requirements for emissions testing are trending away from steady state engine testing in favor of transient conditions found in typical driving, Durbin explained. “This addition will significantly expand our laboratory and measurement capabilities and help us continue our role as leading experts in the field of emissions research," said CE-CERT Director Matthew Barth.

CE-CERT's new heavy-duty chassis dynamometer will allow the testing of a variety of heavy vehicles under loaded and transient in-use conditions with corresponding emissions measurements. The dynamometer configuration is capable of meeting the inertia simulation range requirements of 10,000 to 80,000 lb for each of the cycles listed below. This includes acceleration rates up-to 6 mph/sec, as found in the UDDS Section D Drive Schedule and deceleration rates of up to 7 mph/sec as required for the WHM Refuse Drive Schedule. The dynamometer can also provide a load in excess of 600 HP @ 70 mph. The dynamometer also has the ability to continuously handle 200 Hp @ 15 mph for applications such as yard tractors.

The Dynamometer system is designed to meet the Heavy Duty Drive Schedules for diesel trucks in the weight range of 10,000 to 80,000 lb with acceleration rates for the following cycles:

- CARB HHDDT Cruise Mode Drive Schedule
- UDDS (Urban Dynamometer Drive Schedule)
- CARB 50 mph HHDDT Cruise Cycle
- HHDDT Transient Mode Drive Schedule
- WHM Refuse Drive Schedule
- Bus cycles such as, the CBD, OC Bus cycle, NY bus cycle
- In-use cycles for applications such as yard tractors.



"As part of our strategic plan, Mustang has developed a cost effective series of diesel, petroleum and hybrid certification grade dynamometer systems to address the needs of the global emissions and R&D market. There is a clear and present demand for a full performance cost effective dynamometer systems that offer all of the capabilities and confidence of a certification system at a price point that makes it no longer cost-prohibitive for organization to perform critical emissions studies, hybrid system calibration development, performance evaluation and other cutting edge research technologies. Researchers are in need of dynamometer systems to develop the next generation technologies which mimic the capabilities of the certification requirements, but at a fraction of the cost of a true certification system. That is what we are developing with this series of dynamometers and universities are lining up for them", said Executive Vice President, Donald Ganzhorn.

Appendix E. Additional Test Data and Results

This appendix includes some additional results not presented in the main report, but can be used to support the assumptions and decisions made for the results presented. Following Tables E-1 through E-4 are fuel sample analysis reports.

Appendix F. Engine certification data, labels, and upgrades

This appendix includes the engine executive order Figure F-1 as listed on the ARB website for the family number listed on the engine name plate see Figure F-2 and F-3, Family number ECEXH0540LBH. The ISL G NZ certification is provided in the recently released documents as presented in Figure F-4, 5, and 6.

Changes from ISL G EPA 2013

- **Certification**
  - new Agency Approval (AP) option
- **ECM Calibration**
  - 0.02g NOx calibration
  - Delegated Assembly protected via catalyst / ECM connection
- **Three Way Catalyst (TWC)**
  - Same as ISX12 G and ISL G Euro VI
  - Has extra mid bed temperature sensor that must be added to OEM harness
- **New Closed Crankcase Ventilation (CCV) System**
  - Remote mount CCV filter – to be installed by OEMs
  - Similar to ISL G Euro VI, but with coolant heating (same as ISB6.7 G)
  - Requires OEM installed air/oil and coolant plumbing to and from the engine
- **Crankcase Pressure Sensor**
  - New for diagnostic and OBD purposes

Appendix G. Coastdown methods

Road load coefficients are important where at 65 mph the aerodynamic term accounts for 53% of the resisting force, rolling resistance 32%, driveline losses 6% and auxiliary loads at 9%. These load fractions vary with speed and the square of the speed where a properly configured dynamometer is needed to simulate the loads from 0 to 70 mph. The method for determining coastdown coefficients was published and evaluated as part of a study submitted to the South Coast Air Quality Management District[14]. Typical coastdown procedures assume that vehicle loading force is a function of vehicle speed, drag coefficient, frontal area and tire rolling resistance coefficient and takes the form of equation 1:

$$M\frac{dV}{dt} = \frac{1}{2}\rho A C_D V^2 + \mu M g cos(\theta) + Mgsin(\theta) \qquad \text{(Equation 1)}$$

Where:
M = mass of vehicle in lb (tractor + payload + trailer+ 125lb/tire)
ρ = density of air in kg/m^3.
A = frontal area of vehicle in square feet, see Figure G-1 below
C_D = aerodynamic drag coefficient (unit less).
V = speed vehicle is traveling in mph.
μ = tire rolling resistance coefficient (unit less).
g = acceleration due to gravity = 32.1740 ft/sec^2.
θ = angle of inclination of the road grade in degrees (this becomes zero).

Assuming that the vehicle loading is characteristic of this equation, speed-time data collected during the coastdown test can be used with static measurements (ZET/NZET mass, air density, frontal area, and grade) to solve for drag coefficient (C_d) and tire rolling resistance coefficient (μ). The frontal area is measured based on the method described in Figure G-1 below. However, experience performing in-use coastdowns is complex and requires grades of less than 0.5% over miles of distance, average wind speeds < 10 mph ± 2.3 mph gusts and < 5 mph cross wind[15]. As such, performing in-use coastdowns in CA where grade and wind are unpredictable are unreliable where a calculated approach is more consistent and appropriate. Additionally vehicles equipped with automatic transmissions have shown that on-road loading is also affected by the characteristics of the vehicle transmission, especially when reverse pumping losses at low speed begin to dominate.

UCR's and others recommend a road load determination method that uses a characteristic coastdown equation, with a measured vehicle frontal area (per SAE J1263 measurement recommendations), a tire rolling resistance μ, and a coefficient of drag (Cd) as listed in Table G-1. If low rolling resistant tires are used then the fuel savings can be employed with a slightly improved coefficient as listed. Similarly if an aerodynamic tractor design is utilized (ie a certified SmartWay design) then a lower drag coefficient can be selected. Table G-1 lists the

[14] Draft Test Plan Re: SCAQMD RFP#P2011-6, "In-Use Emissions Testing and Demonstration of Retrofit Technology for Control of On-Road Heavy-Duty Engines", October 2011
[15] EPA Final rulemaking to establish greenhouse gas emissions standards and fuel efficiency standards for medium and heavy duty engines and vehicles, Office of Transportation and Air Quality, August 2011 (Page 3-7) and J1263 coast down procedure for fuel economy measurements

coefficients to use based on different ZET/NZET configurations. Once the coefficients are selected then they can be used in the above equation to calculate coastdown times to be used for calculating the A, B, C coefficients in Equation 2 for the dynamometer operation parameters. From these equations calculate the coastdown times from based on the coefficients in Table G-1 as shown in Table G-2 (65,000 lb, ustd, Cdstd and Table G-1). From Table G-2 one can plot the force (lb) vs average speed bin to get the ABC coefficients for the chassis dynamometer (see Figure G-2). These are the coefficients to enter into the chassis dynamometer then validate via the details of Appendix C. Repeat process until validation criteria is met. Typically one or two iterations is needed to meet the validation criteria.

Table G-1 Constants and parameters for Class 8 heavy duty trucks

Variable	Value	Description
θ	0	no grade in these tests
ρ	1.202	standard air density kg/m^3
μ_{std}	0.00710	standard tires
μ_{adv}	0.00696	low rolling resistant tires
C_{D_std}	0.750	for non-SmartWay tractor
C_{D_adv}	0.712	for SmartWay tractor
g	9.806	nominal value m/sec^2
M	Varies	mass: final test weight kg

[1] The tire rolling resistance, μ, for low rolling resistant tires shows a 1-2% savings (ref SmartWay). As such utilize 0.00686 fpr low rolling resistant tires. In this document the tractors may vary, but the trailers will be assumed similar. As such, if the tractor utilizes the certified SmartWay tractor type then coefficient of drag can be reduced by up to 10% (5% fuel savings) depending on the technology. As such in this guidance document utilize the Cd_adv for SmartWay tractors and Cd_std for non-SmartWay tractors. Additionally, for reference other vocations show higher Cd's, such as the C_D = 0.79 for buses and 0.80 for refuse trucks. Nominal value of gravity is used in this document where actual value can be found by following 40CFR 1065.630 or at http://www.ngs.noaa.gov

$$\frac{dV}{dt} = \frac{1}{2}\frac{\rho A C_D V^2}{M} + \mu g cos(\theta) + g sin(\theta) \qquad \text{(Equation 2)}$$

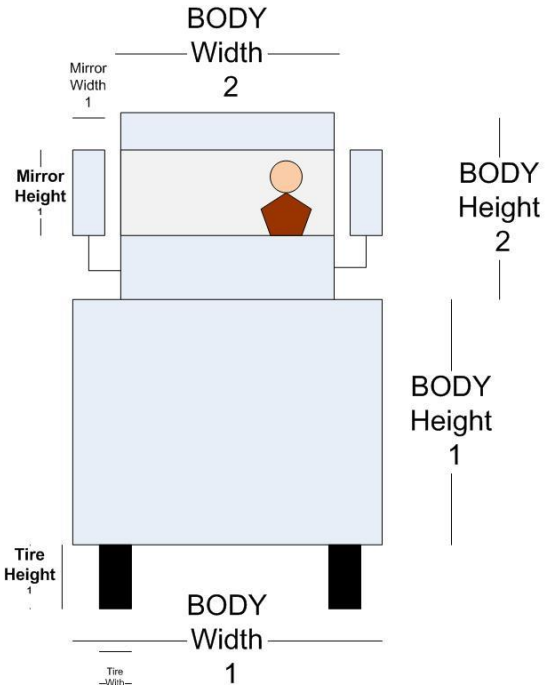

Figure G-1 Vehicle frontal area dimensions method

Using Equation 2 (solution for $\frac{dV}{dt}$ or deceleration), one can calculate the deceleration for each average speed bin (60, 50, … down to 20 mph), see Table G-2. From the deceleration time one can calculate the desired time which is the target for the coast down simulation on the chassis dynamometer. Using the final test weight (M), the total simulated force can be calculated using Equation 1 at each speed bin, see values Table G-2. Plot the simulated force (lb) on the y-axis vs truck speed (mph) on the x-axis. Using a best fit polynomial of order two, calculate the polynomial coefficients A (0^{th} order term), B (1^{st} order term), and C (2^{nd} order term), see Figure G-2. Enter these ABCs into your chassis dynamometer and verify the coast down times match your desired coast down times to within 5%.

The calculation approach is consistent and has proven very reliable for chassis testing heavy duty vehicle and has been used for years by UCR and others. For detailed evaluation of aerodynamic modifications and body styles, UCR recommends investing the time perform in-use coastdowns where sufficient program resources will be needed as per 40 CFR Part 1066, SAE J2263, and J1263.

Acknowledgments

The authors thank the following organizations and individuals for their valuable contributions to this project.

We acknowledge funding from the Truck and Engine Manufacturers Association.

We acknowledge the participation of the California Air Resources Board (ARB) in this program, including involvement in the development of the test plan, the selection of the test vehicles, and their own chassis dynamometer testing of three of the five selected vehicles.

We acknowledge Mr. Don Pacocha, Mr. Eddie O'Neal, and Mr. Joe Valdez of the University of California, Riverside for their contributions in conducting the emissions testing for this program.

Executive Summary

Characterization of the in-use emissions from on-road heavy-duty trucks is an important element of developing accurate emissions inventory estimates. Current-technology diesel engines are equipped with aftertreatment systems designed to meet stringent emissions standards that were put in place in 2007 for particulate matter (PM) and fully phased-in for oxides of nitrogen (NO_x) in 2010. Data from real-world in-use emissions measurements of those modern diesel engines are scarce, however, and show some variation depending on the type of truck tested and the testing conditions. The goal of this work was to obtain data on Class 8 trucks equipped with the newest emission control strategies and operated over in-use cycles on a heavy-duty chassis dynamometer. A particular emphasis was on gathering data that can be used to improve estimates of "zero mile" emission rates (ZMRs) for 2010 and later model year heavy-duty engines/trucks. This information could be analyzed to augment the data being used in the development of emissions inventory models utilized in different levels of the regulatory process, and in particular the California Air Resources Board's (ARB's) EMFAC2014 model.

Five vehicles were tested in this program. The vehicles were all Class 8 heavy-duty diesel trucks equipped with the latest generation of emissions control technology, including a diesel particulate filter (DPF) for PM emissions control and a selective catalystic reduction (SCR) system for NOx emissions control. The vehicles tested ranged in model year from 2012 to 2015, with 4 of the 5 engines being 2014 or newer. The vehicle matrix included 5 engines from heavy-duty engine manufacturers representing the majority of trucks operating in California, with two engines being from the same manufacturer. The engines/vehicles were certified to a 0.20 g/bhp-hr or lower NOx certification limit, with the exception of one credit-using engine that was certified to a 0.35 g/bhp-hr NO_x standard. Each vehicle was tested on UCR's heavy-duty chassis dynamometer over the four phases of ARB's Heavy Heavy-Duty Diesel Truck (HHDDT) test cycle (i.e., idle, creep, transient, and cruise), the HHDDT-short or (HHDDT-S) cycle (which is a high-speed cruise schedule), and the Urban Dynamometer Driving Schedule (UDDS) (which is a cycle considered to be the chassis dynamometer equivalent of the Federal Test Procedure (FTP) engine dynamometer transient test). Three of the five trucks were retested at the ARB's Heavy-Duty Chassis Dynamometer Testing Facility in Los Angeles.[1]

The results of this study are summarized below. As the primary emphasis for this study is on the ZMRs for NOx emissions, NOx emissions are the main emphasis of the executive summary. It should be noted that other emissions, such as PM, total hydrocarbons (THC), and carbon monoxide (CO), were found to be very low under most of the testing conditions. Those emissions are described in greater detail in the main body of the report.

NOx emissions results are presented in Figures ES-1 and ES-2 on a g/mi and g/bhp-hr basis, respectively. The emissions on a g/bhp-hr basis were derived using emissions on a mass basis divided by the engine work. The engine work is obtained by integration of the engine torque and

[1] This report is based on data and analysis from the truck testing conducted at CE-CERT. It is important to note that additional testing was also carried out on a subset of the trucks at the ARB's heavy-duty chassis-dynamometer test facility as part of the agreed upon study effort. The goal was to include all of the data and analysis from both testing efforts in this report, however the ARB data have not been provided for analysis or reporting. The additional ARB data would provide additional insight to the overall project results. It is hoped that ARB will consider their data, in addition to what is reported here, as they improve the EMFAC model.

engine speed channel from the J1939 signal from the engine control module (ECM). The torque signal is estimated using engine speed and instantaneous fuel flow. Note that in both of the figures the emissions for the Creep cycle are divided by 5 to allow the emissions over all 5 cycles to be presented on the same graph. NOx emissions varied depending on the test cycle and the test truck. It should be noted that the NOx emissions for the manufacturer D truck appear to be an outlier with noticeably higher NOx emissions. Some additional testing was conducted on this vehicle subsequent to the main testing of this study after the vehicle's aftertreatment system was regenerated. Given anomalies for the manufacturer D truck, this truck is discussed separately from and in more detail than the results for the manufacturer A1, manufacturer A2, manufacturer B and manufacturer C engine-powered trucks below.

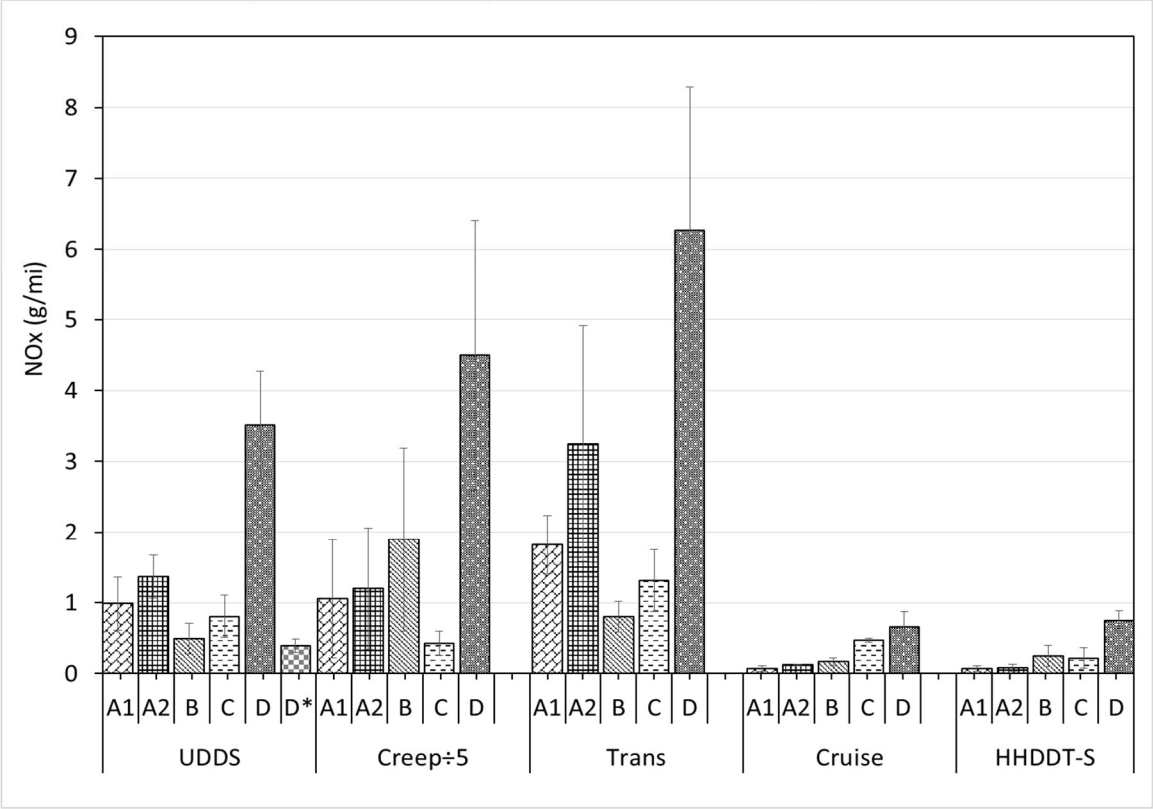
For the manufacturer A1, manufacturer A2, manufacturer B and manufacturer C trucks, NOx emissions over the UDDS cycle ranged from 0.495 to 1.363 g/mi (0.136 to 0.387 g/bhp-hr). On a bhp-hr basis, those emission levels are comparable to the level to which the engines were certified to on an engine dynamometer, with some trucks being below and other being above the 0.20/0.35 NOx g/bhp-hr level. NOx emissions for the ARB transient cycle were slightly higher than for the UDDS, with emission rates ranging from 0.803 to 3.252 g/mi (0.194 to 0.762 g/bhp-hr). The lowest emissions were found over the two cruise cycles. For the HHDDT-S, NOx emissions ranged from 0.067 to 0.249 g/mi (0.023 to 0.078 g/bhp-hr). For the Cruise cycle, NOx emissions ranged from 0.068 to 0.471 g/mi (0.030 to 0.225 g/bhp-hr). The highest NOx emissions were seen for the Creep cycle, which showed NOx emissions ranging from 2.131 to 9.468 g/mi (0.910 to 3.613 g/bhp-hr). The higher NOx emissions for the Creep cycle can be attributed to the fact that the cycle is comprised of short, low-speed accelerations between periods of idle that cover a very short distance (0.124 miles). Such stop-and-go type of driving tends to create high emissions when evaluated on a per mile or per unit of work done basis.

As discussed above, the manufacturer D truck seemed to be an outlier with noticeably higher NOx emissions relative to the other vehicles. In this study, on a g/mi basis, its NOx emissions were 3.519 over the UDDS, 22.505 over the Creep cycle, 6.270 over the Transient cycle, 0.656 over the Cruise cycle, and 0.751 for the HHDDT-S. The lowest NOx emissions for the manufacturer D engine were recorded over the Cruise and HHDDT-S cycles. On a g/bhp-hr basis, NOx emissions for the manufacturer D vehicle were 0.967 for the UDDS, 3.832 for the Creep cycle, 1.430 for the Transient cycle, 0.257 for the Cruise cycle, and 0.234 over the HHDDT-S.

Subsequent to the dynamometer testing conducted at UCR, the manufacturer D vehicle was more extensively evaluated by the manufacturer. The vehicle was initially outfitted with a PEMS, which confirmed the poor NOx conversion efficiency found in the UCR testing. Upon further investigation, it was determined that this specific vehicle had served its entire life as a dealer demonstrator, and as such rarely or never operated with a loaded trailer, and spent a considerable amount of time operating in an idle mode. This type of low temperature, high proportion idle operation is known to cause significant exposure of the aftertreatment system to unburned hydrocarbon in the exhaust stream. An examination of the logged electronic history revealed no OBD faults or other indications of failure or system malfunction. A clear anomaly, however, was that due to its unusual, unladen duty cycle, the engine had never undergone a regeneration event, despite being approximately 2.5 years in service (albeit with only 12,000 miles on the odometer). A series of conventional parked regenerations were performed. After further operation, there was a significant recovery of the aftertreatment NOx-conversion efficiency, as

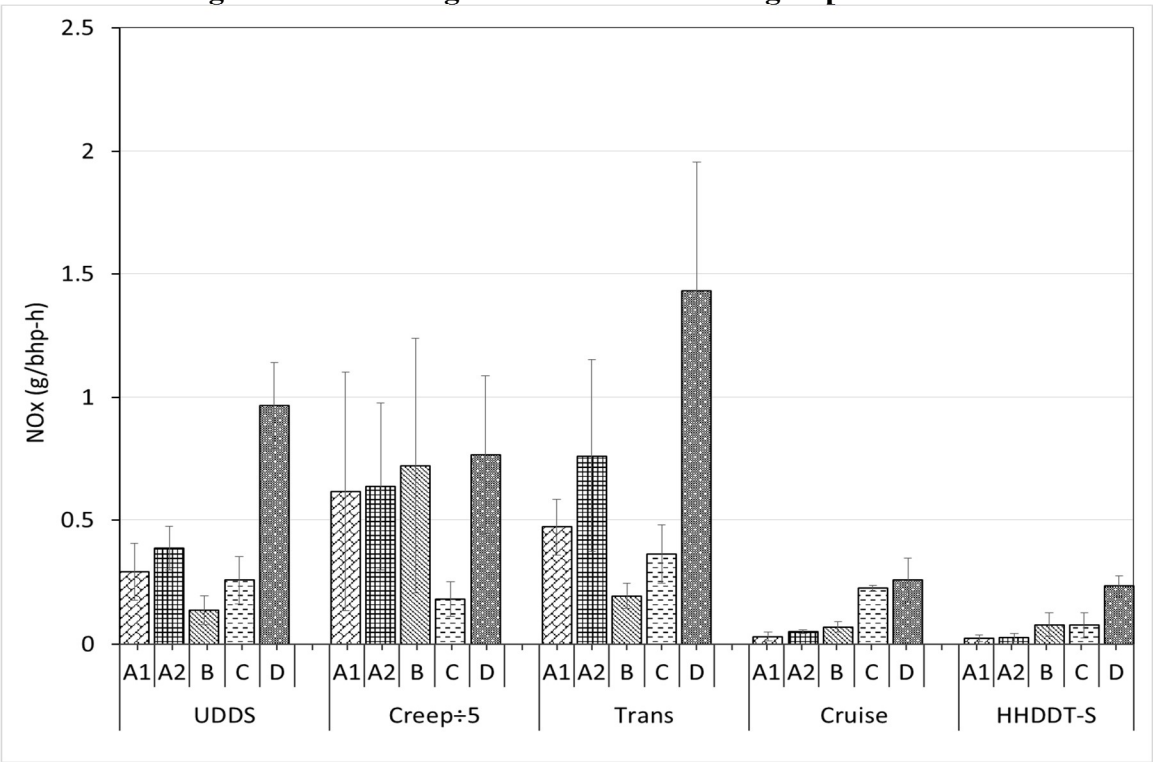
revealed through PEMS measurements. The regeneration intervention is believed to have been fully effective in driving off the accumulated unburned hydrocarbons that were hindering catalytic reaction. Additional chassis dynamometer testing of the manufacturer D vehicle was subsequently conducted at the West Virginia University (WVU) Center for Alternative Fuels Engines and Emissions (CAFEE) Laboratory, replicating the testing that had been performed at UCR, with the exception of a 70,000 lbs. test weight. The results of that testing indicated a NOx emission rate of 0.39 g/mi over the UDDS cycle, near the lower end of the NOx emission rates found in the current study.

Figure ES-1. Average NOx Emissions on a g/mi Basis



Note that D represents the UDDS emissions level found after retesting the manufacturer D1 truck after a regeneration.

Figure ES-2. Average NOx Emissions on a g/bhp-hr Basis.



The results of our study can be compared to the emission factors being used in the EMFAC2014 model. For engines certified to the 0.20 g/bhp-hr NOx level, EMFAC2014 utilizes a ZMR of 1.89. This ZMR is adjusted by a fuel correction factor of 0.93 to account for clean CARB diesel used in California, such that a ZMR of 1.76 was used for the comparisons in this study for 0.20 g/bhp-hr NOx engines. EMFAC2014 does not specifically utilize a ZMR for engines certified to the 0.35 g/bhp-hr NOx level, but the ZMR for those engines can be most directly compared with the 2011 model year ZMR of 3.26. That ZMR also is adjusted by the fuel correction factor of 0.93 to account for the use of clean CARB diesel used in California, resulting in a ZMR of 3.03, which was used for the comparisons in this study relating to 0.35 g/bhp-hr NOx engines. EMFAC2014 is a relatively complicated model, including speed correction factors, tampering, malmaintenance and deterioration rates, and other factors. ZMRs, however, are best approximated by the emissions obtained over the UDDS cycle from low mileage vehicles that are well maintained and checked for any evidence of tampering, such as those selected for inclusion in this study. Consequently, that cycle is used as a comparison point between the current EMFAC2014 model ZMRs and our study results.

The UDDS emission rates from this study, as well as other studies of 2010 and newer heavy-duty vehicles, are presented in Figure ES-3 and ES-4, along with the current EMFAC2014 ZMRs and the NOx Family Emission Limits (FELs) to which the engines are certified. The other studies include a study by the ARB that was utilized to update the emissions factors for its EMFAC model and another UCR study funded by the South Coast Air Quality Management District (SCAQMD), which included several SCR and DPF equipped 2010+ model year vehicles in the test fleets. For the UDDS for the current study, the emissions levels for all of the 0.20 g/bhp-hr NOx trucks, except the manufacturer D truck prior to regeneration, are below the EMFAC2014

value. The NOx emissions for the manufacturer D truck after regeneration restored its NOx-conversion efficiency are also well below the EMFAC2014 value. The average UDDS values for the current study for the 0.20 g/bhp-hr NOx trucks are 0.89 g/mi if the outlier manufacturer D truck is excluded, or 0.77 g/mi if the UDDS emission rate from the manufacturer D truck as tested at WVU, after ensuring regeneration, is included. In both cases, those values are well below the EMFAC2014 value, with the lower value being more representative of the in-use fleet. Similarly, the manufacturer A1 truck that was certified to a 0.35 g/bhp-hr NOx FEL has a UDDS emissions level of 0.99 g/mi, which is well below the 2011 model year ZMR approximation of 3.03 g/mi for 0.35 g/bhp-hr NOx trucks.

The UDDS results for the earlier SCAQMD study, with an average NOx level of 0.86 g/mi, are also well below the EMFAC2014 0.20 g/bhp-hr fuel-adjusted ZMR of 1.76 g/mi. The two manufacturer D trucks from the previous ARB study are comparable to but slightly higher than the EMFAC2014 ZMR, as these two vehicles were the primary source of information used in developing that ZMR. They are higher than all of the other trucks certified to the 0.20 g/bhp-hr, with the exception of the manufacturer D truck under the current study, which is again from the same manufacturer. The other manufacturer A3 truck in the earlier ARB study has NOx emissions higher than the 2011 model year EMFAC2014 ZMR value that approximates the value for 0.35 g/bhp-hr NOx level engines.

As the name implies, the ZMR is the estimated emissions rate at zero miles (i.e., for a new truck). Normally, an adjustment factor would be applied to account for the mileage accumulated on the vehicle. As the five vehicles in this study had low mileages (one of the selection criteria for the study as shown in Figure ES-3), no adjustment factor has been applied for mileage. If an adjustment factor were to be applied, the ZMR estimates based on the UDDS emission results would go down slightly. Overall, this comparison analysis suggests that lower ZMRs for future EMFAC model updates may better represent the in-use emission rates of heavy-duty diesel trucks. This study suggests ZMRs may be better represented by the UDDS emission rates of 0.77 g/mi, perhaps ranging to 0.89 g/mi, for engines certified to a 0.20 NOx standard. A lower possible ZMR value of 0.99 g/mi was also found for an engine certified to a 0.35 NOx standard, but only a single vehicle with this certification level was tested in this study.

Figure ES-3 Comparison of NOx emission rates from this study, and the ARB and SCAQMD studies, for SCR-equipped 2010+ vehicles over the UDDS

	CE-CERT					ARB			SCAQMD

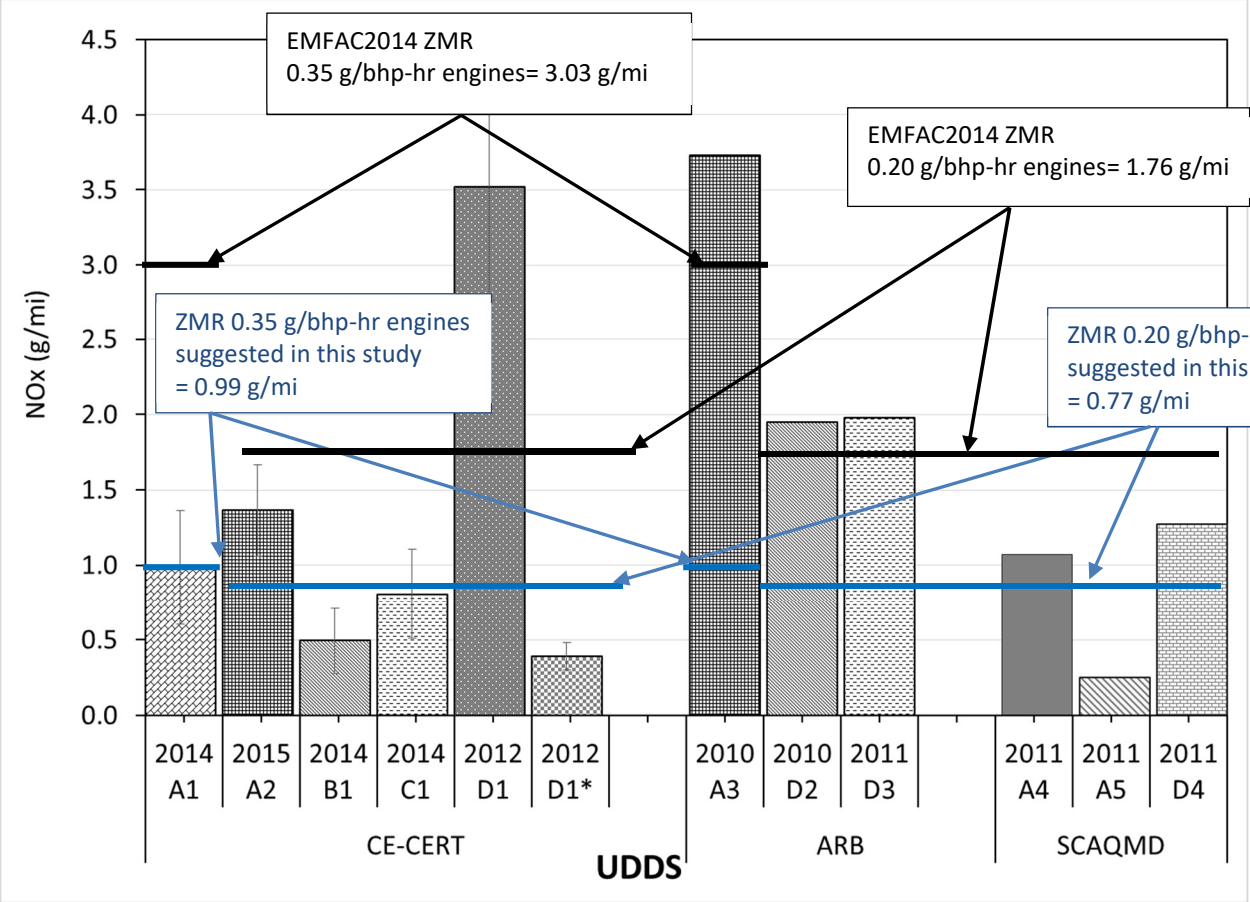
Figure ES-4 Comparison of NOx Zero Mile Rates Between EMFAC2014 and this Study



1 Introduction

Heavy-duty diesel trucks can be significant sources of oxides of nitrogen (NOx) and particulate matter (PM) emissions in urban areas. In order to reduce emissions of NOx and particulate matter (PM) from HDDTs, a series of regulations for heavy heavy-duty diesel engines (HDDE) were implemented starting in 1974, and were last made more stringent in 2007 and 2010. Those rules have required that emissions of NOx and PM be reduced from an estimated unregulated emission level of 16 g/bhp-hr to 0.20 g/bhp-hr and from 1.0 g/bhp-hr to 0.01 g/bhp-hr, respectively. Current-technology diesel engines are now equipped with diesel particulate filters (DPFs) to meet the PM standards for 2007 and newer engines, and selective catalytic reduction (SCR) systems to meet the NOx standards for 2010 and newer engines.

While there are extensive data on the effectiveness of DPFs and SCR systems over certification test cycles run in emissions laboratories, data on in-use emissions from modern diesel engines are scarce and show some variation depending on the type of truck tested and the testing conditions (Miller et al., 2013; Carder et al., 2014; Misra et al., 2015; California Air Resources Board 2015). The need for in-use emissions data is particularly important because HDD engines are certified to meet emission standards before the engines are integrated into a vehicle chassis for commercial use, which commercial uses can span a broad range of applications. Characterization of in-use emissions from on-road heavy-duty trucks is an important element of developing accurate emissions inventory estimates.

The California Air Resources Board (ARB) has been utilizing in-use emissions testing results in the development of emissions factors for its EMFAC model for a number of years (California Air Resources Board, 2015a, 2015b). Those emissions factors are developed from "zero-mile" emissions rates (ZMRs) that can be adjusted to account for engine deterioration with age and for variations in vehicle speed. For the EMFAC2007 model, in-use emissions data were primarily obtained from the CRC E-55/59 study (Clark et al. 2006, 2007) coupled with estimates for 2007 and newer model year vehicles.

For the EMFAC2014 model, a greater emphasis was placed on developing emission factors for vehicles equipped with newer PM and NOx aftertreatment control devices, and incorporating in-use emissions data from 2007 and newer engines/vehicles. Those data were derived from studies conducted by the ARB and the South Coast Air Quality Management District (SCAQMD), which included a limited amount of chassis dynamometer testing over multiple cycles, and over-the-road testing with portable emissions measurement systems (PEMS) over two routes and at three different loads. While this represents an important step in better quantifying emissions from 2007-2009 and 2010 and later model year vehicles, the data are still relatively scarce to serve as the basis for making important emissions inventory projections out to 2020 and beyond. In particular, for the 2010 and later model year technology engines, only 5 vehicles/engines were included in the ARB/SCAQMD studies, with all the engines being in the 2010-2011 model year range, which only covers the earliest implementation years for advanced NOx control strategies. More importantly, of those 5 engines, only 2 were certified to the 0.20 g/bhp-hr NOx standard, and both of those engines were from the same manufacturer. Additionally, 2 of the 5 engines utilized only exhaust gas recirculation (EGR) for NOx control, an approach that had a very limited production run.

The goal of this study is to provide additional information regarding modern heavy-duty diesel vehicles equipped with the newest emission control strategies for reducing NOx. Testing was conducted on 5 HDDTs with model year 2012 to 2015 engines equipped with DPFs and SCR systems. The vehicle matrix included 5 engines from heavy-duty engine manufacturers representing the majority of trucks operating in California, with two engines being from the same manufacturer. The engines/vehicles were certified to a 0.20 g/bhp-hr certification limit, with the exception of one credit-using engine that was certified to a 0.35 g/bhp-hr standard. Each vehicle was tested on UCR's heavy-duty chassis dynamometer over the four phases of ARB's Heavy Heavy-Duty Diesel Truck (HHDDT) cycle (i.e., idle, creep, transient, and cruise), the HHDDT-short or (HHDDT-S) cycle (which is a high-speed cruise cycle), and the Urban Dynamometer Driving Schedule (UDDS) (which is a cycle considered to be the chassis dynamometer equivalent of the engine dynamometer transient test). Three of the HDDTs were also retested at the ARB's Heavy-Duty Chassis Dynamometer Testing Facility in Los Angeles.[2] The results obtained from this study, can augment the data being used in the development of future emissions inventory models that are relied on throughout ARB's regulatory process.

[2] This report is based on data and analysis from the truck testing conducted at CE-CERT. It is important to note that additional testing was also carried out on a subset of the trucks at the ARB's heavy-duty chassis-dynamometer test facility as part of the agreed upon study effort. The goal was to include all of the data and analysis from both testing efforts in this report, however the ARB data have not been provided for analysis or reporting. The additional ARB data would provide additional insight to the overall project results. It is hoped that ARB will consider their data, in addition to what is reported here, as they improve the EMFAC model.

2 Experimental Procedures

2.1 Test Vehicles and Fuels

Five vehicles were tested in this program. All of the vehicles were heavy-duty Class 8 trucks powered by diesel engines equipped with the latest generation of emissions control technology, including a diesel particulate filter (DPF) for PM emissions control and a selective catalytic reduction (SCR) system for NO_x emissions control. The selected vehicles were equipped with engines that were at least model year 2012 and newer, with a preference for 2014 and newer engines. The vehicle matrix included 5 engines from heavy-duty engine manufacturers representing the majority of trucks operating in California, with two engines being from the same manufacturer. The engines/vehicles were certified to a 0.20 g/bhp-hr certification limit, with the exception of one engine that was certified to a 0.35 g/bhp-hr standard. The engines selected have reasonably high sales percentages in the California market. The vehicles all had mileage less than 30,000 miles, with mileage ranging from 2,924 to 28,611 miles. The selection and approval of each test vehicle was done in consultation with both the Truck and Engine Manufacturers Association (EMA) and the ARB. A description of the vehicles/engines is provided in Table 2-1. Vehicles were obtained from different entities, including local truck rental agencies, dealers, and other entities. Three of the five vehicles were also subsequently tested at the ARB Heavy-Duty Chassis Dynamometer Testing Facility in Los Angeles, CA. The results from the testing at the ARB facility are not included in this report, but are expected to be considered and incorporated as part of the next update to the EMFAC model, and will be made publically available at that time.

Table 2-1. Engine/Vehicle Specifications

Engine	*A1*	*A2*	*B*	*C*	*D*
Model Year	2014	2015	2014	2014	2012
Engine Type	Compression-ignition	Compression-ignition	Compression-ignition	Compression-ignition	Compression-ignition
Horsepower	400 HP	550 HP	450 HP	450 HP	415 HP
Vehicle Mileage	28,611	2,924	15,914	7,686	12,640
Displacement	14.9 L	14.9 L	12.8 L	12.4 L	12.8 L
Peak Torque	1450 ft-lbs. @ 1650 rpm	2050 ft-lbs. @ 1200 rpm	450 hp. @ 1800 rpm	1700ft-lbs.@ 1000 rpm	415 hp. @ 1500 rpm
Aftertreatment	DOC/DPF/SCR	DOC/DPF/SCR	DOC/DPF/SCR	DOC/DPF/SCR	DOC/DPF/SCR
Test Period	November 2014	Sept./Oct, 2015	January 2015	December 2014	February 2015
Standard/FEL Level (g/bhp-hr)	NO_x:0.35 PM:0.01	NO_x:0.20 PM:0.01	NO_x:0.20 PM:0.01	NO_x:0.20 PM:0.01	NO_x:0.20 PM:0.01
Certification Level (g/bhp-hr)	NO_x:0.22 PM:0.001	NO_x:0.18 PM:0.000	NO_x:0.17 PM:0.004	NO_x:0.12 PM:0.003	NO_x:0.12 PM:0.003

After acquisition, each vehicle was inspected using a standard checklist to ensure the vehicle was safe to drive and testable on a chassis dynamometer. The checklist utilized for this program is provided in Appendix A.

The test fuel was the fuel in the tank of the vehicle, provided it could be reasonably ascertained to be California No. 2 diesel. The vehicles were topped off, if needed, with a commercially available California No. 2 diesel fuel, prior to testing, to ensure that adequate fuel was available for the full test program.

2.2 Test Cycles

Each vehicle was tested over the four phases of ARB's Heavy Heavy-Duty Diesel Truck (HHDDT) cycle (i.e., idle, creep, transient, and cruise) (Gautam, et al. 2002), the HHDDT short or (HHDDT-S) cycle (Clark et al., 2004) (which is a high-speed cruise schedule), and the Urban Dynamometer Driving Schedule (UDDS) (U.S. Environmental Protection Agency, 2005). The characteristics of each test cycle are provided in Table 2-2 and Appendix B. Two tests were conducted for each of the three test modes. For each test over each of the different test cycles, different numbers of replicates were run. The number of iterations that were conducted on each cycle is provided in Table 2-3, along with the preconditioning sequence and total test time. Conducting multiple iterations of each driving cycle helped to ensure that a sufficient mass of PM was collected for weighing. Note that the preconditioning and number of test iterations were designed to be consistent with the procedures utilized in the earlier testing program the ARB

conducted to update its emission factors for EMFAC2014. The ARB was also involved in the review and approval of this test sequence. The ARB followed the same testing protocol in its retesting of 3 of the 5 vehicles utilized in this study.

Table 2-2. Description of Test Cycles

Schedule	Pre-conditioning	Time (s)	Avg Speed (mph)	Distance (mi)	Number of Iterations	Total Test Time (s)	Description
UDDS	One UDDS	1060	18.86	5.55	3	3180	comparable to FTP engine dynamometer transient cycle
HHDDT Idle	15 minutes at 45 mph	900	0	0	3	2700	Idle of vehicle
HHDDT Creep	15 minutes at 45 mph	256	1.7	0.124	10	2560	Stop and go modes (congestion)
HHDDT Transient	15 minutes at 45 mph	688	14.9	2.9	4	2752	Local street driving
HHDDT Cruise	15 minutes at 45 mph	2083	39.9	23.1	1	2083	Freeway driving
HHDDT-Short	15 minutes at 45 mph	760	49.9	10.5	2	1520	High speed driving

The vehicles were warmed up in the morning by driving them for 15 minutes at 45 mph to bring the vehicles out of a cold-start mode. The vehicles then went through a test sequence that included each of the test cycles with the associated preconditioning cycle. An outline of a typical test day is provided in Table 2-3. Between each test sequence, there was a soak period to allow for analysis of the emissions from the just-completed test, to replace the PM-collection filters for the upcoming test, and to prepare the laboratory instrumentation for the next test. The soak period was typically on the order of 10 to 20 minutes with the engine off. Once those activities were completed, the vehicle went into the preconditioning for the next test, and then, immediately following, was run on the test sequence where emissions were collected. It should be noted that the vehicles were monitored throughout testing to ensure that a DPF regeneration event did not occur during any of the emissions tests. For this study, the only observed regeneration occurred while testing the manufacturer C engine during a preconditioning warm-up. In that one case, it was ensured that the regeneration was completed prior to starting the actual emissions testing.

Table 2-3. Test Sequence for Typical Test Day

Activity		
Vehicle warm up (15 minutes at 45 mph)	Blue is full testing	
Soak (engine off)		
UDDS	Yellow is soak/break	
UDDS x 3		
Soak (engine off)	Red is prep/Conditioning	
15 minutes @ 45 mph		
HHDDT Idle x 3		
Soak (engine off)		
15 minutes @ 45 mph		
HHDDT Creep x 10		
Testing break/soak (engine off)		
15 minutes @ 45 mph		
HHDDT Transient x 4		
Soak (engine off)		
15 minutes @ 45 mph		
HHDDT Cruise		
Soak (engine off)		
15 minutes @ 45 mph		
HHDDT-S x 2		

The road-load coefficients were calculated based on the frontal area of the vehicle and a factor accounting for the general shape of a class 8 tractor. A description of the road-load calculation methodology is provided in Appendix C, along with the specific road-load coefficients used for each tractor. In comparing between vehicles, the primary difference in road-loads between different test tractors is in the measured frontal area of each tractor, with the most significant difference between vehicles being that the manufacturer A2 tractor had a smaller frontal area than the other tractors since it did not have an aerodynamic fairing on the roof of the cab. Note in this case, since the frontal area is based on the area of a bare cab (tractor) without a trailer, the aerodynamic drag for the tractor without the aerodynamic fairing is actually less than that for the other tractors. The actual aerodynamic drag on the road for a truck carrying a box trailer would likely be greater if the tractor did not have a fairing. Road loads can also be determined more directly by on-road coast-downs. This requires finding a roadway that is sufficiently flat, long, and safe to provide a consistent coast down time. This was not done as part of this test program. However, prior to testing, a coast-down was performed was for each tractor on the chassis dynamometer to ensure the coast down time on the dynamometer was similar to that calculated based on the road load coefficients.

The vehicles were tested at a weight of 65,000 lbs. That weight was selected because the Federal Highway Administration estimates that a typical 5-axle semi-truck with a trailer is loaded to an approximately 65,000 lbs. gross combined weight (GCW) (Couch and Leonard, 2011; Federal Highway Administration, 2000). Note that this test weight is slightly greater than the test weight

of 56,000 ±1,000 lbs. used by the ARB in its earlier testing to update EMFAC2014. The choice of a test weight of 65,000 lbs. was reviewed with and accepted by ARB.

2.3 Emissions Testing and Measurements

The chassis dynamometer testing was conducted at the University of California, Riverside (UCR) Center for Environmental Research and Technology's (CE-CERT's) heavy-duty chassis dynamometer facility. A picture of a typical vehicle set-up on the chassis dynamometer at CE-CERT is provided in Figure 2-1. The ARB's retesting of 3 of the 5 subject vehicles was conducted at its Heavy-Duty Chassis Dynamometer Testing Facility in Los Angeles.

Figure 2-1. Typical Setup of Test Vehicles on the Chassis Dynamometer

The emissions measurements were made using CE-CERT's Mobile Emissions Laboratory (MEL). For all tests, standard emissions measurements of total hydrocarbons (THC), non-methane hydrocarbons (NMHC), methane (CH_4), carbon monoxide (CO), NO_x, carbon dioxide (CO_2), and PM, were measured. CO and CO_2 emissions were measured with a 602P nondispersive infrared (NDIR) analyzer from California Analytical Instruments (CAI). THC, NMHC, and CH_4 emissions were measured with 600HFID flame ionization detector (FID) from CAI. NO_x emissions were measured with 600HPLC chemiluminescence analyzer from CAI. A schematic of the experimental setup is provided in Figure 2-2. Fuel consumption was derived from the CO_2, CO, and THC emissions by the carbon balance, using typical densities and carbon weight fractions for California ULSD.

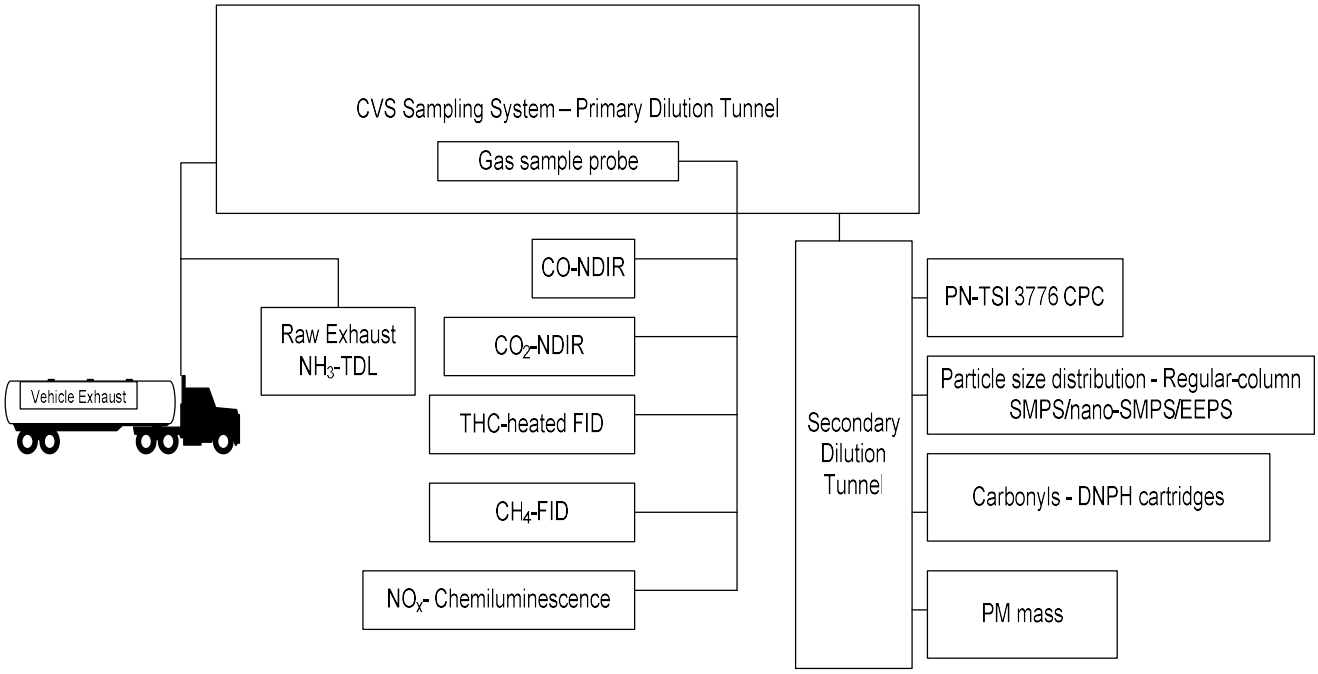
The mass concentrations of $PM_{2.5}$ were obtained by analysis of particulates collected on 47mm diameter 2µm pore Teflo filters (Whatman brand). The filters were measured for net gains using a UMX2 ultra precision microbalance with buoyancy correction in accordance with the weighing procedure guidelines of the Code of Federal Regulations (CFR). Sampling for PM was done cumulatively over the entire duration of the cycles due to the very low mass levels expected for PM.

Solid particle number counts were measured with a TSI 3776 ultrafine-Condensation Particle Counter (CPC) with a 2.5 nm cut point coupled with a catalysis striper (CS). The operating temperature of the CS was 300°C, which is a temperature that is sufficiently high to remove most volatile particles, leaving only solid particles to be detected by the CPC.

An Engine Exhaust Particle Sizer (EEPS) spectrometer (TSI 3090, firmware version 8.0.0) was used for measuring particle size distributions on a concentration and mass basis. The EEPS was used to obtain real-time second-by-second size distributions between 5.6 to 560 nm. The EEPS has a scan time of one second and provides a size range from 6 to 423 nm in electrical mobility. Particles were sampled at a flow rate of 10 L/min, which is considered to be sufficiently high to minimize diffusional losses. Particles were charged with a corona charger and sized based on their electrical mobility in an electrical field. Concentrations were determined through the use of multiple electrometers.

Engine brake power was calculated using ECM broadcast J1939 standardized information, including the engine speed in revolutions per minute (rpm), ECM broadcast actual torque in (%) estimated using engine speed and instantaneous fuel flow, ECM broadcast friction torque in (%), and ECM broadcast reference torque in (ft-lb). These signals are the same signals used for in-use compliance testing according to the in-use test procedures in 40 CFR Part 1065.

Figure 2-2. Schematic of the Sampling Systems and Instruments



3 Heavy-Duty Vehicle Chassis Dynamometer Testing Results

The emissions test results are presented in this section. The figures for each pollutant show the results for each vehicle/fuel/cycle combination based on the average of tests conducted on that particular test combination. The error bars on the figures are the standard deviation over all tests for each test combination. Note that in many figures the emissions for the Creep cycle are divided by 5 to allow the emissions over all 5 cycles to be more clearly presented on the same graph.

3.1 NOx Emissions

NOx emissions for the test trucks are shown on a g/mi and g/bhp-hr basis in Figure 3-1 and Figure 3-2, respectively. NOx emissions varied depending on the test cycle and the test truck. It should be noted that the NOx emissions for the manufacturer D vehicle were an outlier with noticeably higher emissions levels. Additional testing was performed on this vehicle subsequent to the main testing conducted under this study after the vehicle's aftertreatment system was regenerated, and the results are included in Figure 3-1. Given the anomalies relating to the manufacturer D truck, this truck is discussed separately from and in more detail than the results for the manufacturer A1, manufacturer A2, manufacturer B and manufacturer C engine-powered trucks.

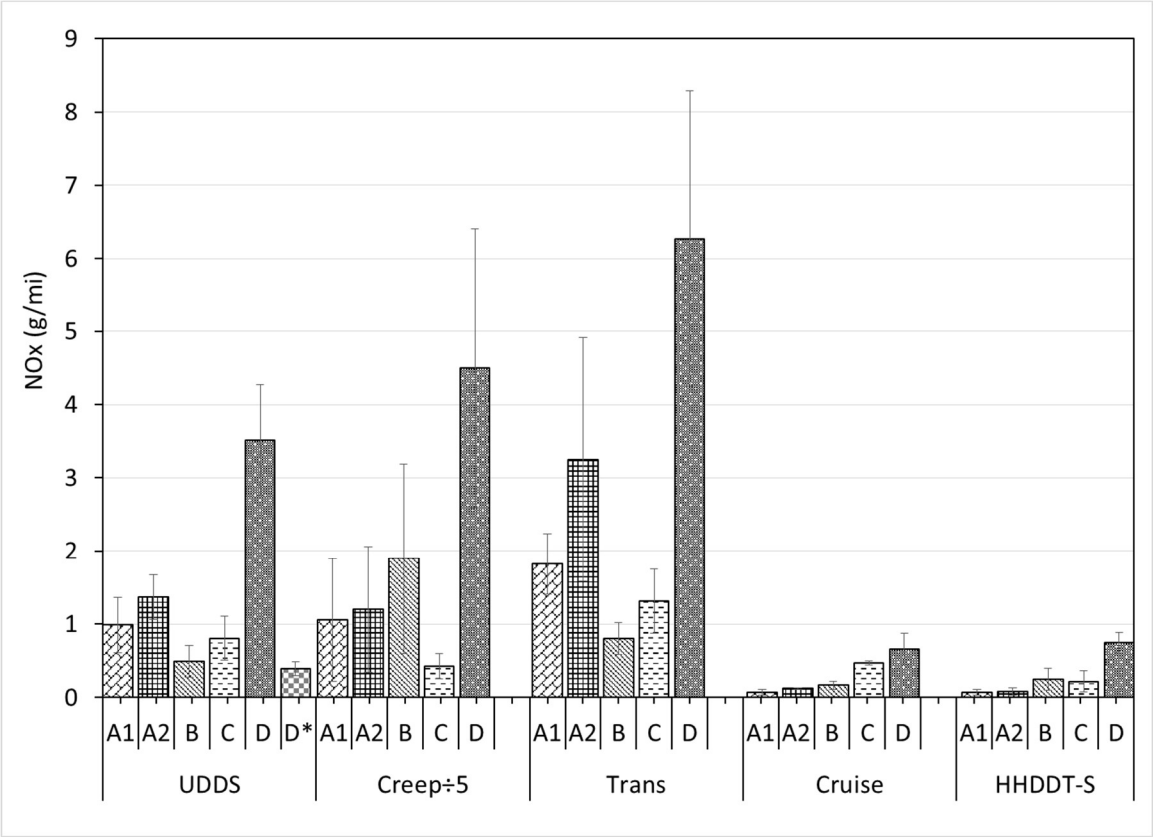
For the manufacturer A1, manufacturer A2, manufacturer B and manufacturer C engine-powered trucks, on a g/mi basis, NOx emissions ranged from 0.495 to 1.363 over the UDDS (the cycle most relevant to ZMRs), from 2.131 to 9.468 over the Creep cycle, from 0.803 to 3.252 over the Transient cycle, from 0.068 to 0.471 over the Cruise cycle, and from 0.067 to 0.249 over the HHDDT-S. The lowest NOx emissions were recorded over the Cruise and HHDDT-S cycles, which produce the highest speeds, loads, and exhaust temperatures. Under those conditions, SCR catalysts are expected to operate at temperatures where NOx conversion efficiencies are robust, leading to relatively low tailpipe NOx emission, even though engine-out NOx levels are likely highest. Higher emissions were observed over the other cycles, which include more transient and lower average speed operation, with different vehicles showing higher or lower emissions on different cycles. The Creep cycle showed the highest NOx emissions on a g/mile or g/bhp basis, since it is comprised of short, low-speed accelerations between periods of idle that yield lower loads and exhaust temperatures, and that cover a very short distance (0.124 miles). Absolute values of NOx are likely lower.

For the manufacturer A1, manufacturer A2, manufacturer B and manufacturer C trucks, on a g/bhp-hr basis, NOx emissions ranged from 0.136 to 0.387 over the UDDS, from 0.910 to 3.613 over the Creep cycle, from 0.194 to 0.762 over the Transient cycle, from 0.030 to 0.225 over the Cruise cycle, and from 0.023 to 0.078 over the HHDDT-S. Emissions were generally comparable to their respective emissions standards over the UDDS. Emissions on a g/bhp-hr basis were higher for the Transient cycle, although the manufacturer B engine on the Transient cycle showed emissions comparable to the UDDS. For the Cruise and HHDDT-S cycles, the emissions for most vehicles were below the NTE standard of 0.30 g/bhp-hr, which is the standard most relevant for regulatory in-use emissions testing of heavy-duty trucks under highway cruise conditions. Emissions over the Creep cycle were the highest for all vehicles. For the Creep cycle, the NOx emissions for the manufacturer A1, manufacturer A2 and manufacturer B truck engines were comparable, with the manufacturer C engine recording the lowest NO_x emissions.

As discussed above, the manufacturer D truck was an outlier with noticeably higher NOx emissions relative to the other vehicles. In this study, on a g/mi basis, its NOx emissions were 3.519 over the UDDS, 22.505 over the Creep cycle, 6.270 over the Transient cycle, 0.656 over the Cruise cycle, and 0.751 over the HHDDT-S. The lowest NOx emissions for the manufacturer D engine were recorded over the Cruise and HHDDT-S cycles. On a g/bhp-hr basis, NOx emissions for the D vehicle were 0.967 for the UDDS, 3.832 for the Creep cycle, 1.430 for the Transient cycle, 0.257 for the Cruise cycle, and 0.234 over the HHDDT-S.

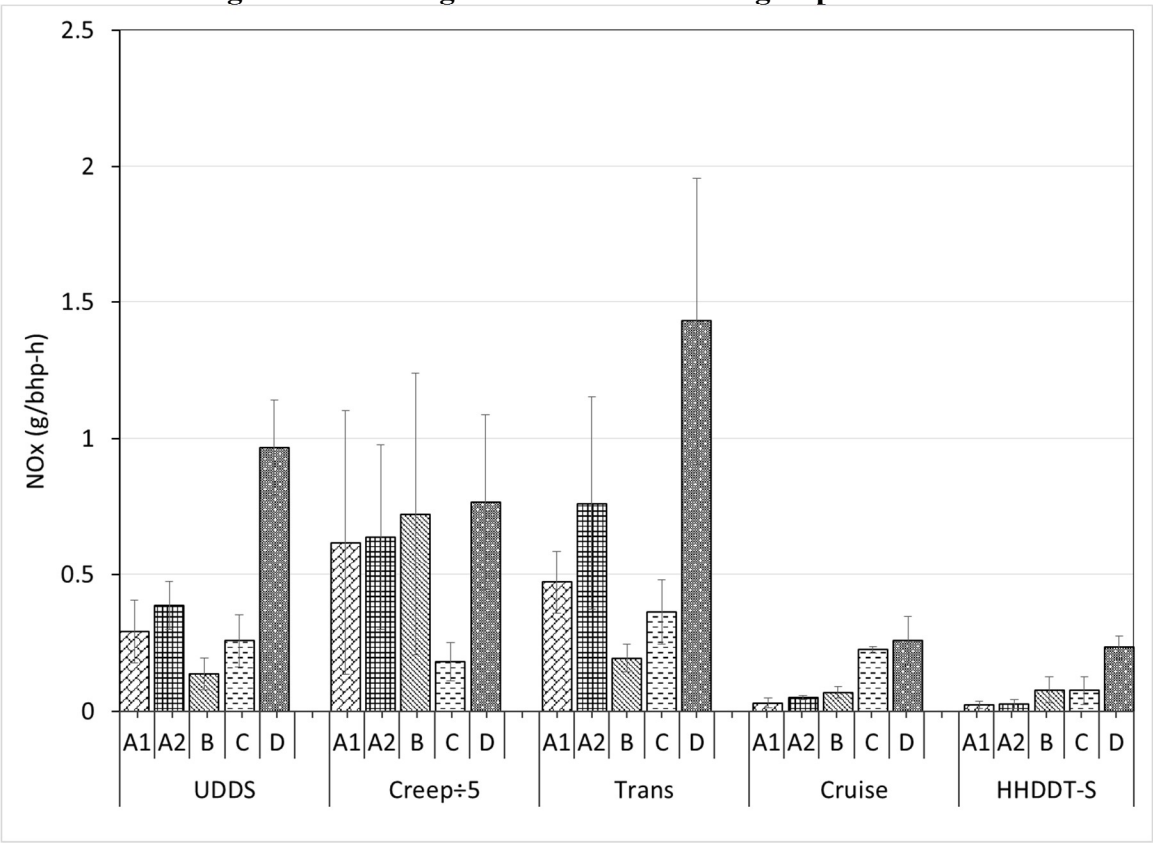
Subsequent to the dynamometer testing conducted at UCR, the manufacturer D vehicle was more extensively evaluated by the manufacturer. The vehicle was initially outfitted with a PEMS, which confirmed the poor NOx conversion efficiency observed from the UCR testing. Upon further investigation, it was found that this specific vehicle had served its entire life as a dealer demonstrator, and as such rarely or ever operated with a loaded trailer, and spent a considerable amount of time operating in an idle mode. This type of low-temperature, high proportion idle operation is known to cause significant exposure of the aftertreatment system to unburned hydrocarbons in the exhaust stream. An examination of the logged electronic history revealed no OBD faults or other indications of failure or system malfunction. A clear anomaly, however, was that due to its unusual, unladen service history and duty cycle, the engine had never undergone a regeneration event, despite being approximately 2.5 years in service (albeit with only 12,000 miles on the odometer). A series of conventional parked regenerations were performed. After further operation, there was a significant recovery of the aftertreatment NOx-conversion efficiency, as revealed through PEMS measurements. The regeneration intervention is believed to have been fully effective in driving off the accumulated unburned hydrocarbons that were hindering catalytic reaction. Additional chassis dynamometer testing of manufacturer D vehicle was conducted at the West Virginia University (WVU) Center for Alternative Fuels Engines and Emissions (CAFEE) Laboratory, replicating the testing that had been performed at UCR, with the exception of a 70,000 lbs. test weight. The results of that testing indicated a NOx emission rate of 0.39 g/mi over the UDDS cycle, near the lower end of the NOx emission rates found in the current study.

Figure 3-1 Average NO_x Emissions on a g/mi Basis



Note that D represents the UDDS emissions level measured upon retesting the manufacturer D truck after ensuring a regeneration event.

Figure 3-2. Average NO_x Emissions on a g/bhp-hr Basis



The NOx emissions from this study can be compared to those from previous studies. Studies that have included SCR-equipped 2010 and later model year production Class 8 trucks include studies conducted by the ARB as part of the development of the EMFAC2014 model (California Air Resources Board, 2015a, 2015b), and a study sponsored by the SCAQMD that included testing by UC Riverside (Miller, et al. 2013) and West Virginia University (WVU) (Carder et al., 2014). The earlier ARB study included a truck equipped with a manufacturer A 2010 engine certified to the 0.35 g NOx/bhp-hr level, and two manufacturer D engines certified to the 0.20 g NOx/bhp-hr level (California Air Resources Board, 2015a, 2015b). In that ARB study, the 2010 manufacturer A truck produced NO_x emissions of 3.73 g/mi over the UDDS, 16.78 g/mi over the Creep cycle, 6.33 g/mi over the Transient cycle, 0.60 g/mi over the Cruise cycle, and 0.74 g/mi over the high-speed Cruise cycle. All of those values are significantly higher than those obtained in this study for trucks tested at CE-CERT. In that same ARB study, a 2010 manufacturer D truck produced NOx emissions of 1.95 g/mi over the UDDS, 16.08 g/mi over the Creep cycle, 6.33 g/mi over the Transient cycle, 0.60 g/mi for the Cruise cycle, and 0.74 g/mi for the high-speed Cruise, while a 2011 manufacturer D truck produced NOx emissions of 1.98 g/mi over the UDDS. The emissions reported for those manufacturer D trucks are lower than that values for the manufacturer D truck tested in this study (before retesting at WVU). In the previous UCR SCAQMD study, UDDS emissions for trucks equipped a manufacturer A 8.3 liter engine (A4), a manufacturer A 11.9 liter engine (A5), and a manufacturer D 12.8 liter engine (D4) were found to be 1.07, 0.25, and 1.27 g/mi, respectively (Miller et al., 2013). Those values are comparable to or lower than the values observed in the present study. In that same UCR SCAQMD study, WVU found slightly NOx higher UDDS emissions of 1.98 g/mi for the manufacturer D vehicle

(D4) (Carder et al., 2015). Misra et al. (2013 and 2016) also conducted some in-use testing with PEMS on 2010 to 2014 model year SCR-equipped trucks on roads in the Sacramento area. They found NOx emissions rates of 0.07 to 0.27 g/bhp-hr for highway driving, consistent with the relatively low results obtained in this study, and NOx emission rates of 0.22 to 1.07 g/bhp-hr for arterial driving, which is more comparable to the UDDS and Transient cycles for this study.

The results of our study can be compared to the emission factors being used in the EMFAC model. For engines certified to the 0.20 g/bhp-hr NOx level, EMFAC2014 utilizes a ZMR of 1.89. This ZMR is adjusted by a fuel correction factor of 0.93 to account for the clean CARB diesel fuel used in California, such that a ZMR of 1.76 was used for the comparisons in this study for the 0.20 g/bhp-hr NOx engines. EMFAC2014 does not specifically utilize a ZMR for engines certified to the 0.35 g/bhp-hr NOx level, but the ZMR for those engines can be most directly compared with the 2011 model year ZMR of 3.26. That ZMR also is adjusted by a fuel correction factor of 0.93 to account for the use of clean CARB diesel fuel in California, resulting in a ZMR of 3.03, which was used for the comparisons in this study relating to the 0.35 g/bhp-hr NOx engines. EMFAC2014 is a relatively complicated model, including speed correction factors, tampering, malmaintenance and deterioration rates, and other factors. ZMRs, however, are best approximated by the emissions obtained over the UDDS cycle from low mileage vehicles that are well maintained and checked for any evidence of tampering, such as those selected for inclusion in this study. Consequently, that cycle is used as a comparison point between the current EMFAC model ZMRs and our study results. The UDDS emission rates from this study, as well as other studies of 2010 and newer model year heavy-duty vehicles, are presented in Figure 3-3 and Figure 3-4, along with the current EMFAC2014 ZMRs and the NOx Family Emission Limits (FELs) to which the engines are certified.

The other earlier studies include a study by the ARB that was utilized to update the emissions factors for the EMFAC model, and another UCR study funded by the South Coast Air Quality Management District (SCAQMD), which included several SCR-equipped 2010+ model year vehicles in the test fleets. For the UDDS under the current study, the emission levels for all of the 0.20 g/bhp-hr NOx trucks, except the manufacturer D truck prior to regeneration, are below the EMFAC2014 value. The NOx emissions for the manufacturer D truck after regeneration restored it NOx-conversion efficiency are also well below the EMFAC2014 value. The average UDDS values for the current study for the 0.20 g/bhp-hr NOx trucks are 0.89 g/mi if the outlier manufacturer D truck is excluded, or 0.77 g/mi if the UDDS emission rate from the manufacturer D truck as tested at WVU, after ensuring regeneration, is included. In all cases, those values are well below the EMFAC2014 value, with the lowest value being more representative of the in-use fleet. Similarly, the manufacturer A1 truck that was certified to a 0.35 g/bhp-hr NOx FEL has a UDDS emissions level of 0.99 g/mi, which is well below the 2011 model year ZMR approximation of 3.03 g/mi for 0.35 g/bhp-hr NOx trucks.

The UDDS results for the earlier SCAQMD study, with an average NOx level of 0.86 g/mi, are also well below the EMFAC2014 0.20 g/bhp-hr fuel-adjusted ZMR of 1.76 g/mi. The two manufacturer D trucks from the previous ARB study are comparable to but slightly higher than the EMFAC2014 ZMR, as those two vehicles were the primary source of information used in developing the ZMR. They are higher than all of the other trucks certified to the 0.20 g/bhp-hr, with the exception of the manufacturer D truck under the current study, which is again from the same manufacturer. The other manufacturer A3 truck in the earlier ARB study has NOx

emissions higher than the 2011 model year EMFAC2014 ZMR value that approximates the value for 0.35 g/bhp-hr NOx level engines.

Also, as the name implies, the ZMR is the estimated emissions rate at zero miles (i.e., for a new truck). Normally, an adjustment factor would be applied to account for the mileage accumulated on the vehicle. As the five vehicles in this study had low mileages (one of the selection criteria for the study, as shown in Figure 3-3), no adjustment factor has been applied for mileage. If an adjustment factor were to be applied, the ZMR estimates based on the UDDS emission results would go down slightly. Overall, this comparison analysis suggests that lower ZMRs for future EMFAC model updates may better represent the in-use emission rates of heavy-duty diesel trucks. This study suggests ZMRs may be better represented by the UDDS emission rates of 0.77 g/mi, perhaps ranging to 0.89 g/mi, for engines certified to a 0.20 NOx standard. A lower possible ZMR value of 0.99 g/mi was also found for an engine certified to a 0.35 NOx standard, but only a single vehicle with this certification level was tested in this study.

Figure 3-3 Comparison of NOx emission rates from this study, and the ARB and SCAQMD studies, for SCR-equipped 2010+ vehicles over the UDDS

	CE-CERT					ARB			SCAQMD		
Maker	A1	A2	B1	C1	D1	A3	D2	D3	A4	A5	D4

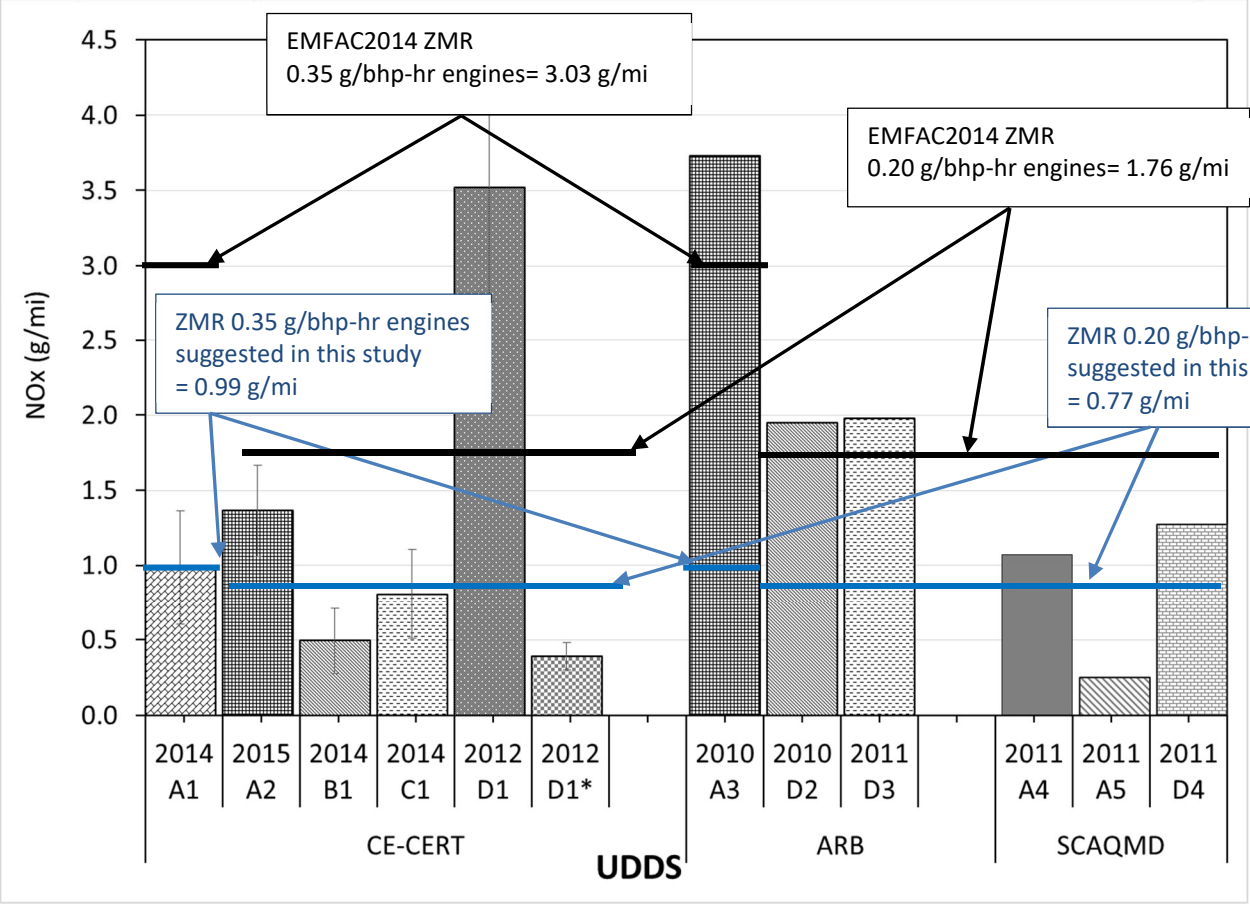
STD/FEL g/bhp-hr	0.35	0.20	0.20	0.20	0.20	0.35	0.20	0.20	0.20	0.20	0.20

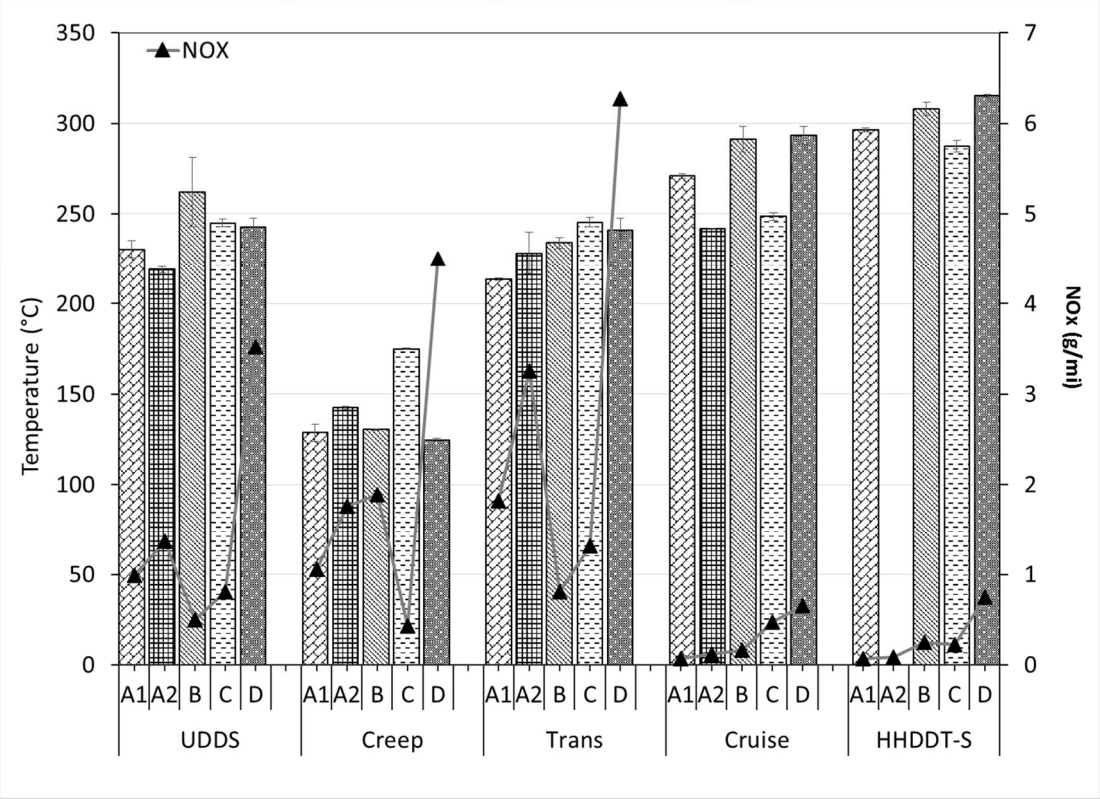
*Note that D1 represents the UDDS emissions level found after retesting the manufacturer D1 truck after a regeneration.

Figure 3-4 Comparison of NOx Zero Mile Rates Between EMFAC2014 and this Study



For SCR-equipped vehicles, NOx emissions are typically strongly correlated to the SCR temperature. Specifically, a minimum exhaust temperature is needed to promote hydrolysis of urea into ammonia (NH_3), which then reduces NOx into nitrogen (N_2) and water (H_2O) (Majewski, 2006). That requisite conversion temperature is typically around 250°C. The SCR inlet temperature for all vehicles in this study is provided in Figure 3-5. The results show that the average SCR inlet temperature is at or above 250°C for the Cruise and HHDDT-S cycles for all of the vehicles, except for the manufacturer A2 vehicle over the Cruise cycle. Note that although the SCR inlet temperature is not available for the manufacturer A2 engine, the SCR outlet temperature for that engine over the HHDDT-S cycle was above 250°C, indicating that the average SCR inlet would be above 250°C, as the inlet temperature was higher than the outlet temperature for all test combinations.

Figure 3-5. Average SCR Inlet Temperature



The average measured NOx emissions are also shown in Figure 3-5, to provide an additional comparison between NOx emissions and SCR inlet temperature. NOx emissions were lowest in most cases for the Cruise and HHDDT-S cycles, consistent with the highly effective conversion rate of NOx when the SCR has reached its effective operational temperature, with the increased NOx reduction efficiency more than making up for the increased NOx engine out emissions at high speed, high load operation. For the UDDS and Transient cycles, the average SCR inlet temperature was in the range of 213 to 261°C. This suggests that the SCR is at or above its operational temperature for only part of those cycles, which is consistent with the higher average NOx emissions observed over the UDDS and Transient cycles compared to the two Cruise mode cycles. The lowest temperature was found over the Creep cycle, where the SCR inlet temperature ranged from approximately 124°C to 174°C. At those lower temperatures, the SCR would not be reducing NOx emissions as effectivity and the denominators in term of g/mi and g/bhp-hr would be very low, so that is the cycle where the highest g/mi NOx emissions were observed.

Additional comparisons between NOx emissions and SCR inlet temperatures are provided in Figure 3-6, Figure 3-7, and Figure 3-8. These Figures show the average SCR inlet temperature for the UDDS, the HHDDT-S, and the all cycles except the Creep, respectively. For these figures the data from the manufacturer D truck have been removed, since it is an outlier, and no SCR temperature data is available for the manufacturer A2 truck over the HHDDT-S. The Creep data are eliminated from Figure 3-8, since the temperature for the Creep cycle are all below those needed for the urea dosing. Linear regression lines are shown in Figure 3-6 and Figure 3-7 for the UDDS and HHDDT-S cycles, respectively. For the UDDS cycle, these results are consistent with the expected trends for NOx emissions as a function of SCR inlet temperature. NOx

emissions are generally found to decrease as the SCR inlet temperature goes from approximately 200 to 250°C. For the HHDDT-S cycle, NOx emissions are very low as the average SCR temperature is well above 250°C. The minor variations in NOx emissions shown on the HHDDT-S chart are likely due to factors other than SCR temperature, as the SCR temperatures are already well above the optimal temperatures needed for good SCR conversion efficiencies.

Figure 3-6. Average SCR Inlet Temperature vs NOx emissions over UDDS

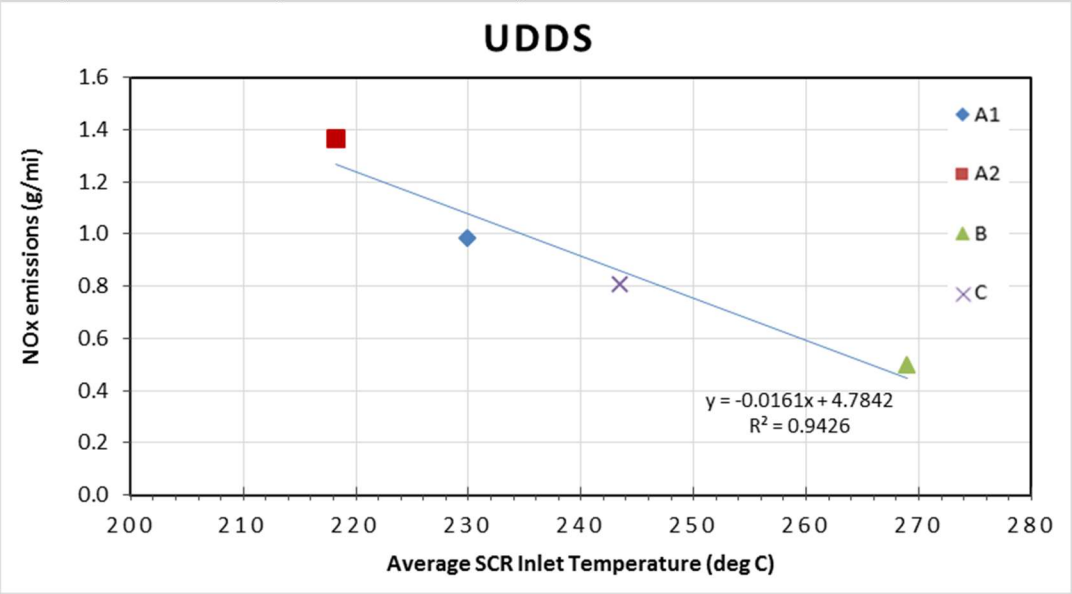


Figure 3-7 Average SCR Inlet Temperature vs NOx emissions over HHDDT-S

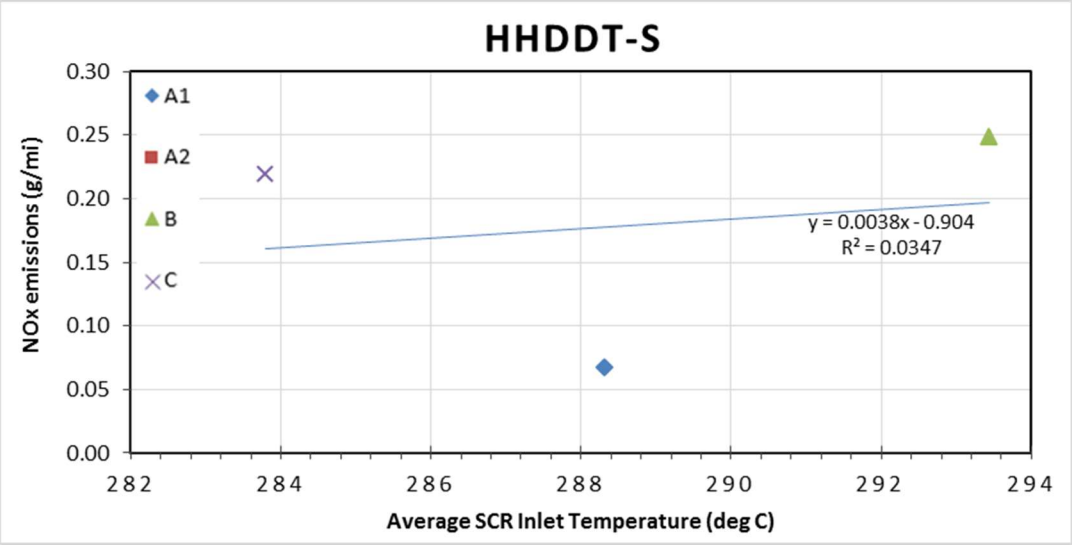

Figure 3-8 Average SCR Inlet Temperature vs NOx emissions

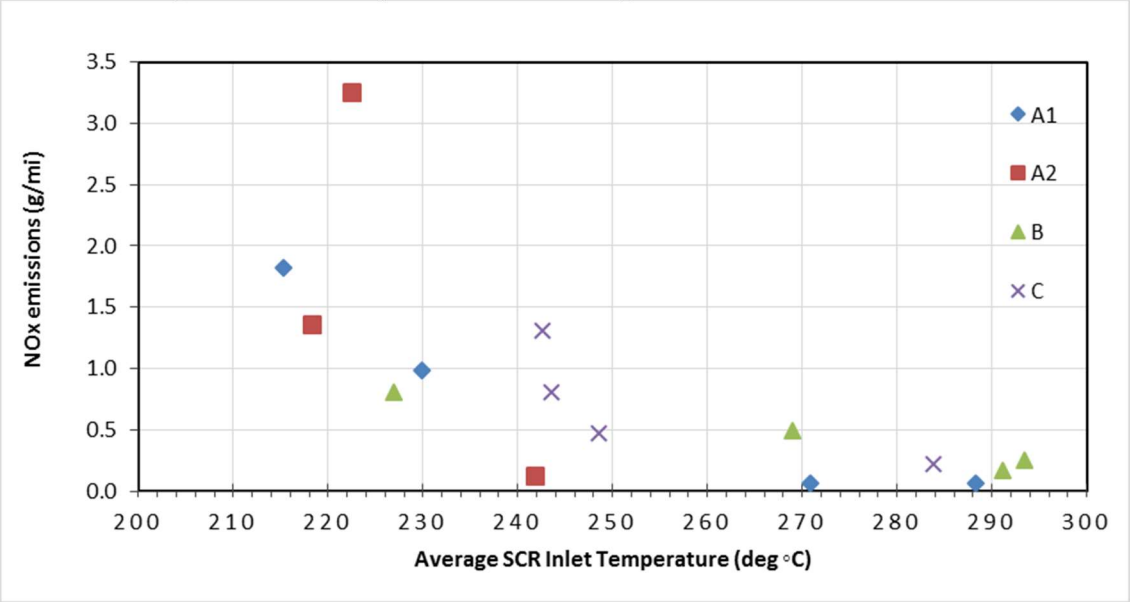

Plots of real-time cumulative NOx emissions over the UDDS are provided in Figure 3-9 to Figure 3-13, along with the corresponding exhaust temperatures measured before the aftertreatment system, before the DPF, and before the SCR. The cumulative NO_x emission show that NO_x emissions for the UDDS cycles are primarily formed during the second and third peaks for the cycle (see Appendix B). At that point, the vehicles are accelerating, while at the same time the exhaust temperature is below 250°C, which is below the temperature where the SCR provides more effective reduction of NOx emissions.

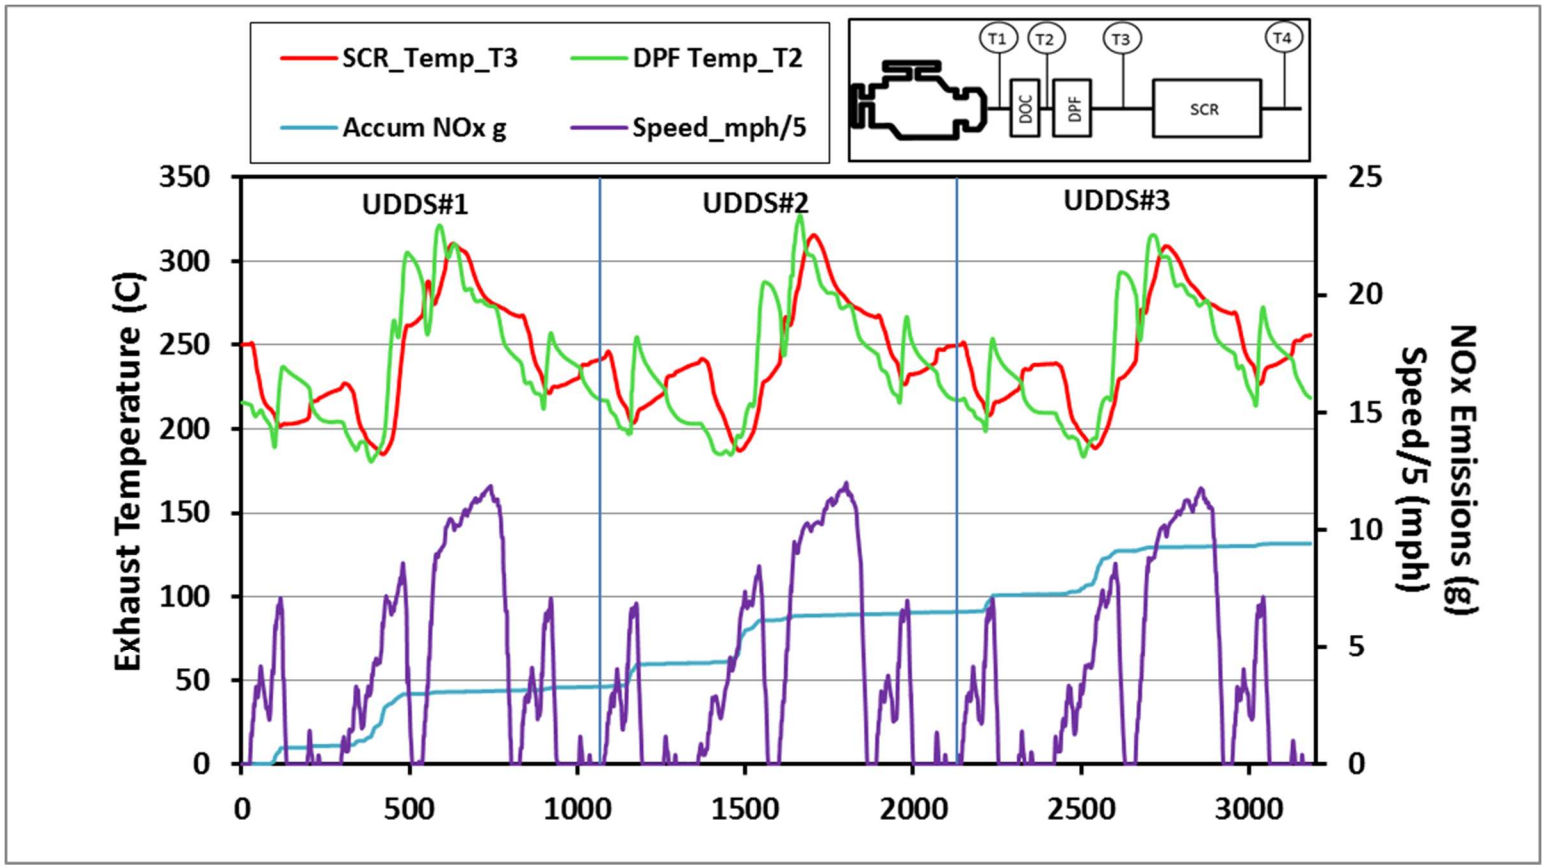

Figure 3-13. Real-time NOx Emissions of UDDS for Manufacturer D (201502100726)

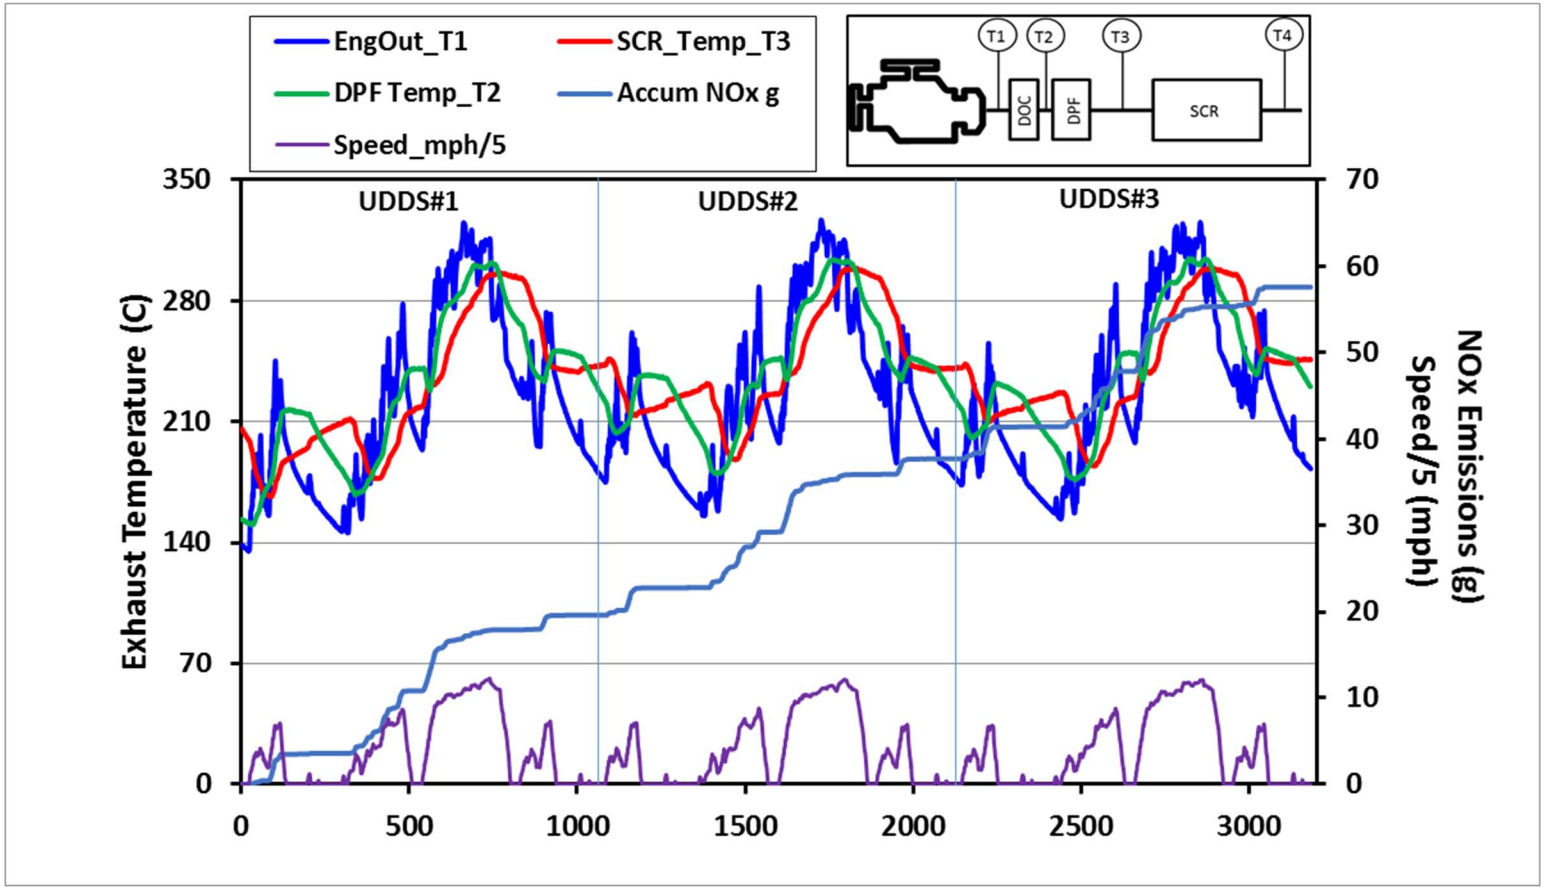

3.2 PM Mass Emissions

Measured PM mass emissions for the test trucks are shown on a g/mi and g/bhp-hr basis in Figure 3-14 and Figure 3-15, respectively.

PM mass emissions were very low for most of the test cycles. PM emissions were below 0.015 g/mi and 0.006 g/bhp-hr for all vehicles over all cycles, except for the manufacturer C truck over the HHDDT-S cycle and the manufacturer A2 truck over the Creep cycle. The PM levels are significantly below the 0.01 g/bhp-hr PM standard under all test conditions, except the manufacturer C truck over the HHDDT-S cycle.

Figure 3-14. Average PM Mass Emissions on a g/mi Basis

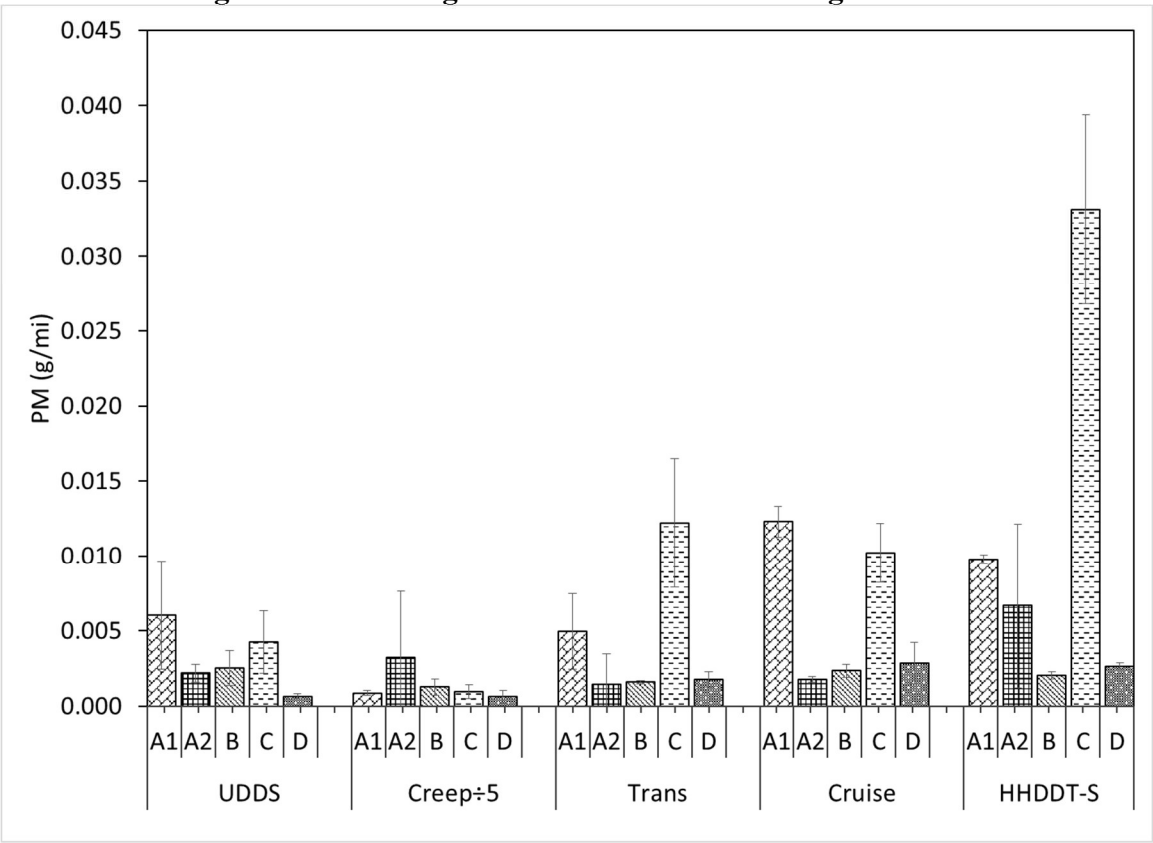

Figure 3-15. Average PM Mass Emissions on a g/bhp-hr Basis

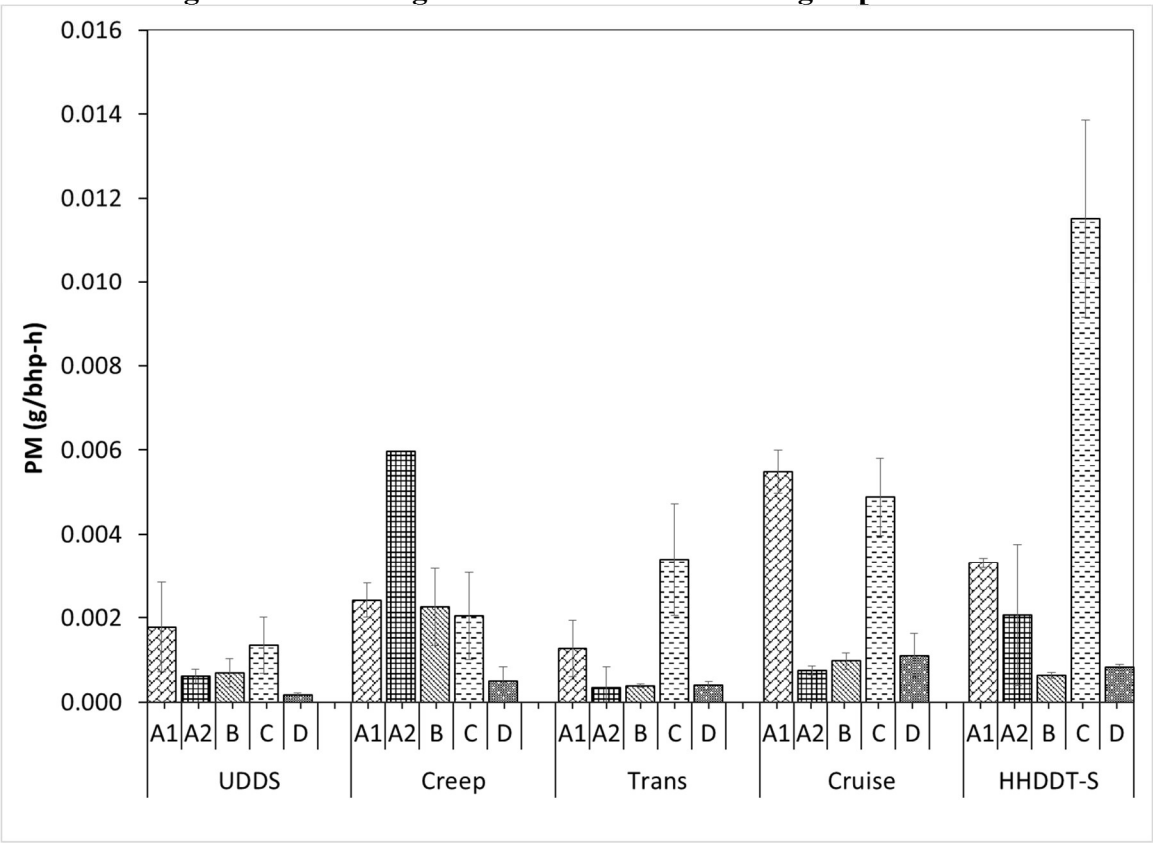

The very low PM levels are consistent with the results of previous studies. For the previous ARB EMFAC2014 study, PM emission rates were below 0.015 g/mi for most vehicle/cycle combinations as well, although three vehicle/cycle points did show PM emission rates ranging from 0.028 to 0.055 g/mi (California Air Resources Board, 2015a, 2015b). In the earlier UCR-SCAQMD study (Miller et al., 2013) of goods movement trucks, PM emissions were ≤0.002 g/mi for most vehicle/cycle combinations, although there were a few vehicle/cycle combinations above 0.002 g/mi for some of the 2010+ vehicles on the Regional and near-dock drayage cycles. Carder et al. (2014) found PM emissions of <0.010 g/mi for a 2010+ SCR-equipped truck over a range of cycles including a UDDS, and near-dock, local, and regional drayage cycles.

3.3 THC Emissions

THC emissions for the test trucks are shown on a g/mi and g/bhp-hr basis in Figure 3-16 and Figure 3-17, respectively.

As expected, THC emissions were very low for most of the test cycles, due to the presence of the DPF/SCR aftertreatment system, and are comparable to background levels in some cases, as indicated by the negative values or the error bars extending below zero for some tests. THC emissions were below 0.034 g/mi and 0.011 g/bhp-hr for all test vehicles over the UDDS, Transient, Cruise, and HHDDT-S cycles, and were below 0.458 g/mi and 0.220 g/bhp-hr for all vehicles over all test cycles. The Creep cycle did show considerably higher THC emissions on a per-mile basis, ranging from 0.241 to 0.458 g/mi, and from 0.015 to 0.046 g/bhp-hr, due its short, low-speed accelerations and longer idle periods.

In comparison with other studies, the ARB EMFAC2014 study showed HC emissions that were below 0.050 g/mi for many vehicle/cycle combinations, although some vehicle/cycle points ranged from 0.117 to 1.442 g/mi, and one vehicle had an emission rate of 2.740 g/mi over the Creep cycle (California Air Resources Board, 2015a, 2015b). In the UCR-SCAQMD study (Miller et al., 2013), THC emission rates over the UDDS were 0.030 g/mi or less for all diesel trucks, except for one 2011 model year manufacturer C truck. Carder et al. (2014) found NMHC emissions of ≤0.005 g/mi for a 2010+ SCR-equipped truck over a range of cycles including a UDDS, and near-dock, local, and regional drayage cycles.

Figure 3-16. Average THC Emissions on a g/mi Basis

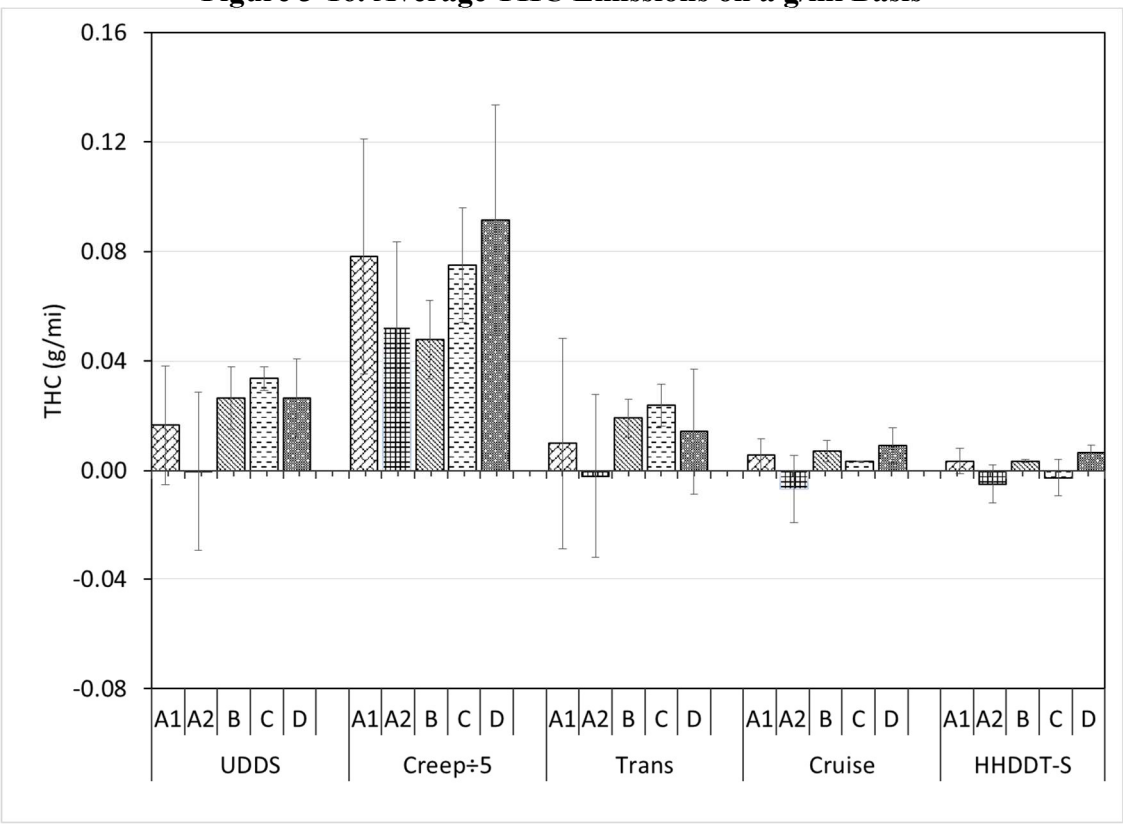

Figure 3-17. Average THC Emissions on a g/bhp-hr Basis

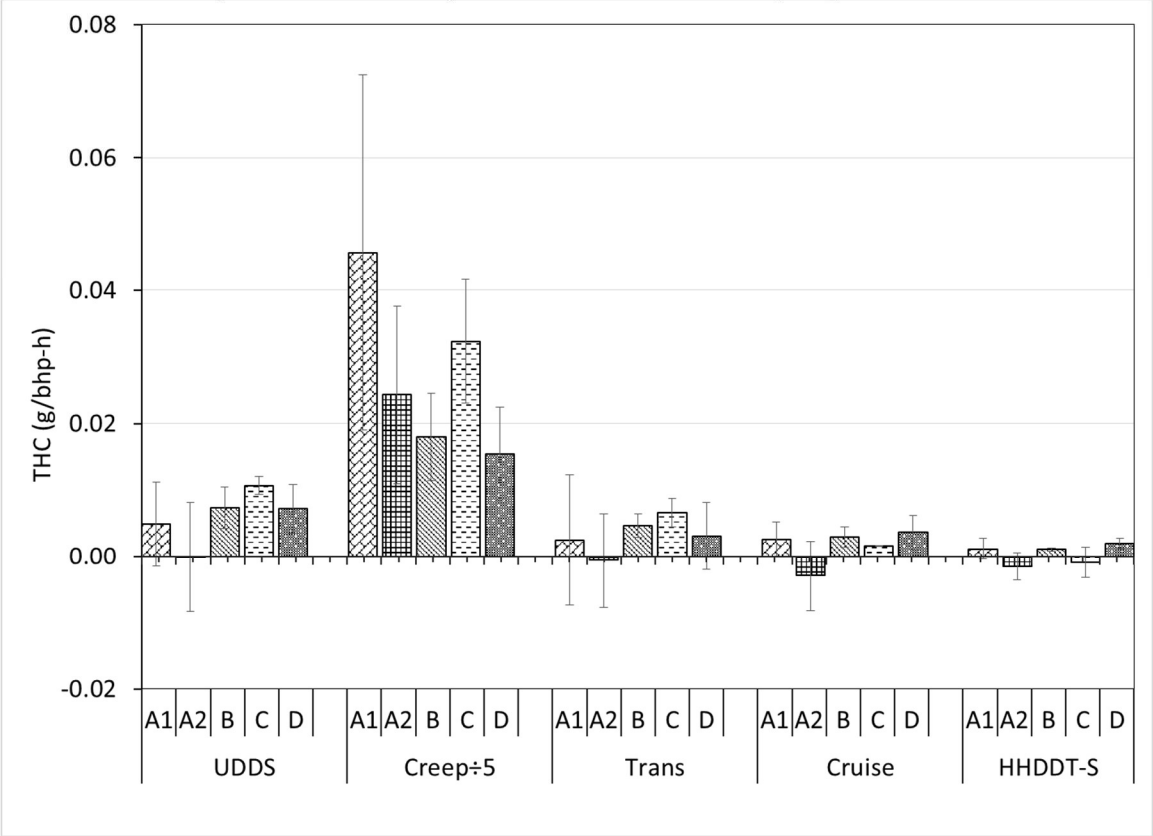

3.4 CO Emissions

CO emissions for the test trucks are shown on a g/mi and g/bhp-hr basis in Figure 3-18 and Figure 3-19, respectively.

CO emissions were very low for most of the test cycles. CO emissions were below 0.2 g/mi for all vehicles over all cycles, except over the Creep cycle and the manufacturer D truck over the Transient cycle. Similarly, on a g/bhp-hr basis, CO emissions were below 0.06 g/bhp-hr for all vehicles, except over the Creep cycle. Emissions over the Creep cycle ranged from 0.004 to 5.042 g/mi and from 0.001 to 1.011 g/bhp-hr. Overall, the CO emission rates were considerably below the 15.5 g/bhp-hr and 14.0 g/bhp-hr standards established by EPA and ARB, respectively, for all vehicles and cycles.

Figure 3-18. Average CO Emissions on a g/mi Basis

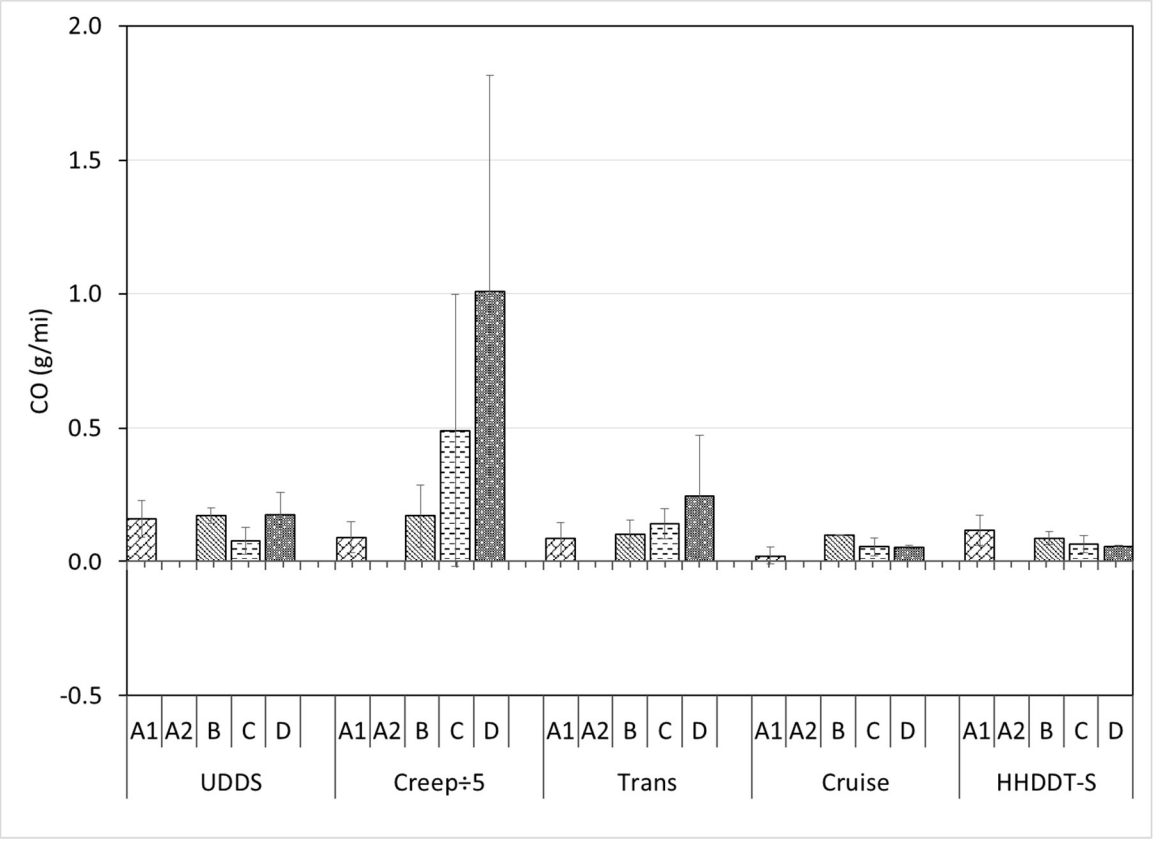

Figure 3-19. Average CO Emissions on a g/bhp-hr Basis

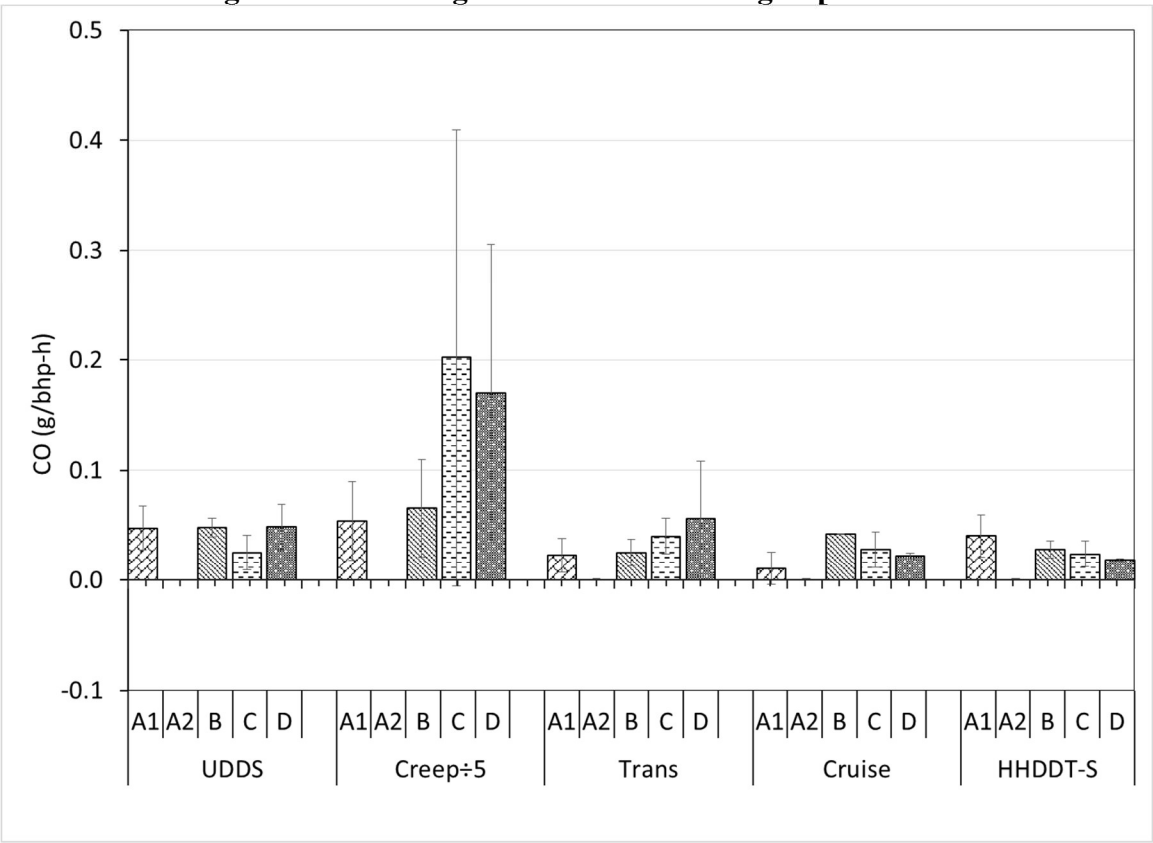

In comparison with other studies, the ARB EMFAC2014 study showed that CO emissions were below 0.500 g/mi for a majority of the vehicle/cycle combinations, although some vehicle/cycle points ranged from 1.64 to 4.75 g/mi, and one vehicle had an emission rate of 9.09 g/mi over the Creep cycle (California Air Resources Board, 2015a, 2015b). In the UCR-SCAQMD study (Miller et al., 2013), CO emission rates over the UDDS were 0.064 g/mi or below for all diesel trucks, except for one 2011 model year manufacturer C truck, with many of those levels being at or below the background level. Carder et al. (2014) found CO emissions of 0.216, 0.749, 0.169, and 0.854 g/mi for a 2010+ SCR-equipped truck over UDDS, and near-dock, local, and regional drayage cycles, respectively.

3.5 Fuel Economy/Consumption and CO_2 Emissions

CO_2 emissions for the five test trucks are shown on a g/mi and a g/bhp-hr basis in Figure 3-20 and Figure 3-21, respectively.

CO_2 emissions over the UDDS cycles ranged from 1864 to 2219 g/mi and 548 to 678 g/bhp-hr. CO_2 emissions over the Transient cycle were similar to those over the UDDS, ranging from 2260 to 2624 g/mi and 584 to 724 g/bhp-hr. CO_2 emissions over the Cruise and HHDDT-S cycles were slightly lower on a g/mi basis. For the Cruise cycle, CO_2 emissions ranged from 1160 to 1443 g/mi and from 518 to 589 on a g/bhp-hr basis. For the HHDDT-S cycle, CO_2 emissions ranged from 1450 to 1743 g/mi and from 491 to 572 on a g/bhp-hr basis. CO_2 emissions were highest over the Creep cycle, where loads are lowest, ranging from 3748.7 to 5095.0 g/mi and 816.6 to 2337.4 g/bhp-hr.

Figure 3-20. Average CO_2 Emissions on a g/mi Basis

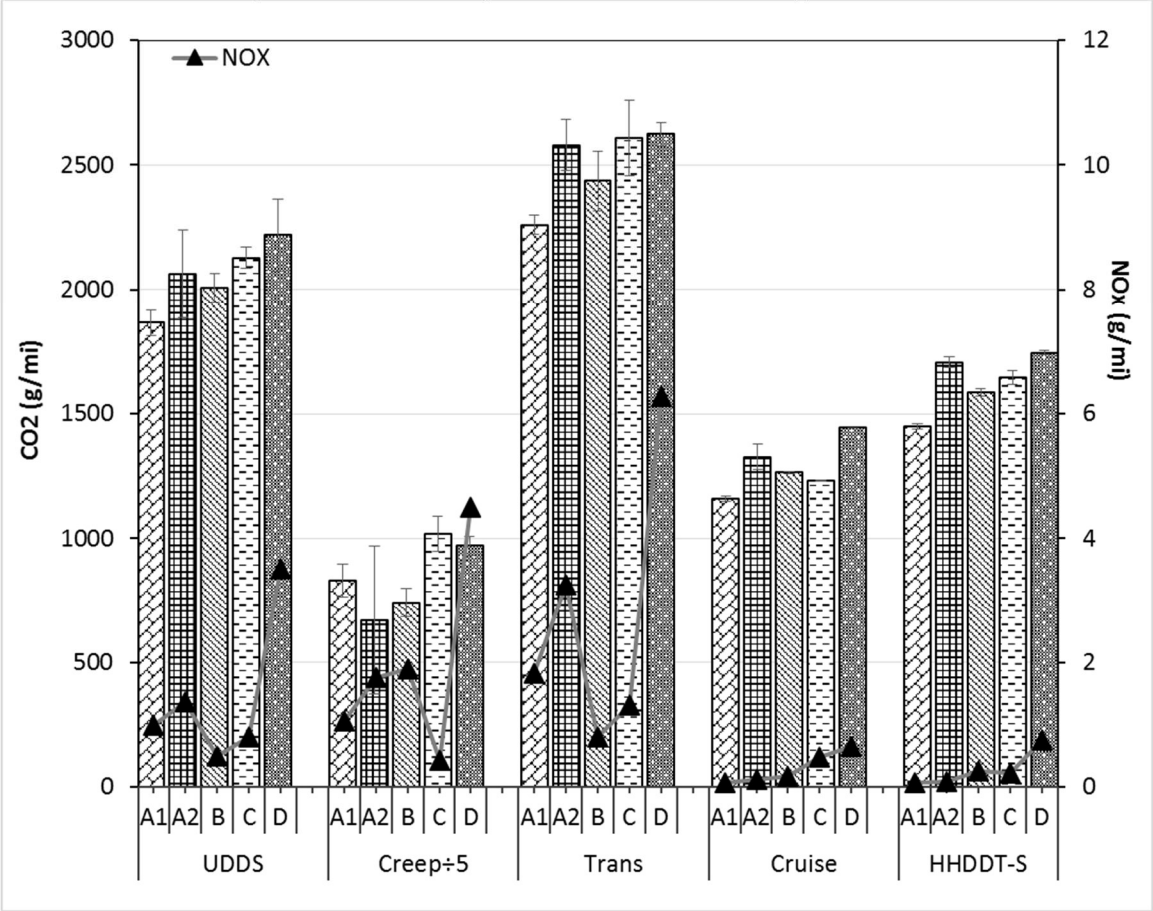

Figure 3-21. Average CO_2 Emissions on a g/bhp-hr Basis

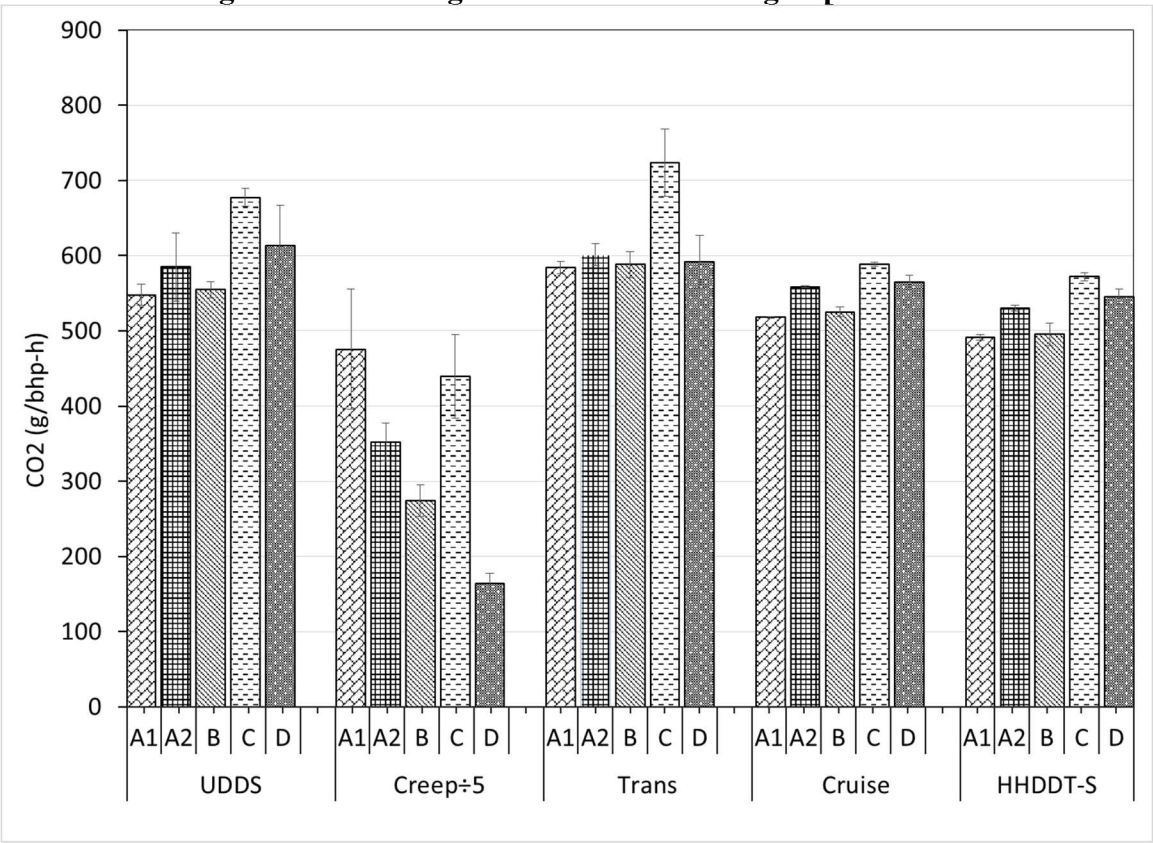

The differences in CO_2 emissions between different vehicles over the same cycle at the same test weight could be more a function of the differences in the dynamometer loading between trucks or differences in the different engine/chassis technologies. Table 3-1 provides a comparison between the chassis dynamometer work in units of bhp-hr and CO_2 emissions in g/mi units. Overall, the results show that the chassis dynamometer work was relatively comparable between different vehicles for the same test cycle, and showed smaller differences than the CO_2 emissions. The biggest differences in the chassis dynamometer work is the lower work for the manufacturer A2 vehicles over the Cruise and HHDDT-S cycles, due to the lack of a roof fairing on the cab, as discussed in section 2.2 and Appendix C.

A closer examination of CO_2 emissions as a function of chassis dynamometer work is provided in Figure 3-22 to 3-25. For those figures, the data for the manufacturer A vehicle have been excluded to provide a closer comparison among the four trucks that had more similar dynamometer loadings. The figures include a dashed line representing the linear regression based on the actual data and a solid line representing the theoretical percentage increase in CO_2 emissions that would be expected for a given percentage increase in work, if the BSFC values for all of the engines were held constant. Interestingly, the slope of the regression for the CO_2 emissions is steeper than what would be expected for a given percentage increase in load, suggesting that the differences in CO_2 emissions for the different trucks over a given cycle are related to more than just simple differences in work performed.

Table 3-1. Comparison of Chassis Dynamometer Work vs. CO_2 Emissions

Cycles	A1		A2		B1		C1		D1	
	Chassis Dyno bhp-hr	CO2 g/mi	Chassis Dyno bhp-hr	CO2 g/mi	Chassis Dyno bhp-hr	CO2 g/mi	Chassis Dyno bhp-hr	CO2 g/mi	Chassis Dyno bhp-hr	CO2 g/mi
UDDS	56.21	1864.9	53.14	2063.4	57.07	2005.7	59.18	2128.3	57.70	2219.0
HHDDT_Creep	2.60	4147.6	2.69	4781.2	3.01	3707.4	3.34	5095.5	2.78	4850.3
HHDDT_Tranient	42.14	2260.1	43.06	2579.9	42.69	2436.2	44.70	2607.3	43.97	2624.7
HHDDT_Cruise	58.60	1160.2	54.45	1326.6	59.70	1264.4	60.68	1232.1	61.01	1443.4
HHDDT-S	66.76	1449.9	59.47	1706.7	68.00	1586.7	70.41	1645.9	68.22	1744.0

Figure 3-22. Correlations of Chassis Dynamometer Work and CO_2 Emissions over the UDDS Cycle

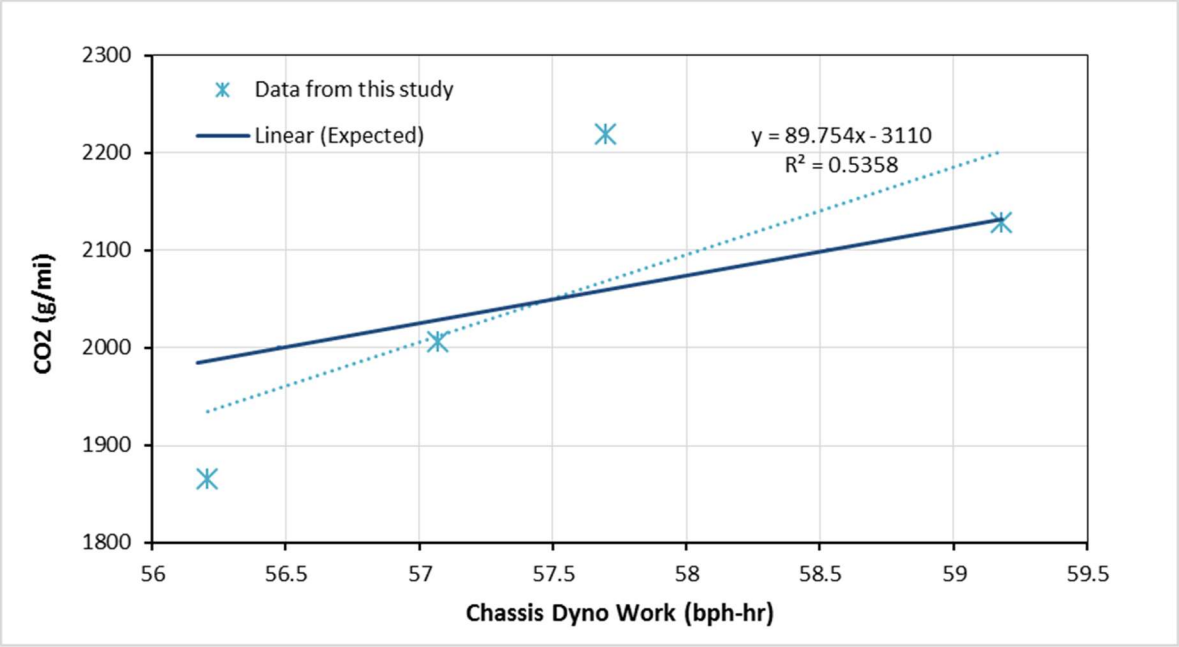

Figure 3-23. Correlations of Chassis Dynamometer Work and CO_2 Emissions over the Transient Cycle

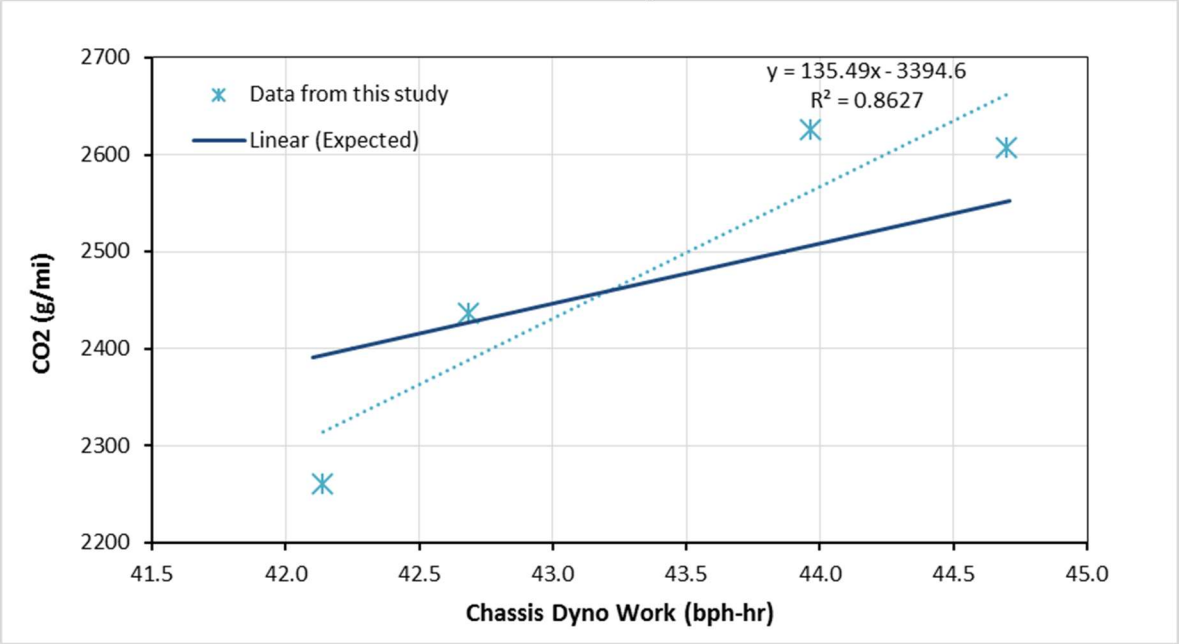

Figure 3-24. Correlations of Chassis Dynamometer Work and CO_2 Emissions over the Cruise Cycle

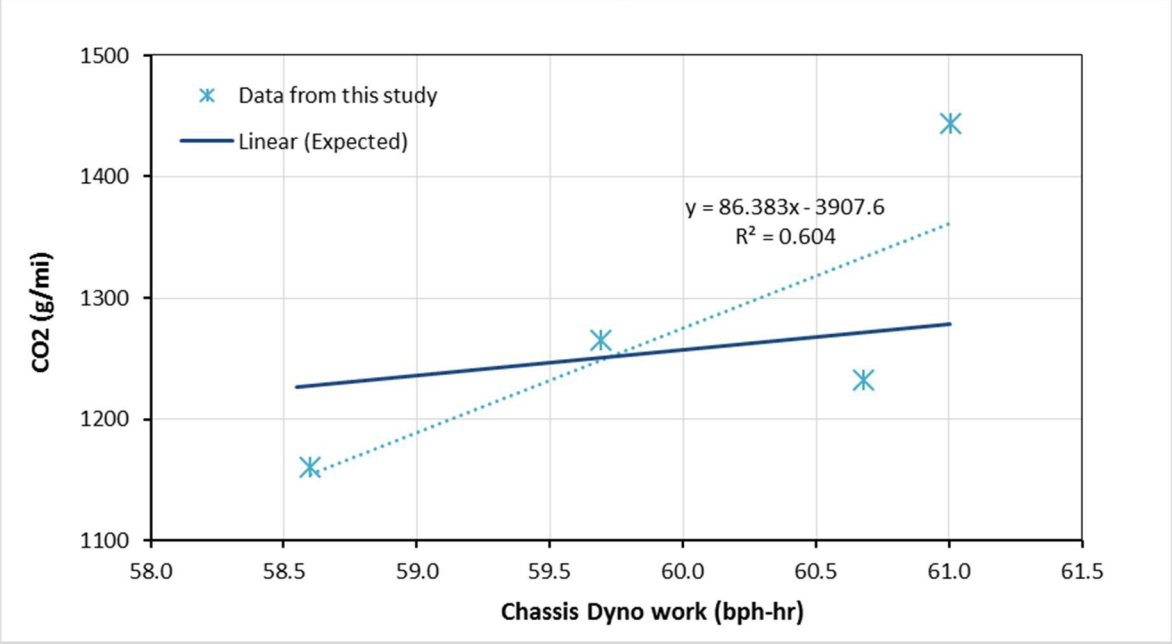

Figure 3-25. Correlations of Chassis Dynamometer Work and CO_2 Emissions over the HHDDT-S Cycle

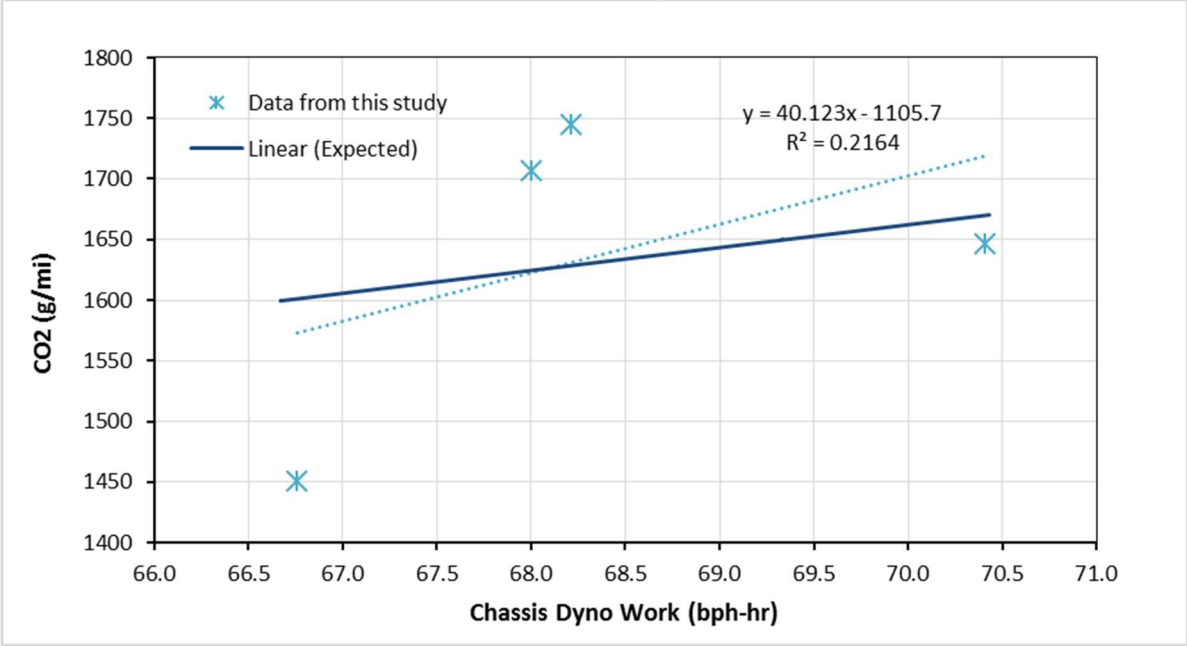


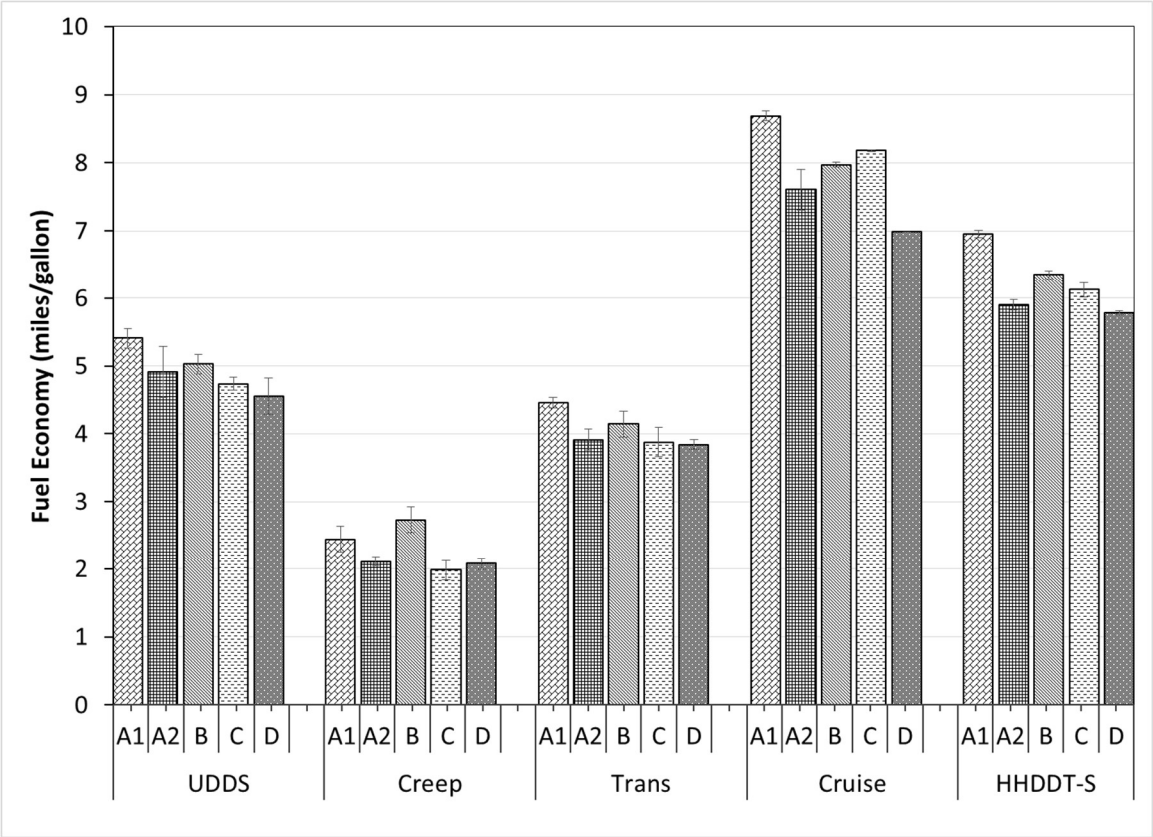
In comparison, CO_2 emissions as measured in the earlier ARB study ranged from 1,831 to 2,964 g/mi over the UDDS, from 2,034 to 2,432 g/mi over the Transient cycle, from 1,014 to 1,558 g/mi over the Cruise cycle, from 1,310 to 1,898 g/mi for the High Speed Cruise cycle, and from 3,805 to 5,006 g/mi over the Creep cycle (California Air Resources Board, 2015a, 2015b). For the previous UCR-SCAQMD study (Miller et al., 2013), CO_2 emissions for the Class 8 diesel trucks ranged from 2,379 to 3,117 g/mi over the hot UDDS cycle. For the previous WVU-SCAQMD study (Carder et al., 2014), CO_2 emissions for 2009 model year and newer Class 8 goods movement diesel trucks ranged from 2,115 to 2,757 g/mi over the UDDS cycle. Note that some of the differences between those various studies could be due to differences in test weight loading, as the ARB study used a weight of 56,000 lbs., the SCAQMD study used a test weight of 69,500 lbs, and the present study used 65,000 lbs. It should also be noted that the range in CO_2 emissions for trucks tested over the same cycle in those two earlier studies is similar to that found in the current study.

For comparison, average NOx emissions for each vehicle/cycle combination are also included in Figure 3-20, as there can be tradeoffs between lowering CO_2 emissions and resultant increases in NO_x emissions. Overall, there do not appear to be significant trends with respect to a CO_2/NO_x emissions tradeoff. In particular, vehicles/engines with lower CO_2 emissions do not necessarily have higher levels of NO_x emissions. Similarly, vehicles/engines with higher NO_x emissions do not exhibit significantly lower CO_2 emissions.

Fuel economy for the five test trucks is shown in Figure 3-26. Fuel economy was similar over the UDDS and Transient cycles. Fuel economy over the UDDS ranged from 4.56 to 5.41 g/mi, while fuel economy over the Transient ranged from 3.84 to 4.46 mi/gal. Fuel economy over the Cruise and HHDDT-S cycles was slightly better, ranging from 6.98 to 8.69 mi/gal for the Cruise cycle, and from 5.78 to 6.95 mi/gal for the HHDDT-S cycle. The lowest fuel economy was found over

the Creep cycle, and ranged from 1.978 to 2.689 mi/gal., due to the slow speeds and stop-and-go nature of the cycle. Again, it should be noted that the differences in fuel economy between different vehicles for the same cycle at the same test weight could be more a function of the differences in the dynamometer loading between trucks due to different frontal areas, as opposed to differences in engine technologies/manufacturers.

Figure 3-26. Average Fuel Economy on a miles/gallon Basis



3.6 Idle Emissions Results

Idle emissions in g/hr units are provided in Table 3-2. For NO_x, idle emission levels varied from 4.7 to 21 g/hr. The manufacturer D truck showed the highest idle NOx emissions, consistent with its higher overall emissions over the other test cycles. PM emissions were relatively low at idle, ranging from background levels to 0.008 g/hr. THC, NMHC, CH_4, and CO idle emissions ranged from 0.09 to 1.37 g/hr, from 0.04 to 0.94 g/hr, from background levels to 0.57 g/hr, and from 0.10 to 6.79 g/hr, respectively. CO_2 idle emissions ranged from 3,552 to 6,820 g/hr.

Idle NOx emissions in EMFAC11 and EMFAC2014 are 30 g/hr and 12 g/hr, respectively, for 2010 and newer model year vehicles, with our results suggesting that EMFAC2014 represents a more realistic value. PM idle emissions in EMFAC11 and EMFAC2014 are 0.072 g/hr and 0.001 g/hr, respectively, for 2010 and newer vehicles, with the EMFAC2014 values being closer to the values found in our study. CO_2 idle emissions in EMFAC11 and EMFAC2014 are 4934 g/hr and 4547 g/hr, respectively, for 2010 and newer vehicles.

The idle emission values observed in this study are generally lower than those that have been found in previous studies of older vehicles. Khan et al. (2006) reviewed idle emissions from 2005 and older engines. They found that idle NO_x emissions varied from near 0 g/hr to 200 g/hr, with a majority of the vehicles equipped with diesel engines and electronic fuel injection having idle emissions between 40 to 160 g/hr. They found that average idle NO_x emissions ranged between 20 and 26 g/hr with the EGR on, but jumped up to 80–90 g/hr when the EGR valve was shut off. PM idle emissions for the electronically controlled engines were typically below 3 g/hr, with PM idle emissions for many of the later generation engines/vehicles (as of 2005) being near the detection limits.

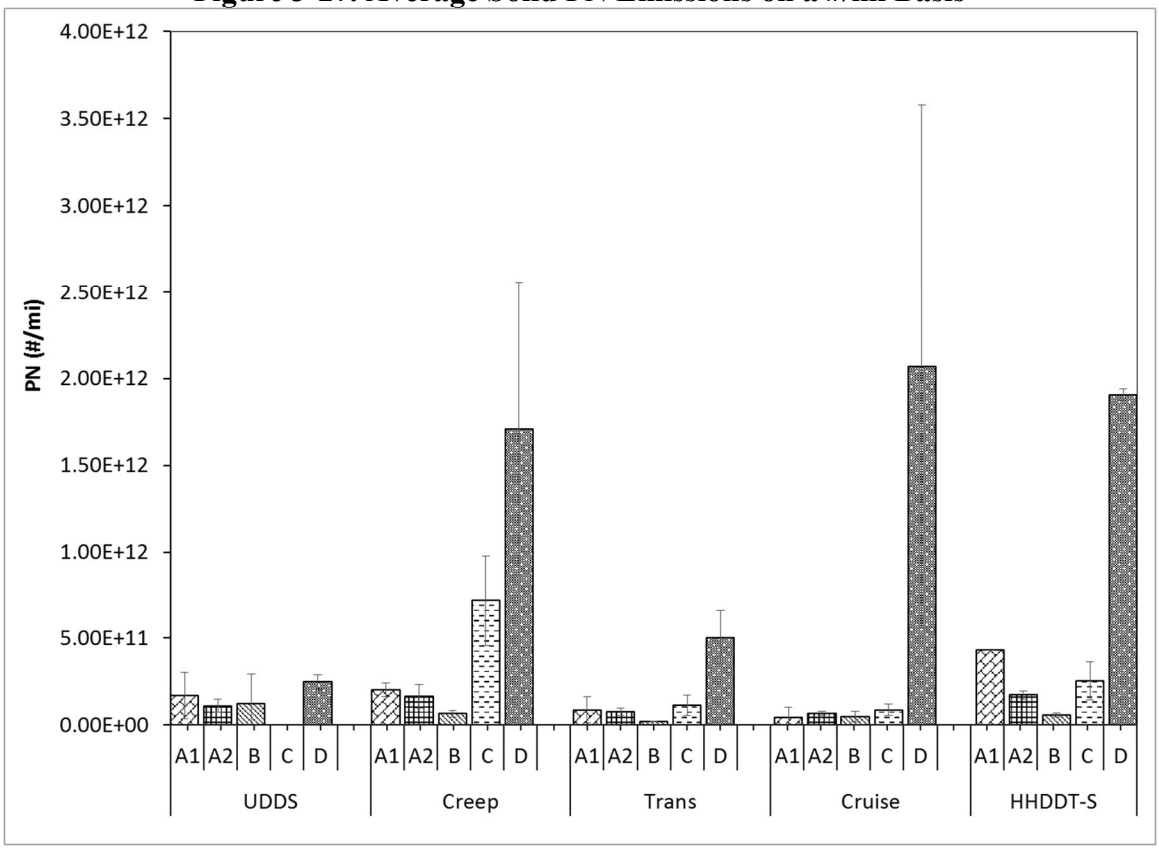
3.7 Solid Particle Number Emissions

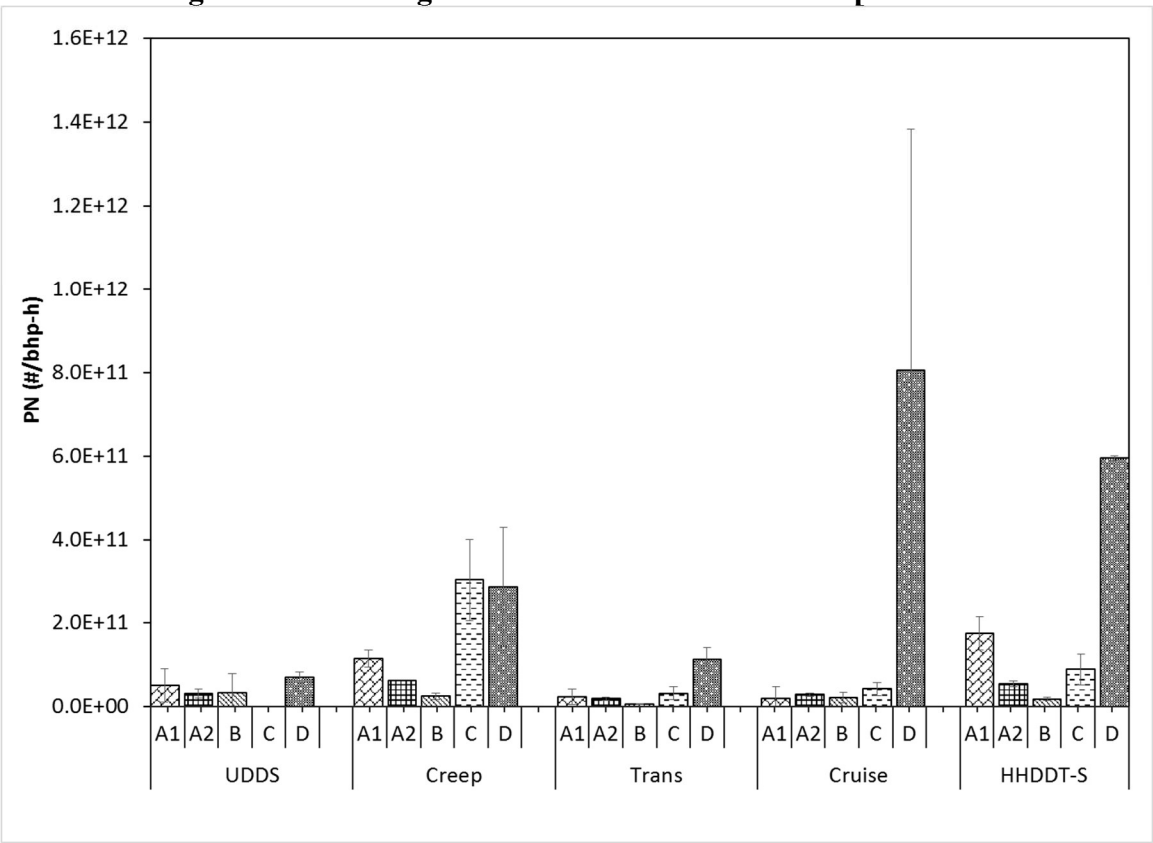
Solid PN emissions for the test trucks are shown on a #/mi and #/bhp-hr basis in Figure 3-27 and Figure 3-28, respectively. Figure 3-27 shows that all the solid PN emissions were under $2.1x10^{12}$ #/mi over all the cycles. On a #/mi basis, solid PN emissions ranged from 1.1 $x10^{11}$ to 2.5 $x10^{11}$ over the UDDS, from $6.5x10^{10}$ to $1.7x10^{12}$ over the Creep cycle, from 1.9 $x10^{10}$ to 5.0 $x10^{11}$ over the Transient cycle, from 4.3 $x10^{10}$ to $2.1x10^{12}$ over the Cruise cycle, and from 5.7 $x10^{10}$ to 1.9 $x10^{12}$ over the HHDDT-S cycle. The lowest solid PN emissions were found over the Transient and Cruise cycles. Solid PN emissions also varied depending on the different trucks. The manufacturer D truck exhibited significantly higher solid PN emissions compared to the other trucks over all the HHDDT cycles. The manufacturer B truck showed the lowest solid PN emissions over the Creep, Transient and HHDDT-S cycles. On a #/bhp-hr basis, solid PN emissions were under 8 x 10^{11} #/bhp-hr for all the cycles, while the solid PN emissions of the manufacturer D vehicle were relatively higher than those of the other trucks, especially over the Cruise and HHDDT-S cycles.

Figure 3-27. Average Solid PN Emissions on a #/mi Basis



* For A2, CS-CPC sampled from second dilution tunnel and results were corrected with dilution factor, others sampled from CVS. The data of C for UDDS was not available.

Figure 3-28. Average Solid PN Emissions on a #/bhp-hr Basis

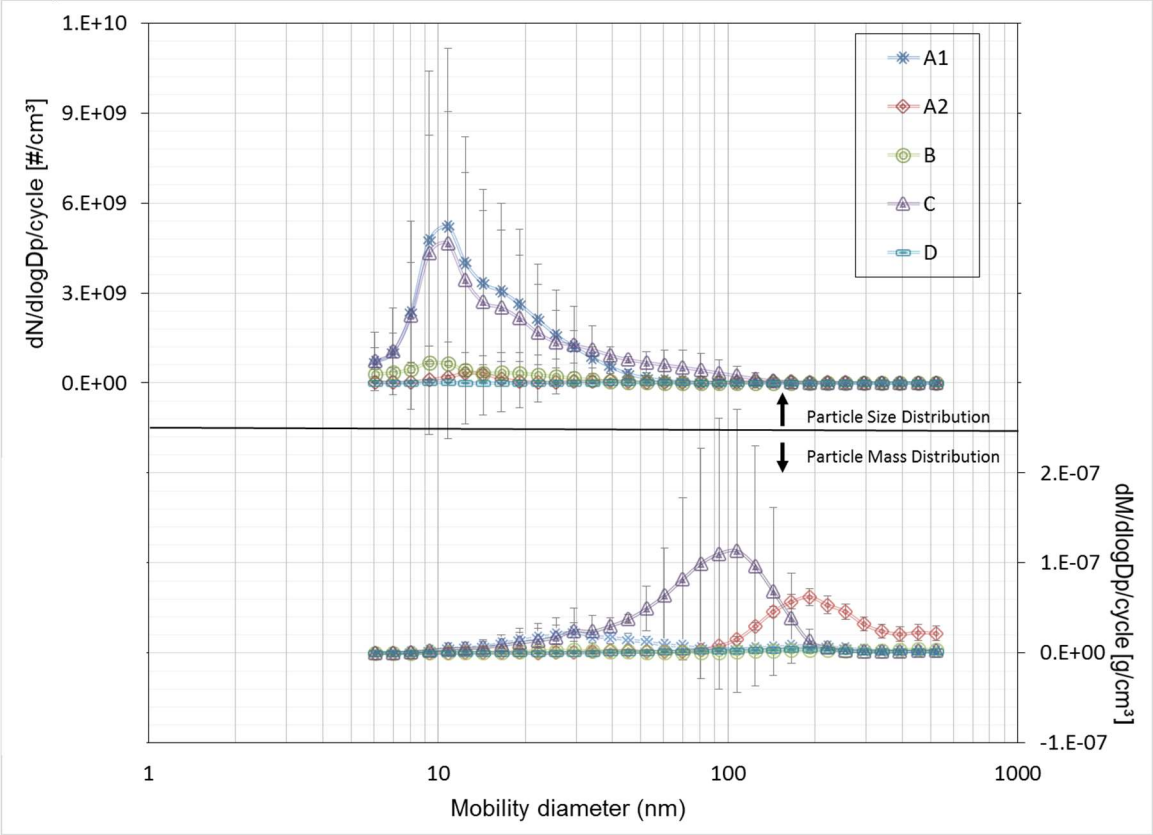


3.8 Particle Size Distributions

The number and mass-based particle size distributions (PSD) for all the cycles are provided in Figure 3-29 through Figure 3-34 (based on EEPS measurements). The number-based PSDs show the average concentration (#/cm^3) as a function of particle diameter over a complete test cycle, and the mass-based PSDs show the distribution of particles by mass (g/cm^3) where the peak diameter represents the largest influence on the PM mass. The particle mass distributions were based on two assumptions from a study by Li et al. (2014). Those assumptions are that all particles were spherical and that the density of particles was 1.46 g/cm^3 for particles smaller than 30 nm and had a functional dependence for particles larger than 30nm. This section is divided into number and mass-based PSD discussions.

For the UDDS cycle, the PSDs for all trucks show a consistent nucleation mode, with a peak particle diameter around 20 nm. The peak concentrations for the manufacturer A1's and manufacturer C engines were relatively higher than for the other trucks. Even though the manufacturer D truck showed higher solid PN emissions over the UDDS, the manufacturer D truck did not have a higher PN concentration for any size bin. This could be attributed to a higher soot component fraction of PM for the manufacturer D truck, whereas the PSDs are based on total PN measurements. Particle mass distributions were dominated by accumulation mode particles, with a peak particle diameter ranging from 30 nm to 200 nm for all trucks.

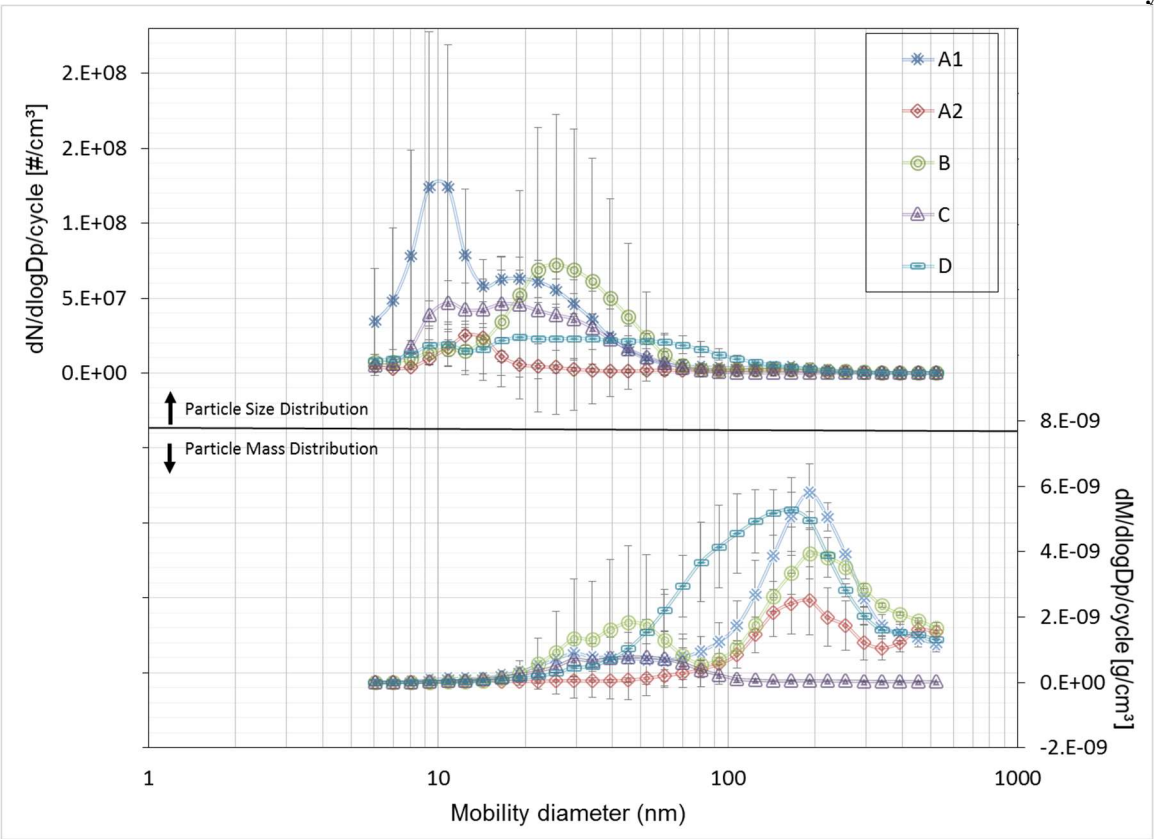
Figure 3-29. Particle Size Distributions and Particle Mass Distributions for UDDS



* For A2, EEPS sampled from second dilution tunnel and results were corrected with dilution factor, others sampled from CVS.

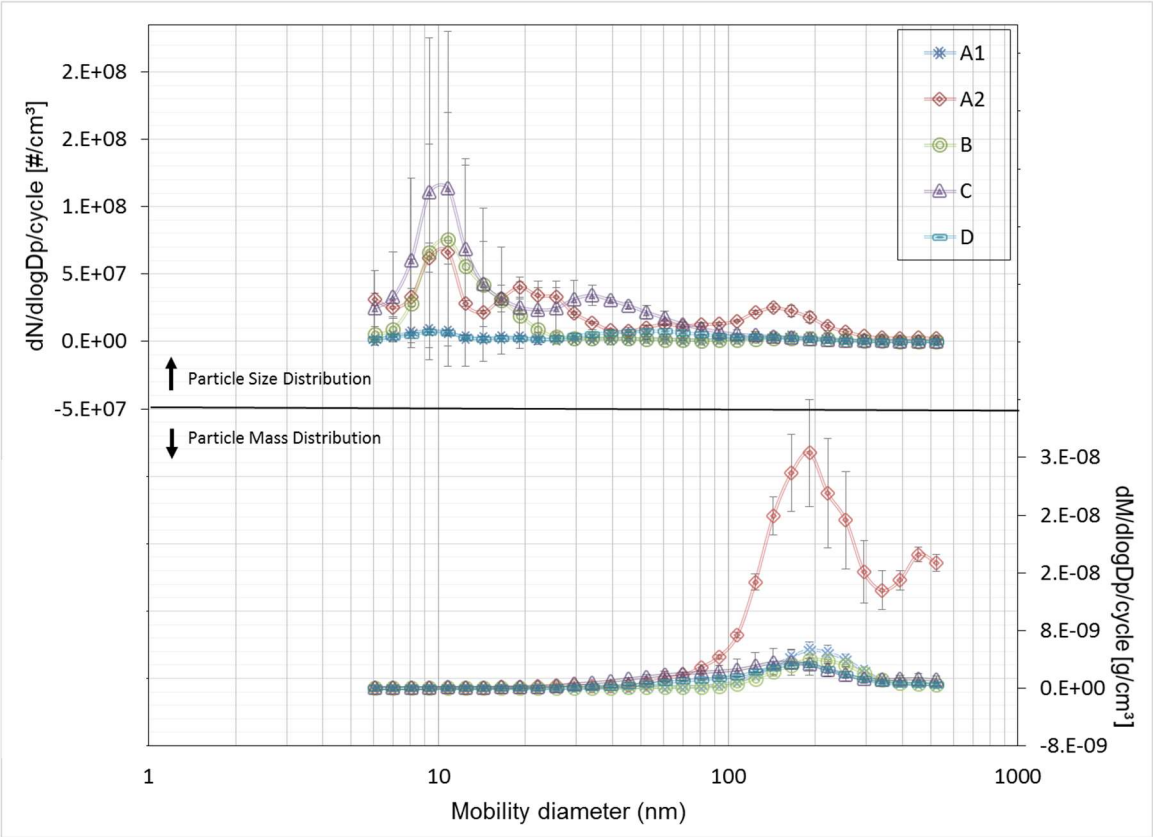
For the Transient cycle, the PSD of the manufacturer C vehicle showed a significantly larger peak compared to the other trucks in the nucleation mode. For the other trucks, the PSDs were predominantly in the nanometer size range, with a peak particle diameter around 20 nm to 50 nm. The particle mass distributions were predominantly accumulation particles with a peak particle diameter around 200 nm, while the manufacturer C vehicle showed a peak around 40 nm-100 nm.

Figure 3-30. Particle Size Distributions and Particle Mass Distributions for Transient Cycle



For the Creep cycle, the PSDs were bimodal for all the trucks, with the highest peak concentrations at particle diameters of 10 nm and lower depending on the different trucks. The manufacturer A2 truck showed another peak around 200 nm particle diameter. For the particle mass distributions, all of the trucks showed significant mass contributions in the accumulation mode particle size range (Dp=200 nm).

Figure 3-31. Particle Size Distributions and Particle Mass Distributions for Creep Cycle



PSD and particle mass distribution results for the Cruise and HHDDT-S cycles were similar, as both were high-speed driving cycles. For the Cruise cycle, the PSDs for the manufacturer A1 and manufacturer C trucks showed significantly higher nucleation mode peaks compared to the other trucks. For particle mass distributions, the manufacturer A1 and manufacturer C trucks showed a significant mass contribution between particle diameters of 20 nm to 50 nm, which suggests that nucleation mode particles contribute considerably higher mass fractions than the accumulation mode over this cycle. For the HHDDT-S cycle, the PSDs and particle mass distributions for the manufacturer A1 and manufacturer C trucks showed a larger peak compared to other trucks in nanoparticle size range (10 nm-50 nm). The higher PM PSDs for the manufacturer C truck over the HHDDT-S cycle is consistent with the higher PM mass seen for this vehicle/cycle combination, as discussed above in section 3.2.

Figure 3-32. Particle Size Distributions and Particle Mass Distributions for Cruise Cycle

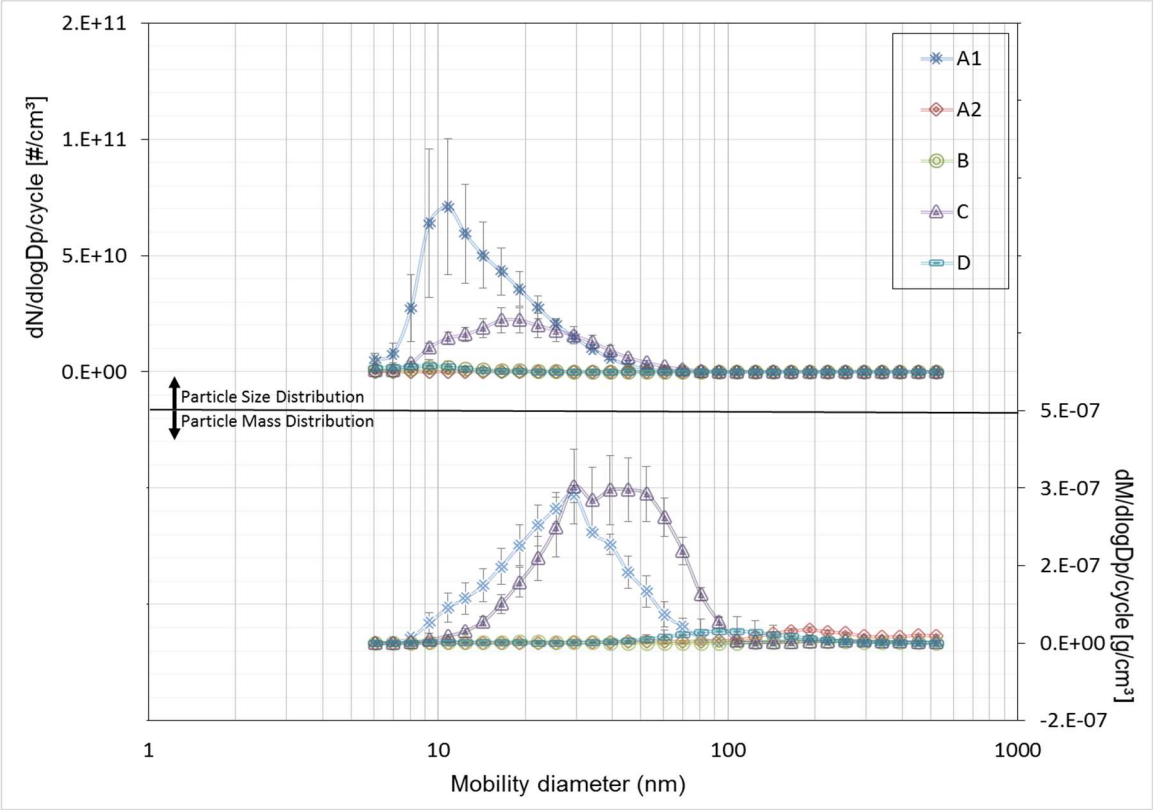


Figure 3-33. Particle Size Distributions and Particle Mass Distributions for HHDDT_S Cycle

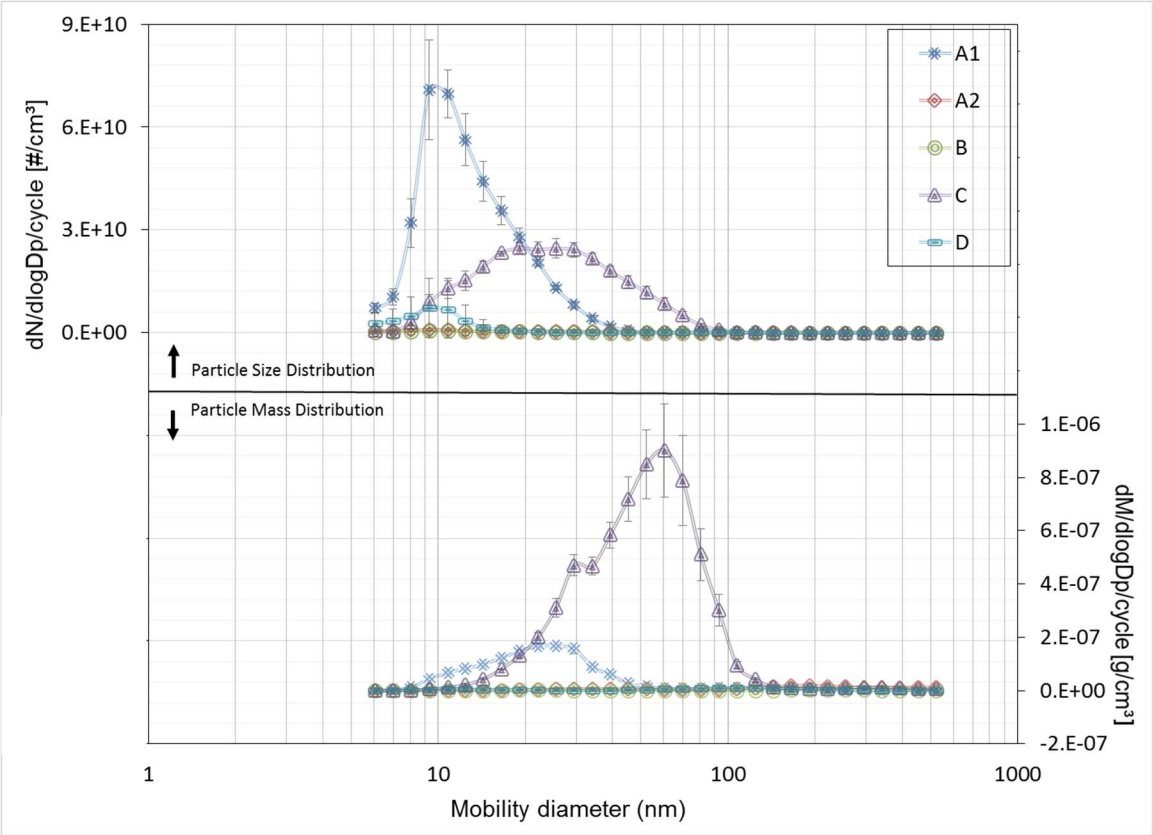
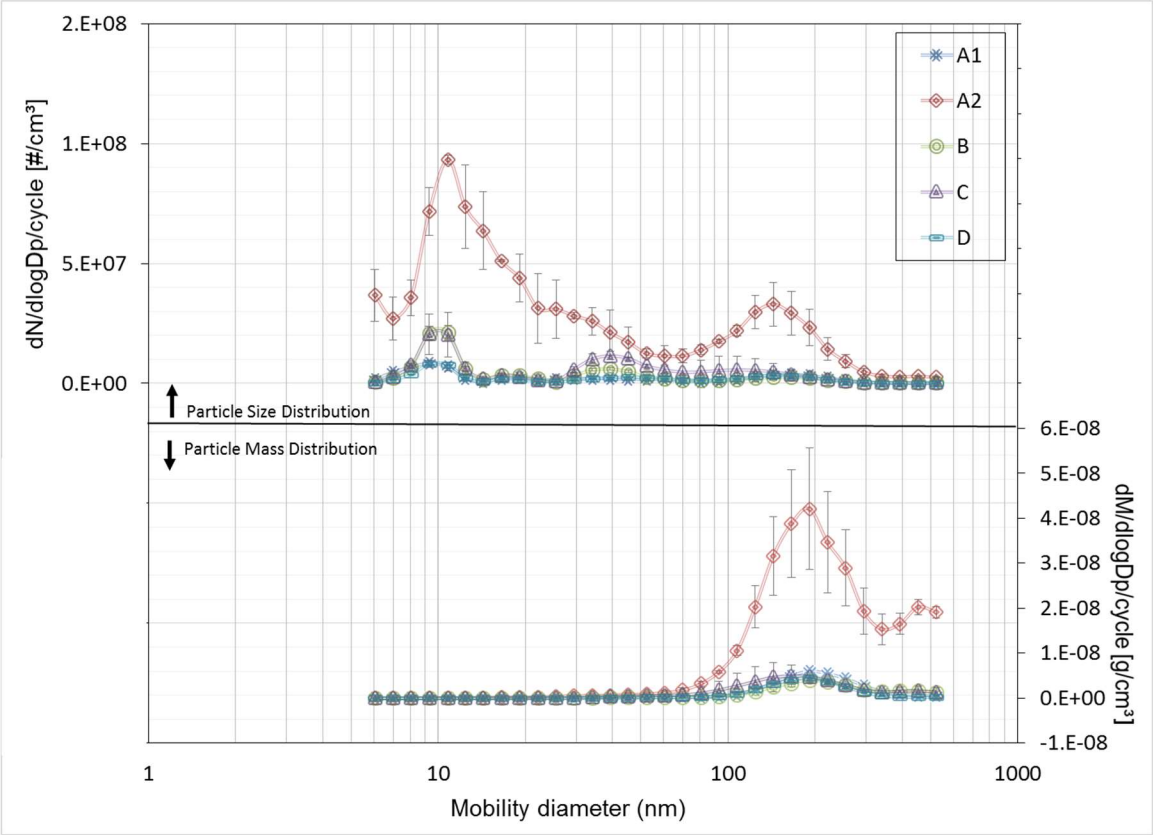


For the Idle cycle, the PSDs were bimodal for all the trucks, with the highest peak concentrations at a particle diameter of 20 nm, and a smaller peak around 40 nm. The manufacturer A2 truck showed a third peak around 200 nm particle diameter. For the particle mass distributions, all of the trucks showed a significant mass contribution at 200 nm particle diameter, which suggests that accumulation mode particles contributed considerably higher mass fractions than the nucleation mode.

Figure 3-34. Particle Size Distributions and Particle Mass Distributions for Idle Cycle



4 Summary and Conclusions

Characterization of in-use emissions from on-road heavy-duty trucks is an important element of developing accurate emissions inventory estimates. The goal of this work was to obtain emissions data on low mileage 2010 and later model year Class 8 diesel trucks equipped with the newest emission control strategies, with a special emphasis on data that can be used to improve estimates of "zero-mile" emission rates (ZMRs). We tested five heavy-duty Class 8 diesel trucks equipped with DPFs for PM emissions and SCR systems for NO_x emissions. The vehicles tested ranged in model year from 2012 to 2015, with 4 of the 5 engines being 2014 or newer. The vehicle matrix included 5 engines from heavy-duty engine manufacturers representing the majority of trucks operating in California, with two engines being from the same manufacturer. The engines/vehicles were certified to a 0.2 g/bhp-hr or a lower certification limit, with the exception of one engine that was certified to a 0.35 g/bhp-hr standard. Each vehicle was tested on UCR's heavy-duty chassis dynamometer over the four phases of ARB's Heavy Heavy-Duty Diesel Truck (HHDDT) cycle (i.e., idle, creep, transient, and cruise), the HHDDT short or (HHDDT-S) cycle (which is a high-speed cruise schedule), and the Urban Dynamometer Driving Schedule (UDDS) (which is a cycle considered to be the chassis dynamometer equivalent of the engine dynamometer transient test). Three of the five trucks were retested using the same testing protocol at the ARB's Heavy-Duty Chassis Dynamometer Testing Facility in Los Angeles.[3] The results of this study are summarized below.

NOx emissions varied depending on the test cycle and the test truck. The NOx emissions for the manufacturer D vehicle appear to be an outlier with noticeably higher emission levels, and subsequent additional testing vehicle on this vehicle was conducted at WVU after determining that the vehicle's service history and lack of regeneration events needed to be taken into account. Given anomalies for the manufacturer D truck, this truck is discussed separately from and in more detail than the results for the manufacturer A1, manufacturer A2, manufacturer B and manufacturer C engine-powered trucks.

For the manufacturer A1, manufacturer A2, manufacturer B and manufacturer C trucks, NOx emissions over the UDDS cycle ranged from 0.495 to 1.363 g/mi (0.136 to 0.387 g/bhp-hr). On a bhp-hr basis, those emission levels are comparable to the level to which the engines were certified to on an engine dynamometer, with some trucks being below and other being above the 0.20/0.35 NOx g/bhp-hr level. NOx emissions over the ARB transient cycle were slightly higher than for the UDDS, with emission rates from ranging 0.803 to 3.252 g/mi (0.194 to 0.762 g/bhp-hr). The lowest emissions were found over the two cruise cycles. For the HHDDT-S, NOx emissions ranged from 0.067 to 0.249 g/mi (0.023 to 0.078 g/bhp-hr). For the Cruise cycle, NOx emissions ranged from 0.068 to 0.471 g/mi (0.030 to 0.225 g/bhp-hr). The highest NOx emissions were seen for the Creep cycle, which showed NOx emission ranging from 2.131 to 9.468 g/mi (0.910 to 3.613 g/bhp-hr). The higher NOx emissions for the Creep cycle can be attributed to the fact that the cycle is comprised of short, low-speed accelerations between periods of idle that cover a very short distance (0.124 miles). Such stop-and-go type of driving tends to create high emissions when evaluated on a per mile or per unit of work done basis.

[3] This report is based on data and analysis from the truck testing conducted at CE-CERT. It is important to note that additional testing was also carried out on a subset of the trucks at the ARB's heavy-duty chassis-dynamometer test facility as part of the agreed upon study effort. The goal was to include all of the data and analysis from both testing efforts in this report, however the ARB data have not been provided for analysis or reporting. The additional ARB data would provide additional insight to the overall project results. It is hoped that ARB will consider their data, in addition to what is reported here, as they improve the EMFAC model.

As discussed above, the manufacturer D truck was an outlier with noticeably higher NOx emissions relative to the other vehicles. In this study, on a g/mi basis, its NOx emissions were 3.519 over the UDDS, 22.505 over the Creep cycle, 6.270 over the Transient cycle, 0.656 over the Cruise cycle, and 0.751 over the HHDDT-S. The lowest NOx emissions for the manufacturer D engine were recorded over the Cruise and HHDDT-S cycles. On a g/bhp-hr basis, NOx emissions for the manufacturer D vehicle were 0.967 over the UDDS, 3.832 over the Creep cycle, 1.430 over the Transient cycle, 0.257 over the Cruise cycle, and 0.234 over the HHDDT-S.

Subsequent to the dynamometer testing conducted at UCR, the manufacturer D vehicle was more extensively evaluated by the manufacturer. The vehicle was initially outfitted with a PEMS, which confirmed the poor NOx conversion efficiency observed from the UCR testing. Upon further investigation, it was determined that this specific vehicle had served its entire life as a dealer demonstrator, and as such rarely or never operated with a loaded trailer, and spent a considerable amount of time operating in an idle mode. This type of low-temperature, high proportion idle operation is known to cause significant exposure of the aftertreatment system to unburned hydrocarbons in the exhaust stream. An examination of the logged electronic history revealed no OBD faults or other indications of failure or system malfunction. A clear anomaly, however, was that due to its unusual, unladen service history and duty cycle, the engine had never undergone a regeneration event, despite being approximately 2.5 years in service (albeit with only 12,000 miles on the odometer). A series of conventional parked regenerations were performed. After further operation, there was a significant recovery of the aftertreatment NOx-conversion efficiency, as revealed through PEMS measurements. The regeneration intervention is believed to have been fully effective in driving off the accumulated unburned hydrocarbons that were hindering catalytic reaction. Additional chassis dynamometer testing of the manufacturer D vehicle was subsequently conducted at the West Virginia University CAFEE Laboratory, replicating the testing that had been performed at UCR, with the exception of a 70,000 lbs. test weight. The results of that testing indicated a NOx emission rate of 0.39 g/mi over the UDDS cycle, near the lower end of the NOx emission rates found in the current study.

The results of our study can be compared to the emission factors being used in the EMFAC2014 model. For engines certified to the 0.20 g/bhp-hr NOx level, EMFAC2014 utilizes a ZMR of 1.89. This ZMR is adjusted by a fuel correction factor of 0.93 to account for the clean CARB diesel fuel used in California, such that a ZMR of 1.76 was used for the comparisons in this study for the 0.20 g/bhp-hr NOx engines. EMFAC2014 does not specifically utilize a ZMR for engines certified to the 0.35 g/bhp-hr NOx level, but the ZMR for those engines can be most directly compared with the 2011 model year ZMR of 3.26. That ZMR also is adjusted by the fuel correction factor of 0.93 to account for the use of clean CARB diesel fuel used in California, resulting in a ZMR of 3.03, which was used for the comparisons in this study relating to 0.35 g/bhp-hr NOx engines. EMFAC2014 is a relatively complicated model, including speed correction factors, tampering, malmaintenance and deterioration rates, and other factors. ZMRs, however, are best approximated by the emissions obtained over the UDDS cycle from low mileage vehicles that are well maintained and checked for any evidence of tampering, such as those selected for inclusion in this study. Consequently, that cycle is used as a comparison point between the current EMFAC2014 model ZMRs and our study results.

The UDDS emission rates from this study, as well as other studies of 2010 model year and newer heavy-duty vehicles, are presented in Figure 4-1 and Figure 4-2, along with the current EMFAC2014 ZMRs and the NOx Family Emission Limits (FELs) to which the engines are certified. The other earlier studies include a study by the ARB that was utilized to update the emissions factors for the EMFAC model, and another UCR study funded by the South Coast Air

Quality Management District (SCAQMD), which included several SCR and DPF equipped 2010+ model year vehicles in the test fleets. For the UDDS under the current study, the emissions levels for all of the 0.20 g/bhp-hr NOx trucks, except the manufacturer D truck prior to regeneration, are below the EMFAC2014 value. The NOx emissions for the manufacturer D truck after regeneration restored its NOx-conversion efficiency are also well below the EMFAC2014 value. The average UDDS values for the current study for the 0.20 g/bhp-hr NOx trucks are 0.89 g/mi if the outlier manufacturer D truck is excluded, or 0.77 g/mi if the UDDS emission rate from the manufacturer D truck as tested at WVU, after ensuring regeneration, is included. In both cases, those values are well below the EMFAC2014 value, with the lower value being more representative of the in-use fleet. Similarly, the manufacturer A1 truck that was certified to a 0.35 g/bhp-hr NOx FEL has a UDDS emissions level of 0.99 g/mi, which is well below the 2011 model year ZMR approximation of 3.03 g/mi for 0.35 g/bhp-hr NOx trucks.

The UDDS results for the earlier SCAQMD study, with an average NOx level of 0.86 g/mi, are also well below the EMFAC2014 0.20 g/bhp-hr fuel-adjusted ZMR of 1.76 g/mi. The two manufacturer D trucks from the previous ARB study are comparable to but slightly higher than the EMFAC2014 ZMR, as those two vehicles were the primary source of information used in developing that ZMR. They are higher than all of the other trucks certified to the 0.20 g/bhp-hr, with the exception of the manufacturer D truck under the current study, which is again from the same manufacturer. The other manufacturer A3 truck in the earlier ARB study has NOx emissions higher than the 2011 model year EMFAC2014 ZMR value that approximates the value for 0.35 g/bhp-hr NOx level engines.

Also, as the name implies, the ZMR is the estimated emissions rate at zero miles (i.e., for a new truck). Normally, an adjustment factor would be applied to account for the mileage accumulated on the vehicle. As the five vehicles in this study had low mileages (one of the selection criteria for the study as shown in Figure 4-1), no adjustment factor has been applied for mileage. If an adjustment factor were to be applied, the ZMR estimates based on the UDDS emission results would go down slightly. Overall, this comparison analysis suggests that lower ZMRs for future EMFAC model updates may better represent the in-use emission rates of heavy-duty diesel trucks. This study suggests ZMRs may be better represented by the UDDS emission rates of 0.77 g/mi, perhaps ranging to 0.89 g/mi, for engines certified to a 0.20 NOx standard. A lower possible ZMR value of 0.99 g/mi was also found for an engine certified to a 0.35 NOx standard, but only a single vehicle with this certification level was tested in this study.

Figure 4-1. Comparison of NOx emission rates from this study, and the ARB and SCAQMD studies, for SCR-equipped 2010+ vehicles over the UDDS

	CE-CERT					ARB			SCAQMD

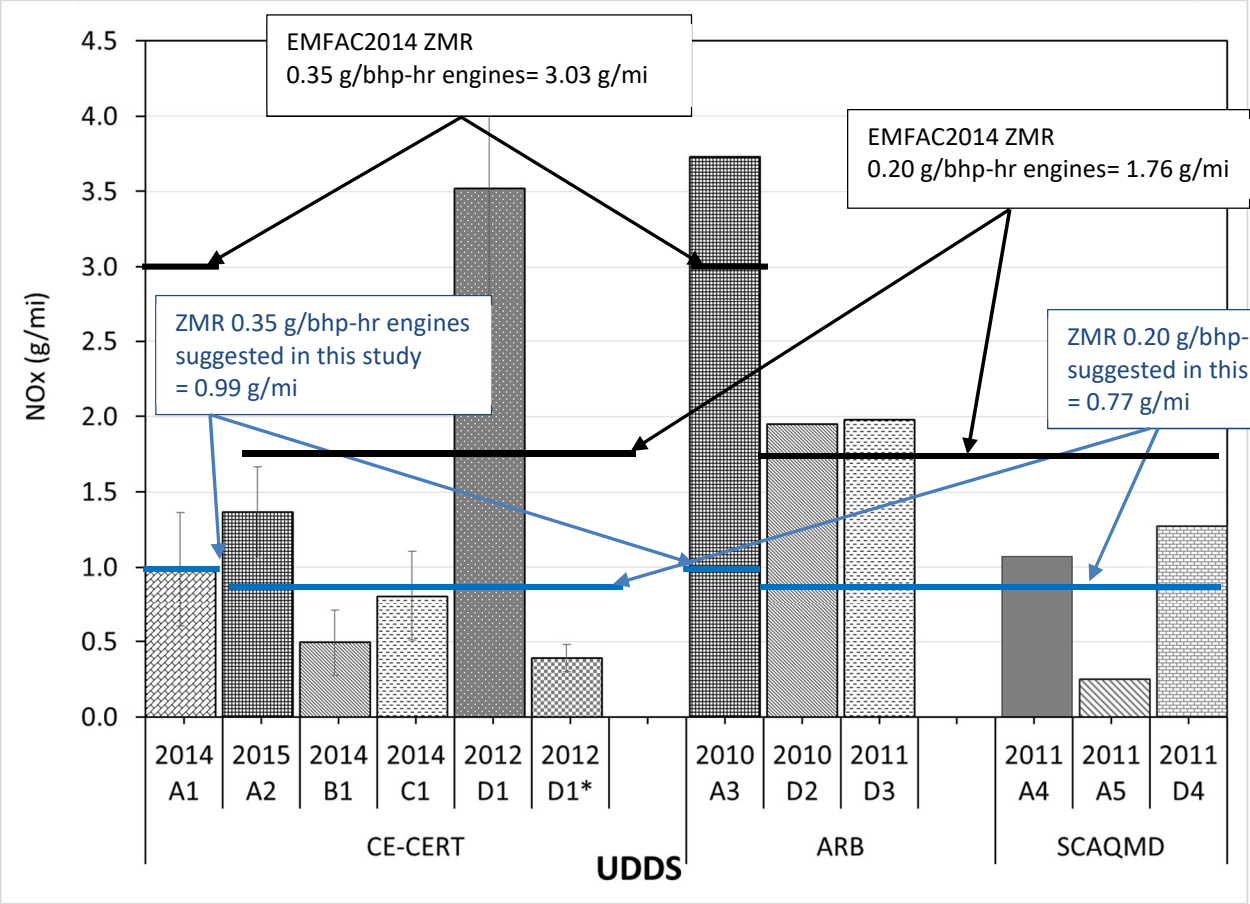
Figure 4-2 Comparison of NOx Zero Mile Rates Between EMFAC2014 and this Study



PM, THC, and CO emissions were found to be very low under most of the testing conditions. PM emissions were below 0.015 g/mi and 0.006 g/bhp-hr for all vehicles and cycles, except for the manufacturer C truck over the HHDDT-S cycle, and the manufacturer A2 truck over the Creep cycle. Over the UDDS, Transient, Cruise, and HHDDT-S cycles, THC emissions were below 0.05 g/mi for all test vehicles. The Creep cycle did show higher THC emissions on a per-mile and bhp-hr basis, ranging from 0.241 to 0.458 g/mi and from 0.015 to 0.046 g/bhp-hr, due its short, low-speed accelerations and longer idle periods. CO emissions were below 0.2 g/mi and 0.06 g/bhp-hr for all vehicles and cycles, except over the Creep cycle, and for one vehicle over the Transient cycle on a g/mi basis. Overall, the CO emission rates are considerably below the standards of 15.5 and 14.0 g/bhp-hr established by EPA and ARB, respectively, for all vehicles and cycles.

The solid PN emissions for all the cycles were under 2.1×10^{12} #/mi for all the cycles. On a g/mi basis, solid PN emissions ranged from 1.1×10^{11} to 2.5×10^{11} over the UDDS, from 6.5×10^{10} to 1.7×10^{12} over the Creep cycle, from 1.9×10^{10} to 5.0×10^{11} over the Transient cycle, from 4.3×10^{10} to 2.1×10^{12} over the Cruise cycle, and from 5.7×10^{10} to 1.9×10^{12} for the HHDDT-S cycle. The PSD for all trucks as assessed with the EEPS instrument showed a consistent nucleation mode, with a peak particle diameter ranging from 20 nm to 50 nm. Particle mass distributions were dominated by an accumulation mode with a peak around 200 nm particle diameter for most of the test cycles.

CO_2 emissions ranged from 1864 to 2219 g/mi over the UDDS, and from 2260 to 2624 g/mi for the Transient cycle. CO_2 emissions ranged from 1160 to 1443 g/mi for the Cruise cycle, and from 1450 to 1743 g/mi for the HHDDT-S cycle. CO_2 emissions were highest over the Creep cycle, where loads are lowest, ranging from 3748.7 to 5095.0 g/mi.

Fuel economy for the UDDS ranged from 4.56 to 5.41, while fuel economy for the Transient ranged from 3.84 to 4.46 mi/gal. Fuel economy over the Cruise and HHDDT-S cycles was slightly better, ranging from 6.98 to 8.69 mi/gal for the Cruise cycle, and from 5.78 to 6.95 mi/gal for the HHDDT-S cycle. The lowest fuel economy was found over the Creep cycle, and ranged from 1.978 to 2.689 mi/gal., due to the slow speeds and stop-and-go nature of the cycle.

Appendix C: Road Load Calculations

The method for determining coast down coefficients at UCR was published and evaluated as part of a previous report to the South Coast Air Quality Management District[4]. Typical coastdown procedures assume that vehicle loading force is a function of vehicle speed, drag coefficient, frontal area and tire rolling resistance coefficient and takes the form of equation 1:

$$M\frac{dV}{dt} = \frac{1}{2}\rho A C_D V^2 + \mu M g cos(\theta) + Mgsin(\theta) \quad \text{(Equation 1)}$$

Where:
M = mass of vehicle in lbs
ρ = density of air in kg/m^3.
A = frontal area of vehicle in square feet, see Figure 1
C_D = aerodynamic drag coefficient (unitless).
V = speed vehicle is traveling in mph.
μ = tire rolling resistance coefficient (unitless).
g = acceleration due to gravity = 32.1740 ft/sec^2.
θ = angle of inclination of the road grade in degrees.

Constant parameters for equation 1	
μ	0.007
C_D	0.75 for Truck 0.79 for Bus 0.80 for Refuse Truck
g	32.1740 ft/sec^2

Assuming that the vehicle loading is characteristic of this equation, speed-time data collected during the coast down test can be used with static measurements (Mass, air density, frontal area, and grade) to solve for drag coefficient (CD) and tire rolling resistance coefficient (μ). The frontal area is measured based on the method described in Figure C-1 below.
However, experience performing in-use coast downs is complex and requires grades of less than 0.5% over miles of distance, average wind speeds < 10 mph ± 2.3 mph gusts and < 5 mph cross wind5. As such, performing in-use coast downs in CA where grade and wind are unpredictable are unreliable where a calculated approach is more consistent and appropriate. Additionally vehicles equipped with automatic transmissions have shown that on-road loading is also affected by the characteristics of the vehicle transmission, especially when reverse pumping losses at low speed begin to dominate.
UCR's and others recommend a coast down method that uses a characteristic coast down equation, with a measured vehicle frontal area (per SAE J1263 measurement recommendations), a tire rolling resistance of 0.007, and a Cd 0.75 (Truck) 0.79 (Bus) and 0.80 (Refuse Truck) in the above equation to calculate coast down times to be used for calculating the A, B, C

[4] Draft Test Plan Re: SCAQMD RFP#P2011-6, "In-Use Emissions Testing and Demonstration of Retrofit Technology for Control of On-Road Heavy-Duty Engines", October 2011
[5] EPA Final rulemaking to establish greenhouse gas emissions standards and fuel efficiency standards for medium and heavy duty engines and vehicles, Office of Transportation and Air Quality, August 2011 (Page 3-7) and J1263 coast down procedure for fuel economy measurements

coefficients in equation 2 for the dyno operation parameters. This approach is consistent and has proven very reliable for chassis testing heavy duty vehicle and has been used for years. For evaluation of aerodynamic modifications and body styles, UCR recommends investing the time perform in-use coast downs.

$$Y = C(x^2) + B(x) + A \qquad \text{(equation 2)}$$

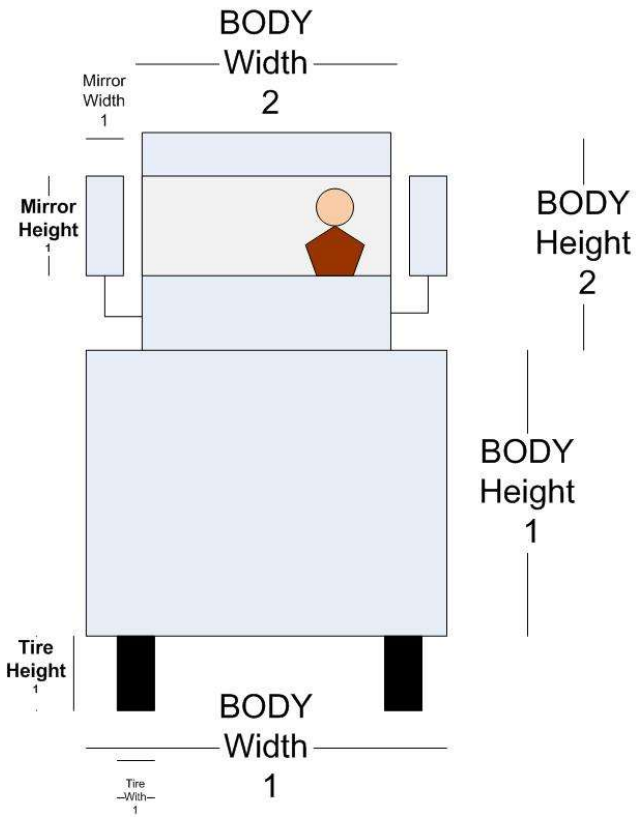

Figure C-1 Vehicle Frontal Area Dimensions Method

The road load coefficients for the specific test vehicles are provided in Table C-1. For comparison, the force applied to the vehicle based on these sets of road load coefficients are also provided in Table C-1. It should be noted that the forces applied for different vehicles were generally more similar for vehicles A1, B1, C1, and D1 compared to A2. This can be attributed to the frontal area calculation, as the manufacturer A2 truck did not have roof fairings on the cab, whereas the other vehicles did, the manufacturer A2 truck had the smallest calculated frontal area, leading to lower loadings at the different speeds. The data for the actual chassis dynamometer verification coast downs compared to the coast down times that would be expected based on the road load coefficients for each vehicle are shown in Table C-2.

Table C-1 Coast Down Coefficient and Road Loads

	MPH	Force (Pounds)				
		A1	A2	B1	C1	D1
	60	1018	895	1023	1069	1065

1 INTRODUCTION

EMFAC2011 represents the next step in the ongoing improvement of the EMFAC series of emissions estimation models. The EMFAC2011 release is needed to support the Air Resources Board's (ARB) regulatory and air quality planning efforts and to meet the Federal Highway Administration's transportation planning requirements. EMFAC2011 includes the latest data on California's car and truck fleets and travel activity. The model also reflects the emissions benefits of ARB's recent rulemakings including on-road diesel fleet rules, Pavley Clean Car Standards, and the Low Carbon Fuel Standard.

In order to incorporate the new detailed data and methods to estimate emissions from diesel trucks and buses and future improvements, staff used a modular emissions modeling approach for EMFAC2011 that departs from past EMFAC versions. The first module, named EMFAC2011-LDV, estimates passenger vehicles emissions. A second module, called EMFAC2011-HD, estimates emissions from diesel trucks and buses. A third module integrates the output of EMFAC2011-LDV and EMFAC2011-HD and provides users with the ability to conduct scenario assessments for air quality and transportation planning. This third module is called EMFAC2011-SG. Together the three modules comprise EMFAC2011.

This section describes and summarizes the major updates to this version of the model. The rest of the document provides a complete discussion of all the updates, revisions, and additions to EMFAC2011, and to the new ARB on-line data tool. Most importantly, the on-line tool is designed to cover most data needs for both summarized and detailed emissions and emission rates. The vast majority of EMFAC users will no longer have to download, learn, and run the model to get the data they need. Much simpler data queries across the internet will suffice.

In July 2012 EMFAC2011 was re-released to highlight new web-database tools that provided improved capabilities for project level assessment. In addition EMFAC2011-LDV and EMFAC2011-SG were updated to correct the number of starts in Santa Clara County for several small categories of gasoline vehicle classes which led to an overestimate of emissions in Santa Clara County. No other counties were affected, and no model algorithms were changed in the update.

New Data

The most important improvement in EMFAC2011 is the integration of the new data and methods to estimate emissions from diesel trucks and buses. EMFAC2011 uses the

same diesel truck and bus vehicle populations, miles traveled and other emissions-related factors developed for the Truck and Bus Rule approved by the Air Resources Board in 2010. EMFAC2011 still provides the same traditional emissions rate detail for these vehicles that user are familiar with in previous EMFAC versions. The model includes the emissions benefits of the truck and bus rule and the previously adopted rules for other on-road diesel equipment. Finally, the impacts of the recession on emissions that were quantified as part of the truck and bus rulemaking are included.

Light-duty motor vehicle fleet age, vehicle type, and vehicle population in EMFAC2011 is based on 2009 California Department of Motor Vehicles data. These data along with the new diesel truck and bus data, satisfies guidance issued by the U.S. Department of Transportation, Federal Highway Administration that requires that vehicle fleet data used in transportation conformity analyses be no older than 5 years.

As in previous releases of EMFAC, travel activity data (which includes vehicle miles traveled, trips, and distributions of vehicle miles traveled by speed and time period) are provided by metropolitan planning organizations (MPOs) that conduct travel demand modeling for the transportation planning process. For EMFAC2011, updated travel activity data was provided by the Southern California Association of Governments (SCAG) for the greater Los Angeles region, by the San Diego Association of Governments (SANDAG) for San Diego County, by the eight San Joaquin Valley MPOs, by the Metropolitan Transportation Commission (MTC) for the Bay Area, and by the Sacramento Area Council of Governments (SACOG) for the greater Sacramento region.

New Modular Model Structure

The new EMFAC2011 comprises a suite of three modules that estimates emissions from diesel trucks, buses, and gasoline powered vehicles. Staff has moved to a modular model structure to accommodate more detailed information about the truck and bus fleet than has been in prior EMFAC versions. The modular structure will also more easily accommodate future model enhancements that are necessary to support on-going program development associated with criteria and greenhouse gas emissions.

The first module, named EMFAC2011-LDV, is used as the basis for estimating emissions from gasoline powered on-road vehicles, diesel vehicles below 14,000 pounds gross vehicle weight rating, and urban transit buses. The algorithms used in EMFAC2011-LDV for passenger cars are the same as used in EMFAC2007

The second module, called EMFAC2011-HD, is the basis for emissions estimates for diesel trucks and buses with a gross vehicle weight rating greater than 14,000 pounds operating in California. This model is based upon the Statewide Truck and Bus Rule emissions inventory that was developed between 2007 and 2010 and approved by the Air Resources Board in December 2010. The truck and bus population and vehicle

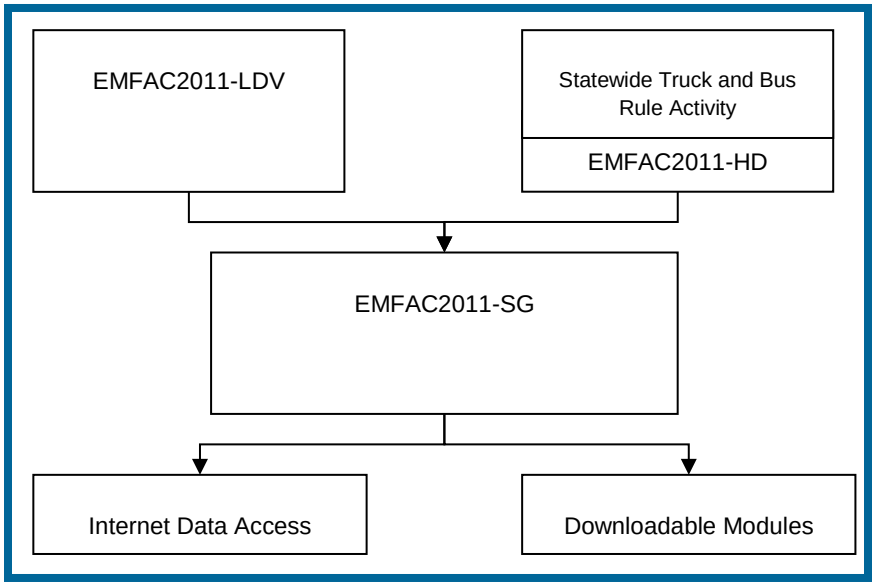
miles traveled estimates in EMFAC2011-HD are identical to those presented to the Board. Emission factors in the Statewide Truck and Bus Rule inventory were based on statewide, annual average emission factors and adjusted for improvements to fuel economy, medium-heavy duty truck emission factors, and other new information. EMFAC2011-HD emissions estimates include all of the improvements made as part of the Statewide Truck and Bus Rule inventory and then add the traditional detailed EMFAC methods that provide emission rates for annual, summer, and winter seasons on a regional basis.

Finally, EMFAC2011 contains a new simplified tool, called EMFAC2011-SG, that provides air quality planners, transportation planners, and other EMFAC users a tool for assessing emissions under different future growth scenarios. This includes conformity analyses of transportation plans and programs with the State Implementation Plans required by federal law, State Implementation Plan inventories, alternative growth scenarios associated with regional transportation planning for greenhouse gas reductions (SB375), and the like.

EMFAC2011-SG takes the output from EMFAC2011-LDV and EMFAC2011-HD and applies scaling factors to estimate emissions consistent with user-defined vehicle miles of travel (VMT) and speeds. The EMFAC2011-SG module also estimates the benefits of Pavley and Low Carbon Fuel Standard regulations.

EMFAC2011's enhanced modular structure and computation requirements can make running the model more resource-intensive than the previous EMFAC release. Therefore, ARB is enhancing data availability by providing a new database through the ARB mobile source emissions inventory web site that provides regional population, activity, emissions, and emission rates at varying levels of detail. Most current EMFAC users will find the new database sufficient for obtaining emissions data to support California Environmental Quality Act (CEQA) assessments and other types of analyses for which the EMFAC model is currently used and will not need to run the model. The model executable files will also remain publicly available on our website, which is located at **http://www.arb.ca.gov/msei/msei.htm**. In July 2012 these tools were updated based on user comments provided to our web site. Figure 1-1 provides a schematic that describes how the modules fit together.

Figure 1-1. EMFAC2011 Schematic



Beyond EMFAC2011

EMFAC2011 is a transition step to a future EMFAC emissions modeling system under development to meet the increasingly demanding needs for data in both the regulatory and planning arenas. Some of the areas of focus for the future EMFAC system that staff is developing over the next two to three years include:

Population, activity, and forecasting:

- Improved capture of recession and fuel price spikes.
- Reflect planned GHG emissions standards and their impact on future year fleet mix.

New Smog Check Algorithms

- Reflect the new Smog Check mandated by State law starting in 2013.

Flexibility for air quality planning better support for long-term scenario assessment

- Scenario development support for tighter National Ambient Air Quality Standards.
- SB375 –Model structure to better support for smart growth planning.
- Better conformity methods to support MPO conformity determinations.

Improved documentation and public availability of model output:

Future model output will be available in raw and processed form over the internet in ways that require minimal processing to understand.

2 USING THE MODULES AND ACCESSING DATA

The EMFAC model has always been used by a wide cross-section of air quality professionals. Typical uses include:

- ARB and air district staff routinely develop emissions inventories to support air quality planning and to meet air quality standards;
- Regional transportation planning agencies that use EMFAC to test whether or not new transportation plans fall within conformity budgets;
- Statewide and Regional transportation planning agencies evaluating land-use changes that impact regional VMT estimates and their impact on emissions;
- ARB staff developing assessments to support regulatory program development;
- ARB and regional air district staff developing emissions inventories to support health risk assessments; and
- Consultants developing fleet average or by model year emission rates for local scale modeling to support project level assessments.

With EMFAC2011, staff has tried to anticipate data needs and to serve common data requests in the form of a web site data serving tool instead of relying solely upon executable models. These tools provide several different ways to access and summarize both emissions and emission rates to the desired level of detail.

The mobile source emissions inventory website is located at

http://www.arb.ca.gov/msei/msei.htm

On the website the user will find EMFAC2011 including each inventory module, technical documentation, and training resources. The website also contains similar information associated with the myriad of different types of mobile sources from cars and trucks to lawnmowers, construction equipment, and other sources.

Instructions on operating each EMFAC2011 module as well as technical documentation of the modules and data improvements are available in this document; locations and information are described in documentation below for each module in the EMFAC2011 suite.

3 EMFAC2011-LDV

3.1 WHEN THE MODULE SHOULD BE USED

EMFAC2011-LDV estimates emissions for gasoline vehicles, urban transit buses, and diesel vehicles less than 14,000 pounds GVWR. This represents a change from EMFAC2007 when a single tool covered all on-road categories. As a result, EMFAC2011-LDV cannot be used by itself to develop a comprehensive statewide on-road vehicle emissions inventory.

To obtain a comprehensive inventory, a user must use additional modules in the EMFAC2011 suite. The easiest way to access EMFAC2011 emissions is to use the new web based data tools available through our website. Alternatively, a user may choose to run EMFAC2011-LDV and EMFAC2011-SG separately, or to run EMFAC2011-SG. In most cases, data served through the internet should be sufficient to answer many user questions without running the model.

EMFAC2011-LDV may be run to obtain emission rates for specific meteorological and speed conditions, and to generate input files for photochemical modeling.

3.2 USER'S GUIDE TO RUNNING THE MODULE

The fundamental design of the EMFAC2011-LDV executable file is the same as EMFAC2007. A comprehensive user's guide was developed for EMFAC2007 and may be used; it is available on our website.

3.3 MODULE IMPROVEMENTS

Many improvements have been made to the EMFAC model between the release of EMFAC2007 and the updated EMFAC2011-LDV. Population, vehicle miles traveled (VMT), speed distributions, vehicle survival curves, and portions of emission rates have all been updated. This section provides an overview to improvements; major improvements are discussed in greater detail in the technical appendices to this document.

3.3.1 POPULATION

In the EMFAC2011-LDV module, vehicle populations are estimated using registration data from the Department of Motor Vehicles. Data from the 2009 registration year was used to update the populations in each vehicle class for 45 age groups and 69 geographic areas. Based on the 2009 registration data, there are approximately 25 million registered vehicles operating in California.

Staff developed an improved methodology for classifying vehicles among vehicle classes. This methodology involves matching DMV registration information to Smog Check data from the Bureau of Automotive Repair and using two different vehicle identification number (VIN) decoders to interpret registration data. The more extensive use of VIN decoders led to a marked improvement in the classification of vehicles among the light-duty truck categories, which are for the most part sport utility vehicles and lighter pick-up trucks. These improvements are apparent in the model from calendar year 2009 and into the future.

Staff retained the historical fleet mix and population estimates embedded in the model for calendar year 2000 and into the past. For calendar year 2000 through 2008, staff connected the historical population estimates based on the previous DMV processing methodology with the new population estimates developed using the updated DMV processing methodology. The impact of this methodology on emissions is not significant when viewed across all vehicle categories. However for a few categories, most notably light-heavy duty vehicles, the difference in fleet mix is significant between before and after calendar year 2009.

3.3.2 VMT AND SPEED DISTRIBUTIONS

For air quality and transportation planning purposes, EMFAC2011-LDV uses the VMT provided by regional transportation planning agencies (RTPA). For EMFAC 2011, ARB received VMT and speed submittals from the Southern California Association of Governments (SCAG), Bay Area Metropolitan Transportation Commission (MTC), San Diego Association of Governments (SANDAG), and San Joaquin Valley Councils of Government. In the absence of recent RTPA data, the model contains default speed distributions and estimated VMT as a function of vehicle population (from DMV) and mileage accrual rates (from the Bureau of Automotive Repair SmogCheck program).

In general regional transportation planning agencies did not reflect the impact of the economic cycle on VMT, and instead dampened future VMT forecasts in light of the slower economic recovery from the recent economic recession. As a result the recession is generally handled through long term rather than short-term forecasts in EMFAC2011-LDV.

Unlike previous versions of EMFAC, VMT estimates from medium and heavy heavy-duty diesel trucks and diesel bus categories are estimated directly from EMFAC2011-HD. When developing these VMT estimates staff accounted for both the short and long term impacts of the economic recession.

3.3.3 EMISSION RATES

3.3.3.1 CARBON DIOXIDE

EMFAC2007 outputs carbon dioxide (CO2) emissions and estimated fuel use using results from chassis dynamometer exhaust tests on the federal test procedure (FTP) assuming fuels oxygenated with MtBE. To update these assumptions for EMFAC2011-LDV, staff analyzed test data from the Unified Cycle (UC) using modern ethanol/gasoline blends consistent with RFG3. The update results in a small change in predicted CO2 emission rates. Details are available in Section 8.

3.3.3.2 CARBON DIOXIDE DISBENEFIT WITH AIR CONDITIONING USE

EMFAC2011-LDV estimates carbon dioxide emissions as a function of the use of air conditioning systems among other factors. The assumed use of vehicle air conditioning is a function of the temperature and relative humidity in the geographical area being modeled. In developing EMFAC2011, staff re-evaluated the algorithm to correctly reference the factors in the calculation.

EMFAC2011-LDV uses a correlation between emissions results on the FTP with 10% additional aerodynamic load and the UC with air conditioning turned on. The correlation has a slope and an intercept term. The intercept (as the ratio of intercept to slope) is added to the BER (basic emission rate) in the model. For LDVs, and MDVs, UC bag 2 (hot, stabilized) emission factors are used as BERs. For all other vehicle types, the average of the FTP Bag 2 (hot, stabilized) and Bag 3 (warm start) results is used. The program was applying the BER twice for LDVs and MDVs, rather than only applying the UC Bag 2 BER. This change led to a decrease of 30,000 tons/day CO2 statewide which is a 5% decrease in emissions from what was previously estimated.

3.3.3.3 EVAPORATIVE DIURNAL BASIC EMISSION RATE COEFFICIENTS

In EMFAC2011-LDV, hydrocarbon evaporative diurnal emission rates are modeled as polynomial equations dependent on ambient temperature and other factors. The polynomial equations generate a conversion factor that converts an evaporative base emission rate to an emission rate at a given temperature. In updating EMFAC2011-LDV, staff determined that several polynomial coefficients in the model were very small and the EMFAC model was not carrying sufficient significant figures in the coefficients. EMFAC2011 now uses additional significant figures in this calculation, which results in an increase of ROG emissions of 0.3 tpd statewide in 2007. The effect is larger in later years (because more zero evap vehicles are present), but it is still a very small effect.

3.3.3.4 EVAPORATIVE RESTING TIME IN HOT SOAK ALGORITHM

In EMFAC, hydrocarbon evaporative emissions generated through the hot soak process are calculated for both full hot soak events (the engine fully cools back to ambient) and partial hot soaks (the engine partially cools until the next start event) using a matrix of resting time values. During evaluation of the evaporative emissions processes for development of EMFAC2011, staff identified that hot soak emissions in EMFAC had been programmed using the time-off matrix of soak times before a cold start. This matrix represented the pre-start soak time as a function of time of day. EMFAC should have been programmed with the time-rest matrix of soak times after a key-off event by time of day. This correction results in an increase of ROG emissions of 8.5 tons/day statewide, which is a 1% increase in emissions.

3.3.3.5 BRAKE WEAR PM

EMFAC2007 estimated total particulate matter for brake wear using an emission factor of 12.8 mg/mile. This emission factor was applied to all vehicle classes on a per mile basis, and reflected emissions testing of asbestos friction-materials from automobile disc brakes. To update EMFAC2011-LDV, staff used two more recent studies performed on new brake materials that replaced the older asbestos based materials. Results from these studies were correlated with wheel load, braking speed, material, and number of brakes per vehicle.

In addition to updating the emission rate during braking events, staff used the same driving cycles upon which exhaust emission rates are derived to estimate the frequency and severity of braking events during driving in California. Staff used the unified cycle for light-duty vehicles, and the transient and cruise cycles for heavy-duty vehicles. Overall, brake wear emissions increase substantially in EMFAC2011-LDV as a result of this update. Details are available in Section 9.

3.3.3.6 GASOLINE EXHAUST PARTICULATE MATTER

Basic emission rates for light duty gasoline vehicles have been updated using data from EPA's project titled 'The Kansas City PM Characterization Study'. These vehicles were certified to Federal Standards. Emissions data was collected under conditions prescribed in the Federal Test Procedures, and vehicles were operated over the LA92 Unified Driving Cycle. Data for newer model years was supplemented by testing conducted at ARB's Haagen Smit Laboratory.

The current LEV II standard for PM is 10 mg/mi and will be in effect until 2016. As these standards are further reduced, we expect various engine technologies to penetrate in the fleet. For example, the percentage of gasoline direct injection (GDI) engines is expected to increase from current levels in order to meet the GHG emission targets. These effects and other results are detailed in Section 10.

3.3.4 OTHER IMPROVEMENTS

3.3.4.1 ELIMINATION OF TRUCK AND BUS CATEGORIES

The vehicle classes in EMFAC2011-LDV that are covered by EMFAC2011-HD are depopulated and effectively turned off in EMFAC2011-LDV since the official inventory for truck and bus categories will be generated by EMFAC2011-HD.

3.3.4.2 VEHICLE SURVIVAL

In the process of developing revised assumptions, staff evaluated vehicle survival curves in EMFAC2007 against curves that were derived using more recent DMV data. In most cases the survival curves derived from the new DMV data were similar to those in EMFAC2007 and as a result no changes were required. However, in two categories (light duty automobiles and light duty trucks 2) survival curves developed using 2005-2009 data were different than those included in EMFAC2007. Survival curves for those two categories were updated in EMFAC2011-LDV as a result. A comparison of old and new survival curves for these categories are shown in Figure 3-1 and Figure 3-2 below.

Figure 3-1. Light Duty Automobile Vehicle Survival Curves: EMFAC2007 vs. EMFAC2011-LDV

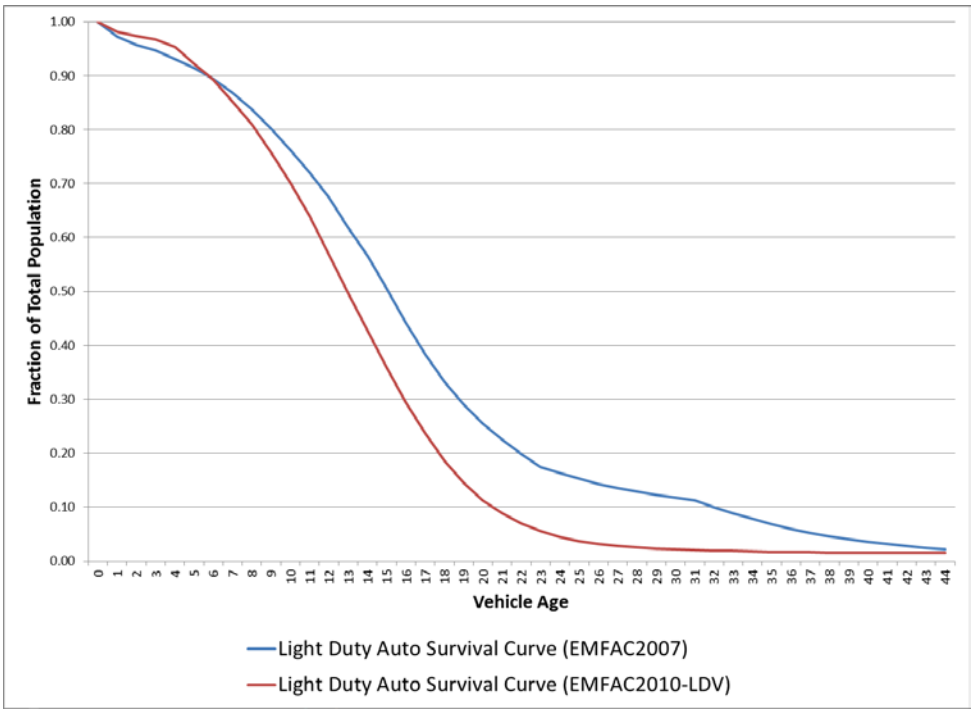


Figure 3-2. Light Duty Truck 2 Vehicle Survival Curves: EMFAC2007 vs. EMFAC2011-LDV

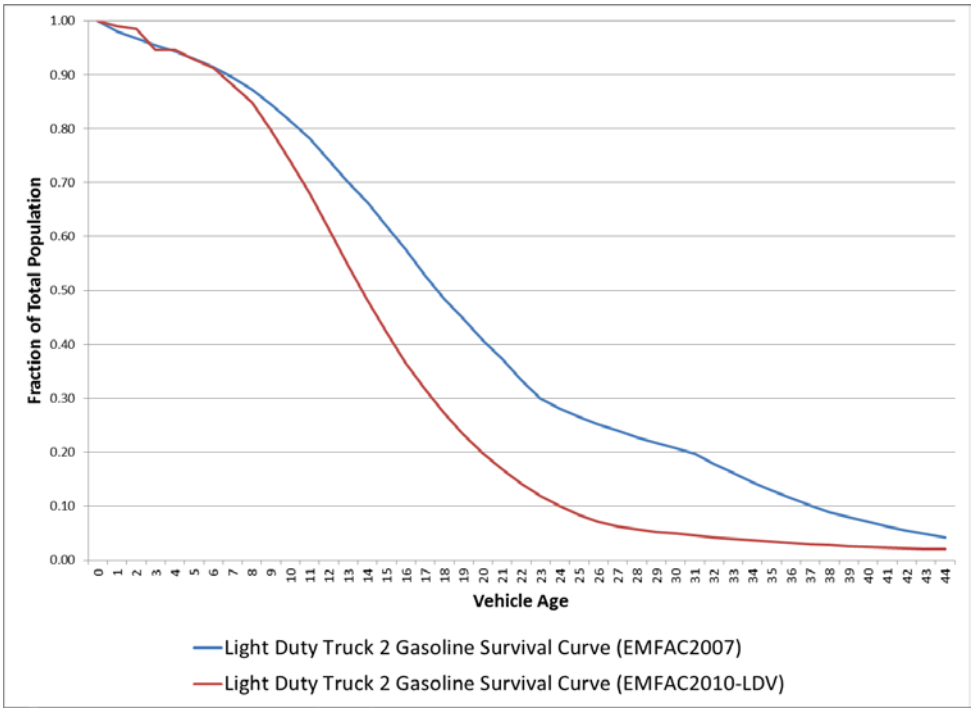
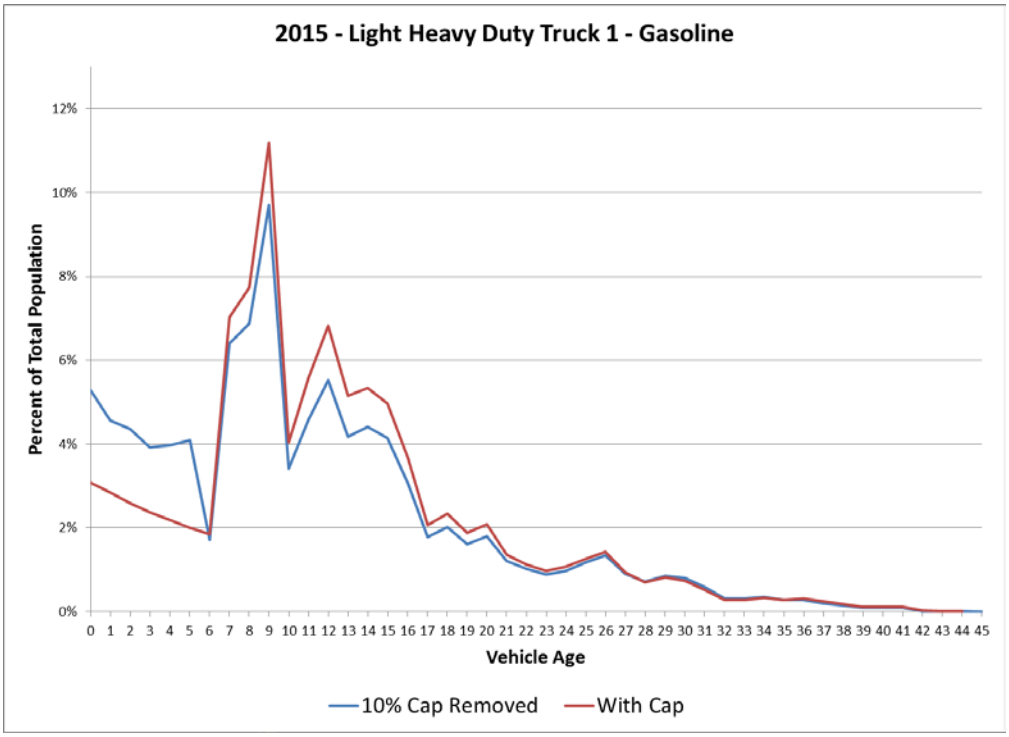


In EMFAC2007 and prior versions of the EMFAC model, new vehicle sales in a given calendar year and vehicle class were a function of the overall population growth rate, the total population in the vehicle class and calendar year, the survival curve for the vehicle class, and a 10% limit on increase in year to year new vehicle sales in any vehicle class. If the 10% cap were calculated to be exceeded, the algorithm capped the increase in new vehicle sales at 10% and allocated the remaining new vehicles to older ages.

One of the impacts of the 2007-2009 economic recession was a major decrease in new vehicle sales with the lowest level of vehicle sales occurring in calendar year 2009. New vehicle sales decreased 20% in light duty automobiles and 75% in light heavy duty trucks relative to 2007. When evaluating EMFAC2011-LDV, it became clear that the 10% cap on increase in new vehicle sales was artificially depressing new vehicle sales in the future and as a result artificially aging the fleet in an unrealistic manner. As a result, that cap was removed. This is illustrated in Figure 3-3. Without the cap, new vehicle sales cannot rise above 10% resulting in a slow smooth increase from 2009, and enhanced survival in older ages. With the cap removed, the survival curve is impacting the population as it should in older ages, and new vehicle sales are more in-line with historical trends.

Figure 3-3. 2015 Light Heavy Duty Truck 1 – Gasoline: Comparison Using EMFAC2007 Approach (10% Cap in Place) Against EMFAC2011-LDV Approach (Cap Removed)



3.3.4.3 LIFETIME MILEAGE

In the EMFAC model, emission rates are a function of the cumulative mileage on the vehicle through an emissions process called deterioration. Cumulative mileage was calculated in EMFAC2007 assuming that a vehicle's cumulative lifetime mileage, which can generally be measured using an odometer, is the sum of the average vehicle's mileage accrual schedule over time. Analysis of available odometer data and academic studies[1] for cars and trucks demonstrated that this assumption is incorrect. The reason for this difference is that when a vehicle is young, the average odometer of a group of similarly aged vehicles in a class is the average of some high accruing and some low accruing vehicles. As vehicles age, higher mileage vehicles are scrapped more quickly than lower mileage vehicles. So, surviving vehicles are more likely to have accrued fewer miles than average when those vehicles were younger. The net result is that the modeled average odometer at a given age is a function of both accrual rates up to that age, and survival rates up to that age for the vehicle class. Observed odometer readings in practice tend to level out to a constant level for older vehicles.

To make this change in the model, staff updated the way in which odometer is calculated in EMFAC. In the new method integrated into EMFAC2011, modeled odometer or lifetime mileage is a function of both mileage accrual rates and vehicle survival rates in the following equation:

$$\text{ODOMETER (10)} = \sum_{i=1}^{10} accrual(i) * survival(i)$$

This change leads to a small change in emissions in any calendar year, but effectively places a cap on deteriorated emission factors in older vehicles. Details on the emissions impact are available in Section 12.16.

3.3.4.4 TEMPERATURE AND RELATIVE HUMIDITY PROFILES

Due to the importance of environmental conditions on emissions, correction factors are used in EMFAC to adjust the laboratory-based emissions rates when actual ambient environmental conditions differ from the standard laboratory conditions under which emissions testing is conducted. More specifically, correction factors for ambient temperature and relative humidity are used to adjust base-rate exhaust emissions (running and starts, especially starts) and evaporative emissions (i.e., diurnal, hot-soak, running loss and resting loss) for non-standard conditions. Emission rates are adjusted for ambient temperature conditions that vary from 75 degrees Fahrenheit or absolute humidity that varies from 75 grains of water per pound of dry air (gr/lb). The default profiles are based on region-specific meteorological conditions that have occurred on days that ambient pollutant concentrations challenge attainment and maintenance of air

[1] Greenspan, A., Cohen, D, (1996). Motor Vehicle Stocks, Scrappage, and Sales. October 30, 1996. Available at: http://www.federalreserve.gov/pubs/feds/1996/199640/199640pap.pdf.

quality standards in a region, specifically the new federal 8-hour standard and the federal 24-hour $PM_{2.5}$ standards.

For each region, approximately 24 total days over 12 years (1996-2007) were selected for analysis. Key differences between this update and prior updates to the default temperature and relative humidity profiles in the models are as follows:

Profile Scenarios. The current update addresses four scenarios of environmental conditions:

- **ozone** exceedance conditions based on the new federal 8hr ozone standard;
- **PM** exceedance conditions based on the new federal 24-hour $PM_{2.5}$ standard;
- **monthly** average ambient environmental conditions; and
- **annual** average (based on monthly average data).

The last update to default temperature and relative humidity profiles occurred in late 2006, which only addressed summertime conditions based on data analyses spanning March through October.

Spatial-Weighting Schemes. In the last update, EMFAC summer profiles were developed with VMT weighting and simple averaging. In this current update, the spatial weighting by VMT is still used for EMFAC profile development.

Relative Humidity Calculation. Previously, temperature (T) and relative humidity (RH) profiles were developed independent from each other using the same selected days of simultaneously-collected T and RH data. Thus, these matched pairs of T and RH were dissociated and then averaged independently. A deficiency with this approach is that it allows the known, dependent relationship between temperature and pressure to be broken. To fix this methodological deficiency and better maintain the site- and day-specific relationship between temperature and relative humidity in this update, a different methodology was used. With this new method and for a specific monitoring location, hourly temperature averages are calculated first from simultaneously-collected pairs of T and RH values. Next, a relative humidity value for each of the resulting averaged temperature values is selected or interpolated from the original, matched pairs of T and RH via cross-referencing on temperature values. Because NOx emissions are sensitive to humidity, this change in methodology affects NOx emission estimates.

Data Period of Record and Screening Criterion. The Federal 8-hour ozone standard and 24-hour $PM_{2.5}$ standard have been revised since the previous update of temperature and relative humidity profiles. This update utilizes the present Federal 8-hour ozone and 24-hour $PM_{2.5}$ standards.

Use of Imputed Data. Missing data at one site are imputed if the data at that site are systematically related to the data measured for at least one other site. Using imputed data helped raise the number of sites with “complete” data from 1996 to 2007 from less than 100 to 156 sites.

Overall, the updated temperature and relative humidity profiles lead to +/- 5% change for ROG and NOx for ozone (summer) and PM (winter) profiles relative to previous estimates in EMFAC2007.

3.3.4.5 UPDATE TO NUMBER OF LIGHT-HEAVY DUTY VEHICLE STARTS

Emissions from gasoline powered vehicles during starts are higher than during normal vehicle operation because control equipment does not function optimally when a vehicle is cold. EMFAC2007 assumed 33 trips per day for gasoline powered light-heavy duty trucks, which are defined as having a gross vehicle weight rating between 8500 and 10,000 pounds. Staff reviewed this assumption, and found that given the uses for these vehicles the number of starts was excessive, leaving roughly 2 miles of driving per start and a mean time between trips of 15 minutes or less.

Staff re-evaluated the original data that were used to develop vehicle start estimates and found that Federal Express and United Parcel Service trucks seemed to be over-represented in the gasoline vehicle sample. When data were evaluated across both diesel and gasoline vehicles, staff estimated 15 starts per day. That value was used to update EMFAC2011-LDV.

3.3.4.6 UPDATE TO ASSUMED TO COMPLIANCE WITH THE LEV2 REGULATION

In November 1998 staff adopted new light duty vehicle emission standards (LEV2) that began implementation in 2004. In EMFAC2000 staff integrated the compliance pathways into EMFAC based on assumptions developed during rulemaking. The LEV2 standards set an average emissions target across vehicle classes, which allowed vehicle manufacturers some room to manufacturer different combination of vehicle technologies to meet the standard. In developing EMFAC2011 staff reviewed these assumptions.

Three updates were made. First, staff identified that when compared to certification data EMFAC assumed that by 2010 about 70% of new passenger cars would be certified to the partial zero emission vehicle (PZEV) standard, and be partially offset by a small fraction of dirtier vehicles. In reality, vehicle manufacturers sold 20% PZEV and 70% ultra-low emission vehicles or ULEV. In essence vehicle manufacturers sold a different mix of cars than assumed in EMFAC2007, but that met the same LEV2 emissions standards. Second, staff updated light-duty diesel sales fractions based on actual sales data. Since diesel cars sold after 2004 had to meet gasoline vehicle emissions standards, this had no impact on emissions. Finally, staff integrated new assumptions about penetration of zero-emission vehicles. EMFAC2007 had assumed a small fraction of ZEVs would be sold in the previous decade. Those sales were overestimated, and staff updated ZEV sales with actual sales data. Staff also updated ZEV forecasts between 2010 and 2017. Some electric vehicles are expected to be available because of the advent of plug-in hybrids that provide a relatively long all-electric range. Details are available in Sections 12.12 and 12.18.

3.3.4.7 JULY 2012 UPDATE TO SANTA CLARA COUNTY

In July 2012 corrected the number of starts in the LDV module code for gasoline urban bus, school bus, other bus, motorcycle, and motorhome vehicle categories in Santa Clara County. The number of starts in Santa Clara County had been incorrectly entered into the model code, which led to an overestimate of ROG emissions in Santa Clara County. On a statewide basis, fixing the error decreases ROG emissions by roughly 2%. The following table highlights the updated assumptions.

Santa Clara Summer Episodic On-Road Motor Vehicle Trips (Gas Fuel) (Calculated Using EMFAC2011 SG ver 1.0)									
Cal. Year	**1990**	**2000**	**2005**	**2007**	**2010**	**2014**	**2017**	**2020**	**2023**

4 EMFAC2011-HD

4.1 INTRODUCTION AND DESIGN

Commercial heavy-duty diesel trucks and buses are defined as commercial diesel buses and trucks exceeding 14,000 pounds gross vehicle weight rating (GVWR). Combined these categories are the single largest source of NOx and diesel PM2.5 in California.

Beginning in 2007, staff began the process of redesigning the truck and bus emissions inventory in order to support development of the Drayage Truck and Statewide Truck and Bus Rules. These rules were ultimately adopted and amended between 2008 and 2010. In developing this new analysis, staff integrated new data and assumptions into an expanded methodology that builds upon modeling techniques in embedded EMFAC2007. The expanded approach accounts for the differences in trucking and busing operations which are a function of vehicle registration type, body type, and vocation.

EMFAC2011-HD is written in two parts. The activity portion of the inventory, which includes current, back-casted, and forecasted population / VMT is written in Microsoft Access. These activity estimates are the same as those assumed for the Truck and Bus Rule Amendments adopted in December 2010. The emission factor portion of EMFAC2011-HD is written in Visual Basic and MySQL. Whereas the December 2010 regulatory inventory relied upon statewide annual average emission rates adjusted for several updates, EMFAC2011-HD incorporates the same updates (as well as additional updates to temperature, relative humidity profiles, and regional speed distributions) into the full programming breadth that was previously included in the EMFAC model.

4.2 BASIC METHODOLOGY

Emissions are calculated as the product of a population of vehicles, the number of miles each vehicle travels, and emission rates per mile as shown below. Beneath this simple equation lies a series of data and assumptions about the population, miles traveled, and emission rates per vehicle model year in a given calendar year, growth and attrition estimates, deterioration, and other factors that affect emissions estimates, all of which is described in documentation developed for the Truck and Bus Rule or in this document. We applied the concept separately for each analysis category of trucks that shares similar travel, service, size, age or other characteristics.

$$\sum_{MY,\,C} \left(POP_{MY,\,C} \times AC_{MY,\,C} \times ER_{MY,\,C,\,R}\right) = EMS_{CY},$$

where: $POP_{MY,\,C}$ is the population of trucks for model year MY within each analysis category C for a given calendar year;

$AC_{MY,\,C}$ is the accrual rate (miles traveled per year) per truck by model year MY and analysis category C in a given calendar year;

$ER_{MY,\,C}$ is the calculated emission rate, in grams pollutant per mile driven, assuming regional speed distributions, regional temperature and relative humidity profiles by hour of day, and category specific cumulative mileage accrual over the life of the truck, by model year MY, analysis category C, and region R;

EMS_{CY} is the emissions calculated in tons per day for a given calendar year.

4.3 WHEN THE MODULE SHOULD BE USED

EMFAC2011-HD estimates emissions for commercial vehicles equipped with medium heavy or heavy-heavy duty diesel engines. The module outputs emissions from these categories assuming the benefits of recently adopted Rules. A user can run EMFAC2011-HD separately, or to obtain emissions estimates across all vehicle categories within a region, a user can use the new on-line database of EMFAC2011 output available through our website, may use the EMFAC2011-SG, or may run EMFAC2011-LDV and EMFAC2011-HD separately. In most cases, data served through the internet should be sufficient to answer many user questions without running the model.

4.4 RELATIONSHIP TO REGULATORY INVENTORIES

Population and activity estimates for years covered by the regulatory inventory are identical to those assumed for the Truck and Bus Rule amendments that were adopted by the Board in December 2010. Additional activity estimates have been made for the prior to 2000 and after 2025 so that emissions can be provided from the model for the full intended range of EMFAC2011: 1990-2035. EMFAC2011-HD generates emission rates using the same algorithm as EMFAC2007, but incorporates all of the emission factor related updates made as part of the regulatory inventory (chip reflash, updated medium heavy-duty base emission factors, etc.), and includes updated speed, temperature, and relative humidity profiles developed for EMFAC2011. More information on the truck and bus rules is available at: http://www.arb.ca.gov/msprog/onrdiesel/onrdiesel.htm.

4.5 ACTIVITY

Activity estimates are identical to those assumed for the Statewide Truck and Bus Rule Amendments in 2010 and cover the years 2000, 2002, 2004, 2005-2025. Detailed documentation on the methods and assumptions used are available at: **http://www.arb.ca.gov/regact/2010/truckbus10/truckbusappg.pdf;** **http://www.arb.ca.gov/msprog/onrdiesel/ab1085compliance.htm;** and **http://www.arb.ca.gov/regact/2008/truckbus08/appg.pdf.**

4.5.1 FORECAST/BACKCAST OUTSIDE OF REGULATORY INVENTORY

For forecasting activity beyond 2025, the methodology for growth trend follows the same approach as the regulatory inventory. For most of the medium and heavy-heavy duty diesel truck inventory, we assumed the same year to year growth rates as in EMFAC2007. Growth of Statewide construction truck fleets activity is based on the construction activity growth and the activity distributions to air basins are based on population growth. For activity prior to 2000, we used the trend of California diesel fuel sales to on-highway consumers between 1990 and 2000 from Energy Information Administration (EIA, California No 2 Diesel Adjusted Sales/Deliveries to On-Highway Consumers). The back-casted statewide activities for construction truck fleets followed the EIA fuel sales trends as most other truck fleets and distributed to air basin based on population growth. The activities outside of regulatory inventory for buses, drayage trucks, agricultural trucks, public and utility fleets and solid collection vehicles are assumed to follow their respective long term growth trends. As in the regulatory inventory, sales adjustment factors developed based on new truck sales were used to adjust the average age distribution in the baseline. We assume sales adjustment factors are 1 for all pre-1985 models and used the average of the newest five model year sales adjustments in the regulatory inventory for all additional forecast model years.

4.6 EMISSION FACTORS

In developing the Statewide Truck and Bus Rule emissions inventory, staff revised the emission factors for medium heavy-duty diesel trucks (MHDDT), made adjustment to the NOx emission rates of 2006-2011 model year heavy heavy-duty diesel trucks (HHDDT) and MHDDT, and updated the HHDDT and MHDDT CO2 emission rates as well as the HHDDT NOx idle emission rates. These adjustments were made outside of EMFAC2007. In developing EMFAC2011-HD, staff integrated these adjustments that were not included in EMFAC2007 but were included in the Statewide Truck and Bus Rule emissions inventory. Details are available in Section 11, and the following describes at a high level the revision and update of truck emission factors in EMFAC2011 relative to EMFAC2007.

4.6.1 MEDIUM HEAVY-DUTY TRUCK EMISSION RATES

In EMFAC2007, staff did not update the emission factors for medium heavy-duty trucks (MHDDT). Since the release of EMFAC2007, emission test data for MHDDT were made available by the Coordinating Research Council (CRC) through its E55/59 project final report. As a result, staff revised the MHDDT emission factors using the new test data in EMFAC2011.

The method of calculating MHDDT ZMR and DR is the same as that used for deriving emission factors of heavy heavy-duty trucks (HHDDT) in EMFAC2007. The test data were divided into a number of model year groups based on the general emission trends as well as changes in heavy-duty diesel engine emission standard and emission control technology. For each model year group, the zero-mile emission rates and deterioration rates for HC, CO, NOx, and PM were calculated.

4.6.2 2006-2011 MODEL YEAR NOX EMISSION RATE ADJUSTMENT

A review of the certification data shows that some engine manufacturers introduced 1.2 g/bhp-hr NOx heavy-duty engines one year earlier than required and one manufacturer chooses to meet USEPA 2010 NOx standard without using selective catalytic reduction. Staff updated the 2006-2011 model year HHDDT and MHDDT emission factors in EMFAC2011 to reflect how engine manufacturers complied with the 2007 engine standards and how they comply with the 2010 engine standards between 2007 and 2011.

4.6.3 HHDDT AND MHDDT CO2 EMISSION RATES

In EMFAC2007, CO2 emission rates of diesel trucks were assumed to remain constant regardless of model year, technology, activity, and other factors. However, with the emphasis on greenhouse gas emissions control over the past few years, staff decided to update CO2 emission rates for individual model years in EMFAC2011. During the Board's In-Use On-Road Diesel Vehicle rulemaking, staff evaluated available data to determine how improvements in engine technology and increasingly stringent criteria pollutant emission control requirements have affected the fuel economy of trucks. Staff reviewed multiple data sources to characterize the variations in the fuel economy values of trucks in California. After fuel economy was estimated, fuel usage was then converted to CO2 emissions.

4.6.4 MHDDT IDLE EMISSION RATES

As with the revision of MHDDT running exhaust emission rates, the available CRC E55/59 idle emission test data allowed staff to revise the MHDDT idle emission rates in EMFAC2011. The method of analysis is the same as that used for calculating HHDDT idle emission rates in EMFAC2007. The high idle correction factors for HHDDT in EMFAC2007 are also applicable to MHDDT.

4.6.5 HHDDT NOX AND CO2 IDLE EMISSION RATES

The EMFAC2007 NOx idle emission rates of HHDDT for 2007 and subsequent model years were projected based on the then prevailing assumption that engine manufacturers would adopt a 5-minute shut-off mechanism to comply with ARB's anti-idle rules. However, the certification data show that all engine manufacturers have instead chosen to meet the ARB requirements with the 30 g/hour NOx idle emission rate option. As a result, staff revised the NOx idle emission rates of 2008+ model year trucks in EMFAC2011 to reflect the engine certification data.

The CO2 idle emission rates of HHDDT were also updated in EMFAC2011. In EMFAC2007, an average CO2 idle emission rate was used for all model years. To be consistent with the revision to the CO2 exhaust emission rates of HHDDT, in EMFAC2011 idle emission rates of CO2 were calculated for individual model year groups.

5 EMFAC2011-SG

5.1 BACKGROUND ON CONFORMITY

State and federal law require regional planning agencies prepare both a transportation plan to benefit public mobility and an air quality plan to benefit public health. Under the federal Clean Air Act, transportation activities that receive federal funding or approval must be found to be fully consistent with the plan developed to meet federal clean air standards, known as the State Implementation Plan, or SIP. The requirement that federal activities--especially transportation plans and projects--be shown to help communities attain federal air quality standards is known as conformity.

Conformity applies to federal transportation decisions in all areas that are designated "nonattainment" for specific pollutants (ozone, carbon monoxide, particulate matter) by the U.S. EPA. These are areas that have recorded violations of the National Ambient Air Quality Standards. "Attainment" areas that have adopted air quality maintenance plans are also subject to conformity. Areas that have exceeded the more stringent California air quality standards but are within national standards are not subject to conformity (however, the California Environmental Quality Act applies to all projects in the state).

Adoption by a metropolitan planning organization (MPO) of a 20-year regional transportation plan (RTP), or a short-term federal transportation improvement program (TIP), must include a conformity analysis prepared by the MPO. In addition, sponsors of transportation projects that require a federal approval are responsible for assessing project conformity. Final determinations of conformity for RTPs, TIPs and projects are made by the Federal Highway Administration and the Federal Transit Administration.

Conformity assessments are part of a broader regional transportation planning process carried out by the MPO, or by another transportation agency in less urbanized areas. Because joint transportation and air quality planning assists both conformity assessments and air pollution reduction efforts, local air districts and transportation planning agencies regularly consult with each other and with involved state and federal agencies. Local transportation and air quality planning processes are also open to interested organizations and members of the public.

For RTP and TIP demonstrations, conformity first involves an emissions test. The air quality plan (SIP) forecasts levels of pollutant emissions that will enable steady progress toward attainment of air quality standards by Clean Air Act deadlines, backed up by control strategies that will enable these levels to be reached. Such forecasts are divided by emissions source. The on-road mobile source portion of the forecast is known as a motor vehicle emissions budget. To be found in conformity with the SIP, a

region's transportation plan and program must be found to result in emissions that are within each emissions budget.

In July 2012 staff identified a typographical error in the EMFAC2011-LDV module code that incorrectly assigned trips in gasoline powered school buses, urbant transit buses, other buses, motocycles, and motorhomes in Santa Clara County. These trips were overestimated as a result, which led to an overestimate of ROG emissions in the Bay Area and for the Statewide total. The EMFAC2011-LDV module has been corrected and re-released. New input files to SG were generated for Santa Clara County. The module code and algorithms in the EMFAC2011-SG module were not otherwise affected by this change.

5.2 THE EMFAC2011-SG TOOL

The EMFAC2011 modeling package contains a suite of modules for modeling different vehicle categories including:

- EMFAC2011-LDV, a Fortran-based module mainly representing light-duty fleet (an update to the original EMFAC model), and
- EMFAC2011-HD, a Visual Basic/SQL-based module representing the heavy-duty diesel trucks/vehicles.

Since the two modules are written on two different software platforms, and each contains a different portion of the motor vehicle fleet, outputs from both modules are needed to be processed externally to create the entire motor vehicle fleet inventory. Therefore, the EMFAC WIS processor (in the EMFAC LDV model) is no longer adequate to perform a complete regional transportation conformity analyses.

Staff developed a new module called EMFAC2011-SG. EMFAC2011-SG is developed in Microsoft® Access platform, and replaces the functionalities of the WIS module in EMFAC for transportation conformity purposes. EMFAC2011-SG is an external module that uses the inventory from EMFAC2011-LDV and EMFAC2011-HD modules and scales the emissions based on changes in total VMT, VMT distribution by vehicle class, and speed distribution. EMFAC2011-SG processes data only at a sub-area level. A sub-area is defined as a county that is split by county, air basin, and air district boundaries. Each sub-area within the county is a GAI. In order to process regional scenarios (State, Air Basin, Air District, MPO, County), the module needs to process all sub-Areas in its domain and aggregate the results. Therefore, for a single “Statewide” regional modeling scenario, the module will need to run and aggregate the results of all 69 sub-areas (GAIs). Regional-level outputs are aggregated as part of module output.

Therefore, the module will produce individual outputs for each GAI, but also produce the aggregated region-level output (Statewide output). EMFAC2011-SG uses the VMT-weighted speed distribution at the daily level, and allows users to generate MPO-level outputs, in addition to the Statewide, Air Basin, Air District, County, and Sub-Area level outputs. EMFAC2011-SG inputs and outputs are generated in Microsoft Excel format (*.xls).

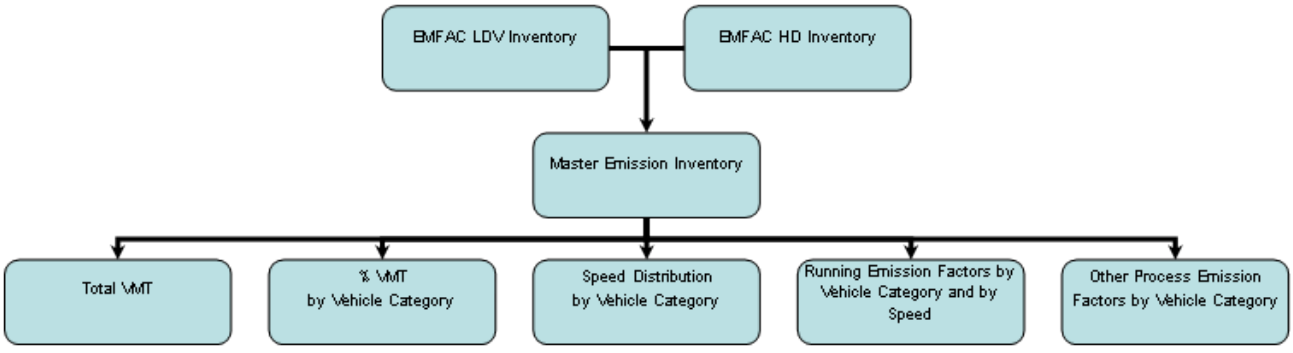
5.3 MODULE LOGIC

Since transportation plans and policies are created by the local governments, the vehicle usage and speed profiles vary greatly at the sub-area level. Therefore, the EMFAC2011-SG module was also developed to process speed data at the sub-area level.

EMFAC2011-SG uses the combined Burden-level outputs from the two modules (EMFAC2011-LDV and EMFAC2011-HD) disaggregated by Model-year and Speed (5-MPH increments) as the base inventory. The base inventories are pre-processed by sub-area, calendar year and season, and are available to download along with the SG package. Users are required to download the inventories for the regions of interest to their computers.

Each sub-area modeling case is called a 'Scenario' (defined by sub-area, calendar year, and season). When a user models a scenario, the EMFAC2011-SG module imports the data from the corresponding base inventory file, and disaggregates the data into different parameters as shown in Figure 5-1.

Figure 5-1. Schematic of EMFAC2011-SG Logic



Based on the modeling parameters, SG uses the following equations to calculate the emissions by Vehicle Category (VC):

$$\text{Running Emissions}_{\text{VC}} = \text{Total VMT} \times \text{VMT Fraction}_{\text{VC}} \times \left[\sum_{\text{Speed}=5}^{70} \text{Speed Fraction}_{\text{Speed,VC}} \times \text{Running Emission Factor}_{\text{Speed,VC}}\right]$$

$$\text{Other Process Emissions}_{\text{VC}} = \text{Total VMT} \times \text{VMT Fraction}_{\text{VC}} \times \text{Process Emission Factors}_{\text{VC}}$$

Where:

$$VMT\ Fraction_{VC} = \frac{VMT_{VC}}{Total\ VMT}$$

$$Speed\ Fraction\ (\%\ VMT_{Speed}) = \frac{VMT_{Speed,\ VC}}{Total\ VMT_{VC}}$$

$$Running\ Emission\ Factor\ (g/mile) = \frac{Default\ Running\ Emissions_{Speed,\ VC}}{Default\ VMT_{Speed,\ VC}}$$

$$Process\ Emission\ Factor\ (g/mile) = \frac{Default\ Process\ Emissions_{VC}}{Default\ Total\ VMT_{VC}}$$

5.4 MODULE OVERVIEW

The EMFAC2011-SG module has three main inputs, and one optional input:

- Base Inputs
- VMT Distribution by Vehicle Category
- Speed Profiles
- Regional Scenario (optional)

The modeling parameters in all three inputs are defined at the sub-area level. In order to correlate the data in the three input sheets, the module identifies each case as a "Scenario". In order to process regional scenarios, users are required to classify all the "scenarios" into groups; the module processes each scenario individually and aggregates data by groups at the end of module execution.

User Input #1: Base Inputs

- This is the most important input for the module. It contains scenario definitions that include sub-area, calendar year and season, and selections for VMT profile (module defaults or user defined), VMT by Vehicle Category (module defaults or user defined), and Speed distribution type (module defaults or user defined) for each scenario.
    - If the "VMT profile" entry for the scenario is *User* defined, then the user also needs to enter the "New Total VMT" data (miles/day)
- *Input Variables:*
    a. Group (Integer) – Identifier for grouping/aggregating the scenarios
    b. Area (Text) – Denotes the Area/Region name for each group
    c. Scenario (Integer) – Index representing order of modeling scenario
    d. Sub-Area (Text)
        - Options: Selected from a list of 69 sub-areas (CoABDis or GAI)
    e. CalYr (Calendar year)
        - Options: Any calendar year between 1990 and 2035
    f. Season (Text)
        - Options: "Annual", "Summer", or "Winter"
    g. Title (Text)
    h. VMT Profile (Text)
        - Options: "Default" (module default) or "User"(user-defined)
    i. VMT by Vehicle Category (Text)
        - Options: "Default" (module default) or "User"(user-defined)
    j. Speed Profile (Text)
        - Options: "Default" (module default) or "User"(user-defined)

k. New Total VMT (Numeric) – Represents user-defined total daily VMT (miles/day)
    - If the scenario VMT Profile is designated as “Default”, then the “New Total VMT” cell can be empty (user entry for “New Total VMT” will be ignored)
    - If the scenario ‘VMT Profile’ and the ‘VMT by Vehicle Category’ are designated as “User” (user-defined), then the “New Total VMT” cell can be empty (the VMT from the “VMT by Vehicle Category” table will be used in the calculations; user entry for “New Total VMT” will be ignored)
    - If the scenario VMT Profile is designated as “User” (user-defined), and the ‘VMT by Vehicle Category’ is designated as “Default” (module default), only then the “New Total VMT” cell needs to be populated (here, the Default VMT fractions by Vehicle Class are used to apportion the User provided “New Total VMT”)

User Input #2: VMT by Vehicle Category

- Contains daily VMT data by Vehicle Category, and is a required input if the “VMT by Vehicle Category” entry for the scenario is *User* defined,
    - Data entered in the “VMT_by_VehCat” worksheet (in miles/day)
- *Input Variables:*
    a. Group
    b. Area
    c. Scenario
    d. Sub-Area
    e. CalYr
    f. Season
    g. Title
    h. Veh & Tech: EMFAC2011 Vehicle Category
    i. New VMT: Daily VMT by Vehicle Category

User Input #3: Speed Profile

- Contains the speed distribution by vehicle category (represented by % VMT in each speed bin for an average day), and is a required input if the “Speed Profile” entry for the scenario is *User* defined
    - Data entered in the “Speed_Profile” worksheet
- *Input Variables:*
    a. Group
    b. Area
    c. Scenario

d. Sub-Area
e. CalYr
f. Season
g. Title
h. Veh & Tech: EMFAC2011 Vehicle Category
i. EMFAC2007 Veh & Tech: EMFAC2007 Vehicle Category
j-w. 5MPH-70MPH: Speed Distribution (% VMT at each speed bin) for Speeds 5 - 70 MPH @ 5 MPH increments

Optional User Input: Regional Scenarios

- This is an optional input for modeling
  - Allows users to create Regional (multi-GAI) scenarios outside the module, and import them into the module
- *Input Variables:*
  a. Group
  b. Group Type
  c. Area
  d. Calendar Year
  e. Season
- *Regional Scenario Groups*
  - All scenarios that need to be aggregated together should be classified in the same "Group" in the Scenario_Base_Inputs table
    - So if the user needs to run "Statewide 2008 Annual" and "Statewide 2010 Annual", then user should create two "Groups"
      - All scenarios related to Statewide Sub-Areas that relate to 2008 Annual period in one group
      - All scenarios related to Statewide Sub-Areas that relate to 2010 Annual period in another group
    - All input tables (Scenario_Base_Inputs, Scenario_VMT_by_VehCat, and Scenario_Speed_Profiles) need to identify the Group, Area name, Scenario, Sub-Area, CalYr, Season, and Title for each Scenario
  - If users only need Sub-Area (GAI) runs, then
    - All scenarios should be grouped in the 'Default' Group # (1)
    - Area name category should be "-" [Area name "-" denotes that it is not part of any "regional" run, and these results will not be aggregated by Group (results will still be generated))
  - For any scenarios where Area name <> "-", outputs will be aggregated based on Group ID
  - Module allows Regional Scenario table to be imported using the "Load/Run Regional Scenarios (External Files)" option

5.5 ASSESSING CO2 BENEFITS FOR THE PAVLEY RULE AND LOW CARBON FUEL STANDARD

EMFAC2011-SG outputs carbon dioxide (CO2) emissions both with and without the Pavley Rule and Low Carbon Fuel Standard. The method for calculating benefits is consistent with the Pavley-I and LCFS post-processor used for analysis for SB375, and estimates benefits only for CO2, not criteria pollutants. The method requires applying correction factors to by model year emissions inventory output. Because EMFAC2011-SG runs on emissions inventories summed across model years, the correction was applied to CO2 emissions estimates when developing the input inventory files for SG. The correction is not embedded in the EMFAC2011-SG module code; it is embedded in the emissions data that are input to EMFAC2011-SG.

The calculation used to adjust CO2 emissions is very simple, and derived from assessments developed during staff regulatory support efforts for the two programs.

- Pavley-I: A clean-car standard to reduce greenhouse gas (GHG) emissions from new passenger vehicles (LDA-MDV) from 2009 through 2016 (reduction factors are presented in Table 5-1).
- Low Carbon Fuel Standard: A fuel standard that requires a reduction of at least 10 percent in the carbon intensity of California's transportation fuels by 2020 (reduction factors are presented in Table 5-2).

Table 5-1. Pavely I Reduction Factors

Model Year	LDA/LDT1	LDT2/MDV
2008 and older	0.00%	0.00%
2009	0.00%	0.90%
2010	3.50%	5.20%
2011	14.40%	12.00%
2012	25.30%	18.50%
2013	27.20%	19.90%
2014	28.80%	21.00%
2015	31.70%	23.00%
2016 +	34.30%	25.10%

Table 5-2. LCFS Reduction Factors

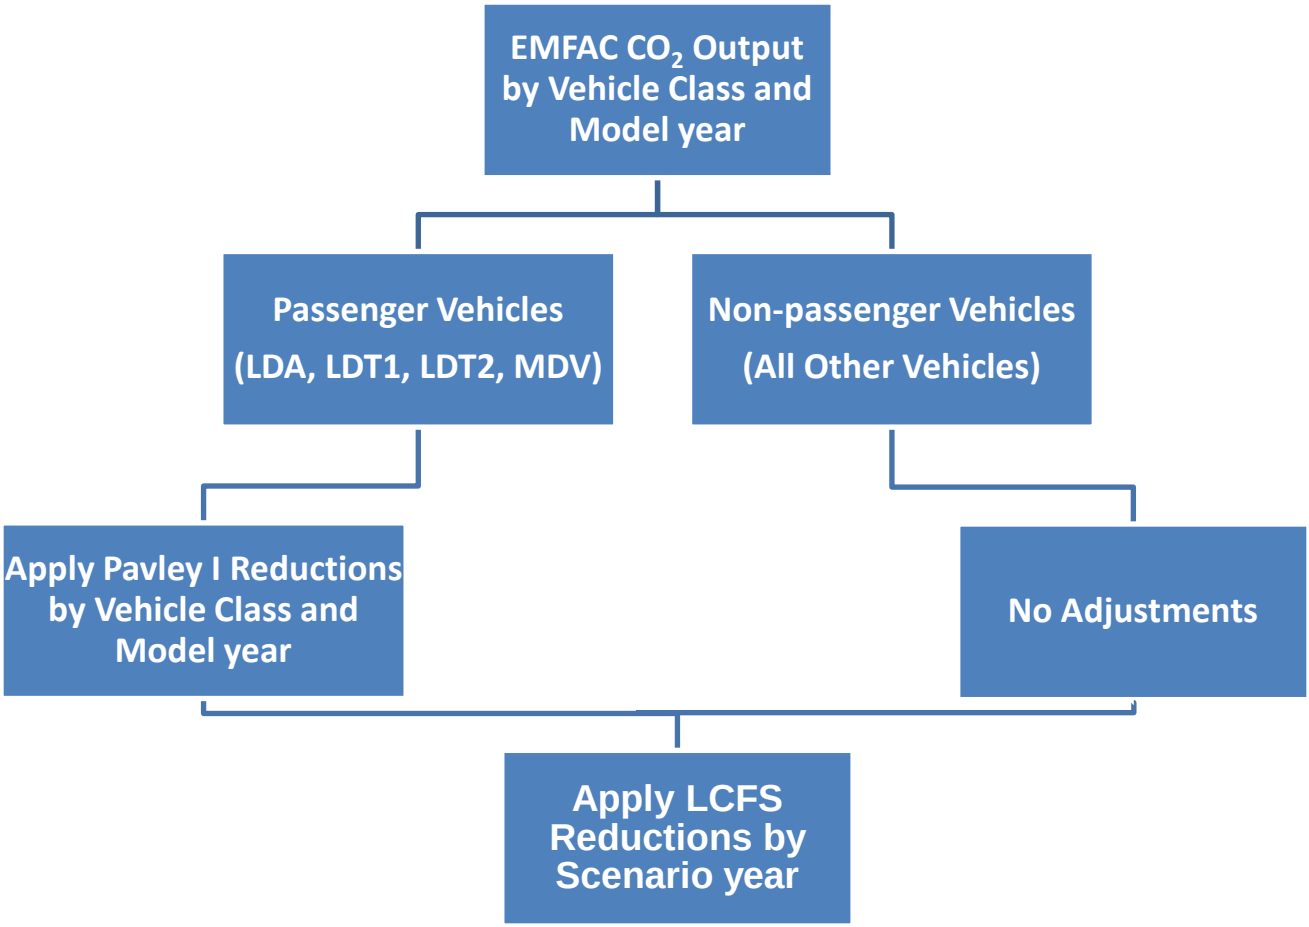
Calendar Year	Reduction Factor
2010	Reporting Only
2011	0.25%
2012	0.50%
2013	1.00%
2014	1.50%
2015	2.50%
2016	3.50%
2017	5.00%
2018	6.50%
2019	8.00%
2020 +	10.00%

LCFS reduction factors are based on the carbon intensity reductions required by the LCFS Regulation for transportation fuels used in California as provided from the Staff Report titled "California's Low Carbon Fuel Standard" dated October 2009.

Measured on a lifecycle basis, the carbon intensity represents the equivalent amount of carbon dioxide (CO_2e) emitted from each stage of producing, transporting, and using the fuel in a motor vehicle.

In order to calculate the CO2 emissions reductions from the two regulations, the following five-step process was used:

1. Extract CO_2 emission data from EMFAC by Vehicle Class and Model Year
2. Disaggregate the data into two groups:
    a. Passenger vehicles (LDA, LDT1, LDT2, MDV)
    b. Non-passenger vehicles (All other vehicles)
3. Apply the Pavley I reduction factors to the Passenger vehicles CO_2 emissions by vehicle class and model year
4. Aggregate the total CO_2 emissions for each vehicle class
5. Apply the Low Carbon Fuel Standard reduction factors to all vehicles based on the calendar year



EMFAC CO_2 Output by Vehicle Class and Model year
Passenger Vehicles (LDA, LDT1, LDT2, MDV)
Non-passenger Vehicles (All Other Vehicles)
Apply Pavley I Reductions by Vehicle Class and Model year
No Adjustments
Apply LCFS Reductions by Scenario year

5.6 MODULE OUTPUTS

The model outputs are denoted by “EMFAC2011-SG Output” and contain the Input Filename (e.g. if the Input Filename is “Sample”, the Output file will be called “EMFAC2011-SG Output - Sample”). The output files are created in Microsoft® Excel format (.xls), and contain the following variables:

- Group
- Area
- Scenario
- Sub-Area
- Calendar Year
- Season
- Title
- Veh & Tech
- EMFAC2007 Category
- Vehicle Population
- VMT (miles/average weekday)
- Trips (trips/average weekday)
- TOG Emissions (tons/average weekday)
- ROG Emissions (tons/average weekday)
- CO Emissions (tons/average weekday)
- NO_x Emissions (tons/average weekday)
- CO2 Emissions (tons/average weekday)
- CO2 Emissions (including Pavley I and LCFS adjustments) (tons/average weekday)
- PM_{10} Emissions (tons/average weekday)
- $PM_{2.5}$ Emissions (tons/average weekday)
- SO_x Emissions (tons/average weekday)
- Fuel Consumption – Gas and Diesel (1,000 gallons/average weekday; not adjusted for Pavley-I or LCFS)

The following process emissions are generated for each pollutant:

- All Pollutants - Running, Idling, Starting, and Total Exhaust
- ROG and TOG - Diurnal, Hot-Soak; Running and Resting Losses; Total
- PM10 and PM2.5 - Break wear, Tire wear, Total

The model appends the outputs for all scenarios defined in an input file in the same output file. The model also aggregates the results of all the scenarios that are classified in the same group, and appends the aggregated output for the group in the same file (along with the outputs for all sub-areas).

- For a single statewide regional case, the model will create a single Excel output table containing 70 sets of outputs (69 sub-area/GAI results, and 1 Statewide-totals result). The number of data rows will depend on number of Vehicle Categories applicable to each sub-area.

Table 5-3 provides sub-area classifications that can be run in EMFAC2011-SG. Table 5-4 provides vehicle categories classified by several vehicle category classification schemes that can be summarized using EMFAC2011.

6 OVERVIEW OF INCREMENTAL CHANGES

EMFAC2011 emissions estimates are the sum of emissions estimated using the EMFAC2011-LDV and EMFAC2011-HD modules. While there have been many improvements to the EMFAC modeling system for EMFAC2011, overall activity and emissions are generally similar to those estimated using EMFAC2007.

6.1 POPULATION

To understand the differences in estimated population between EMFAC2007 and EMFAC2011, it is useful to recall differences between the population data in the two models. EMFAC2011 was updated with 2009 DMV data and 2010 commercial diesel truck population estimates. Both of these population data sources are impacted by the 2007-2009 economic recession, which substantially reduced new vehicle sales, and to a limited degree, vehicle populations. In contrast, EMFAC2007 contained 2005 population data; 2009 population estimates were forecasted using VMT forecasts provided by regional transportation agencies prior to the EMFAC2007 release.

EMFAC2007 contained 2000-2005 DMV data and backcast populations prior to 2000. The DMV data input to EMFAC contained anomalies in the 2004 and 2005 data that led the 2004 population to be underestimated and the 2005 population to be overestimated, primarily for heavy-duty trucks. The inconsistency in population and activity data in EMFAC2007 led to an increase in estimated population in 2005, coupled with an estimated decrease in population between 2005 and 2006 in most areas, primarily but not exclusively for heavy-duty trucks.

EMFAC2011 contains 2009 DMV data in EMFAC2011-LDV, and 2010 estimated truck populations developed from multiple data sources in EMFAC2011-HD. The process of using of multiple data sources to model populations in the HD module started with the Statewide Truck and Bus Rule inventory, and was developed specifically to correct for anomalies in truck data provided by DMV in their registration database. 1990-2008 calendar year populations are backcast using historical regional VMT trends in EMFAC2011. The anomaly present in EMFAC2007 has been removed for EMFAC2011.

Population comparisons are shown in Figure 6-1, Figure 6-2, and Figure 6-3 for Statewide, South Coast, and San Joaquin Valley respectively.

Figure 6-1. Statewide Population: EMFAC2011 vs EMFAC2007

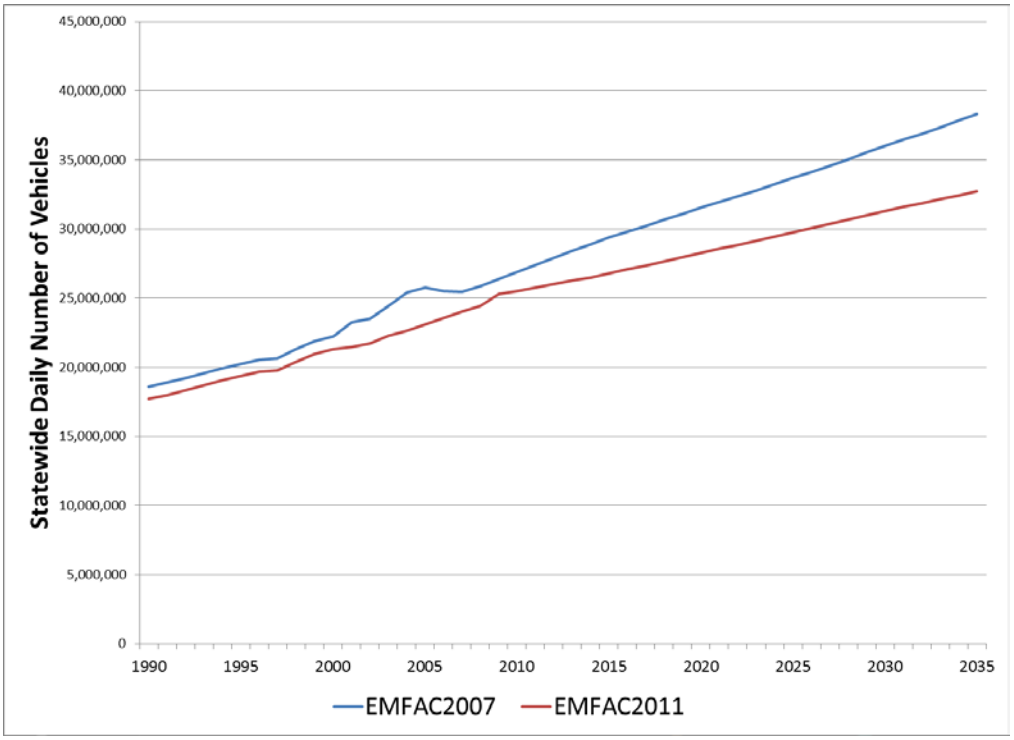

Figure 6-2. South Coast Population: EMFAC2011 vs EMFAC2007

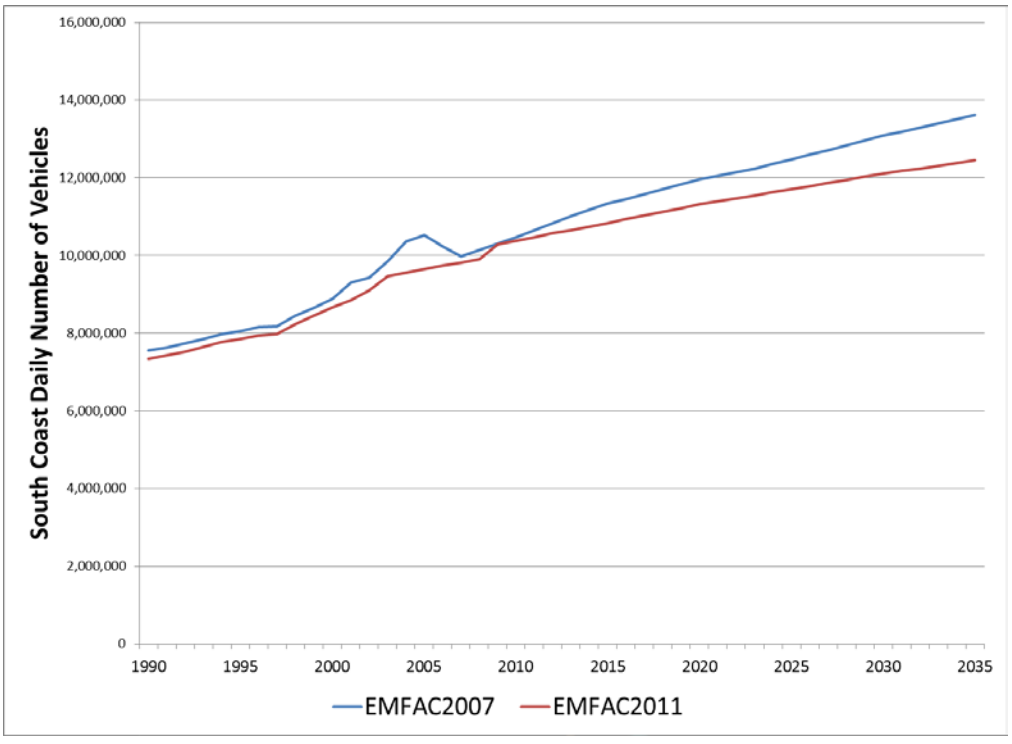

Figure 6-3 San Joaquin Valley Population: EMFAC2011 vs EMFAC2007

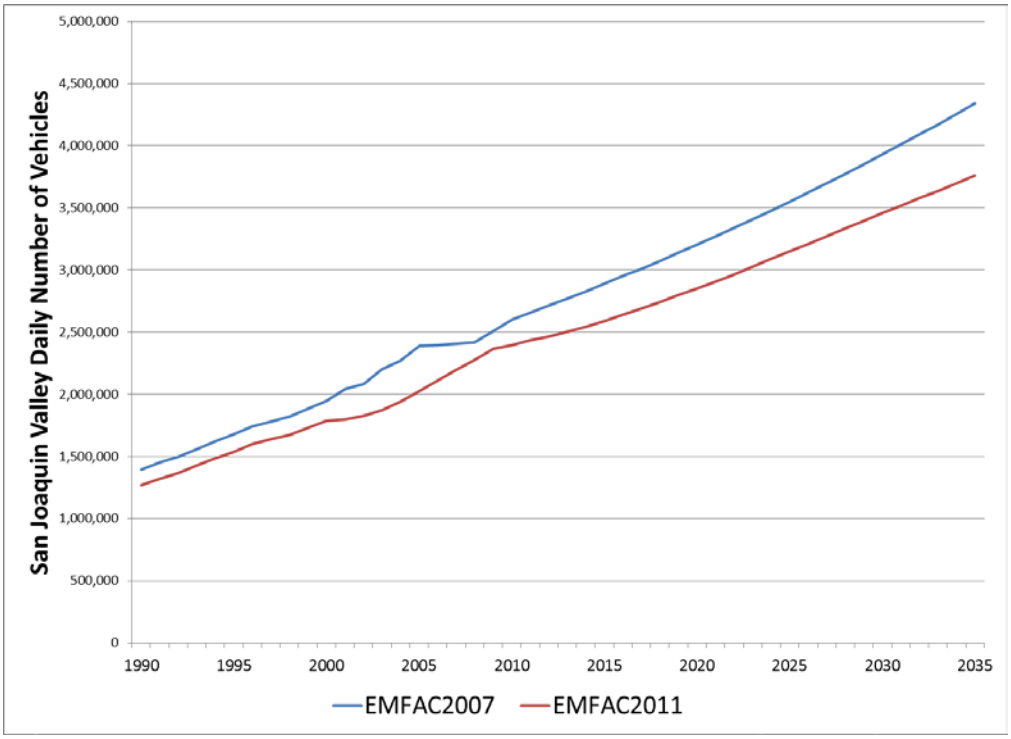

6.2 ACTIVITY

EMFAC2011 contains VMT estimates that have been updated by regional transportation planning agencies relative to what was submitted for EMFAC2007. In evaluating the data, long term forecasted VMT is lower in the new data than the submittals for EMFAC2007, which is reflective of the impact of the economic recession. However the full immediate impact of the recession is not generally reflected in the submitted activity data, and not all agencies provided updated data. As a result, on a statewide basis, VMT estimates from 1990-2008 are very similar between EMFAC2011 and EMFAC2007, with the exception of the population anomaly in EMFAC2007 discussed above. This is shown in Figure 6-4. Both South Coast and San Joaquin Valley VMT estimates are slightly lower in 2009, which results in a slightly lower VMT backcast between 1990 and 2008. The EMFAC2007 anomaly in VMT in both South Coast and the San Joaquin Valley has been corrected in EMFAC2011. Forecast VMT is slightly lower due to the recession. This is shown in Figure 6-5 and Figure 6-6.

Figure 6-4. Statewide VMT Estimates: EMFAC2011 vs. EMFAC2007

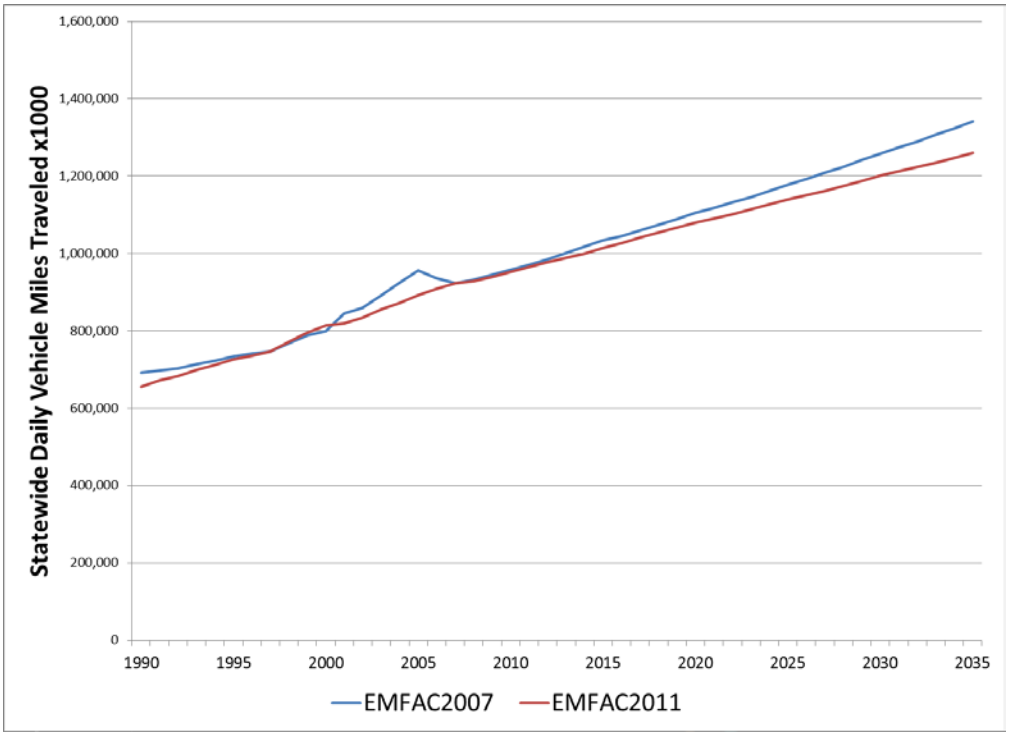

Figure 6-5. South Coast VMT Estimates: EMFAC2011 vs. EMFAC2007

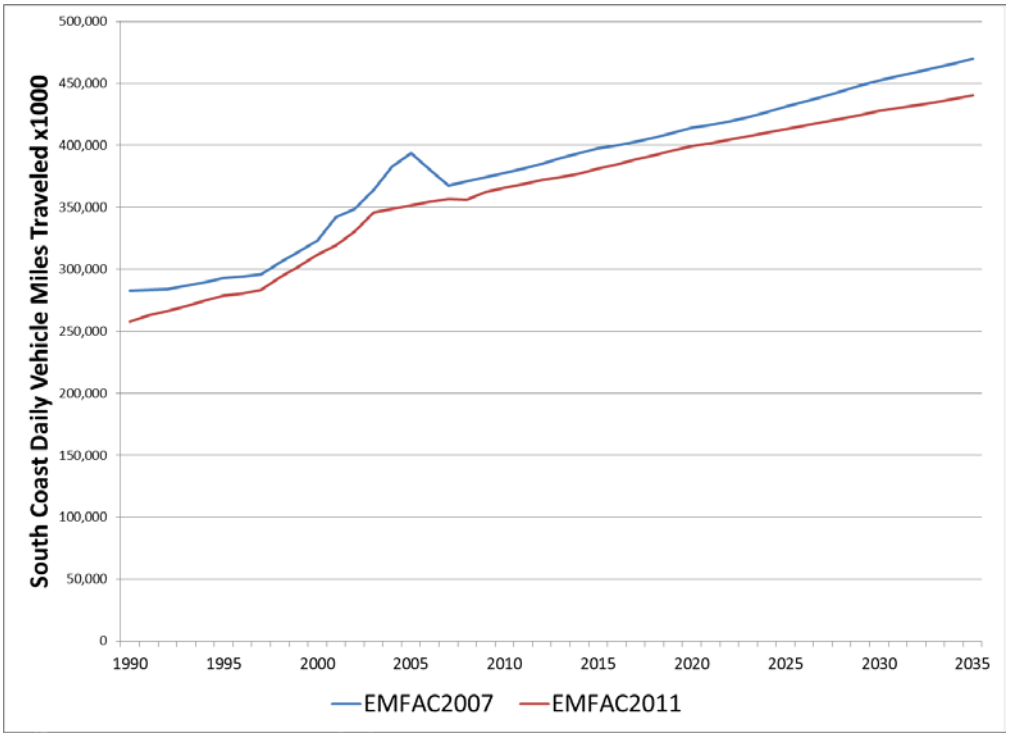

Figure 6-6. San Joaquin Valley VMT Estimates: EMFAC2011 vs. EMFAC2007

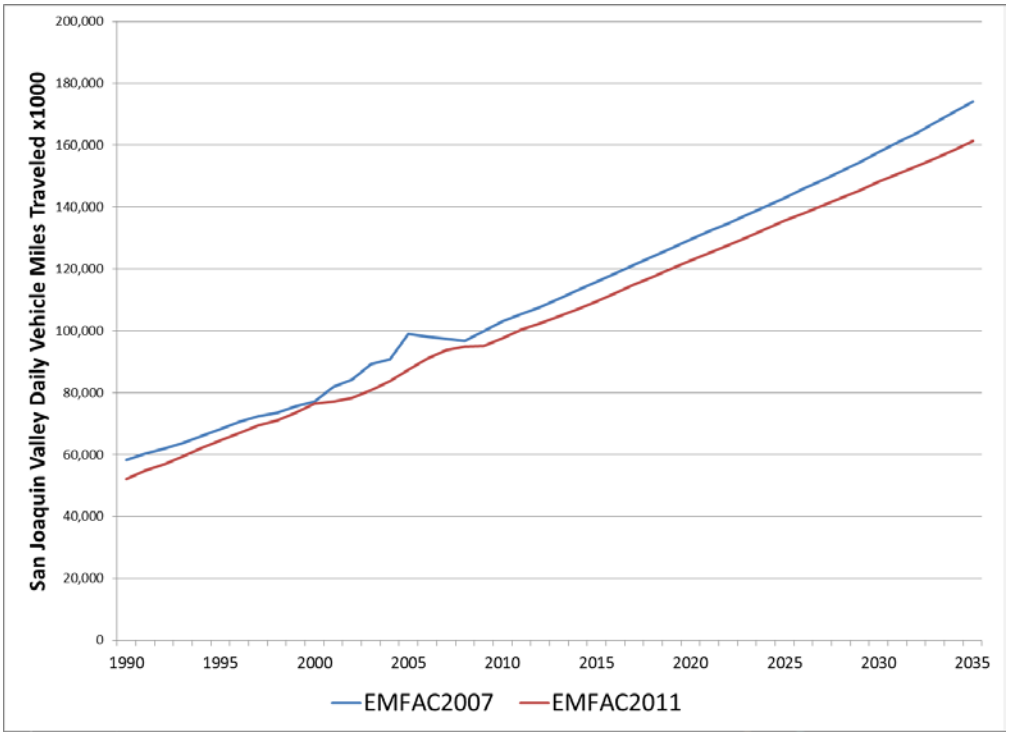

6.3 CARBON DIOXIDE EMISSIONS

Carbon dioxide emissions estimates are reduced by reductions in VMT that occur regionally as a result of updated VMT estimates, and as a result of minor improvements to CO2 emission rates described in Sections 3.3.3.1, 3.3.3.2 and 4.6.3. Estimated CO2 emissions are shown in Figure 6-7, Figure 6-8, and Figure 6-9 for Statewide, South Coast, and the San Joaquin Valley respectively.

All three charts show the significant impact that the Pavley-I Clean Car Standards and the Low Carbon Fuel Standard are projected to have in reducing fossil carbon dioxide emissions in the future. All three charts also show that the population anomaly in EMFAC2007 led to an anomaly in CO2 emissions which has been corrected in EMFAC2011.

In the San Joaquin Valley, the estimated heavy-duty truck VMT fraction relative to VMT from all vehicles decreased between EMFAC2007 and EMFAC2011. As a result, the projected light duty vehicle VMT increased between EMFAC2007 and EMFAC2011. Because light duty vehicles are more fuel efficient than heavy-duty vehicles, this led to an incremental decrease in projected CO2 emissions in the San Joaquin Valley per mile driven.

Figure 6-7. Statewide CO2 Emissions: EMFAC2011 vs. EMFAC2007

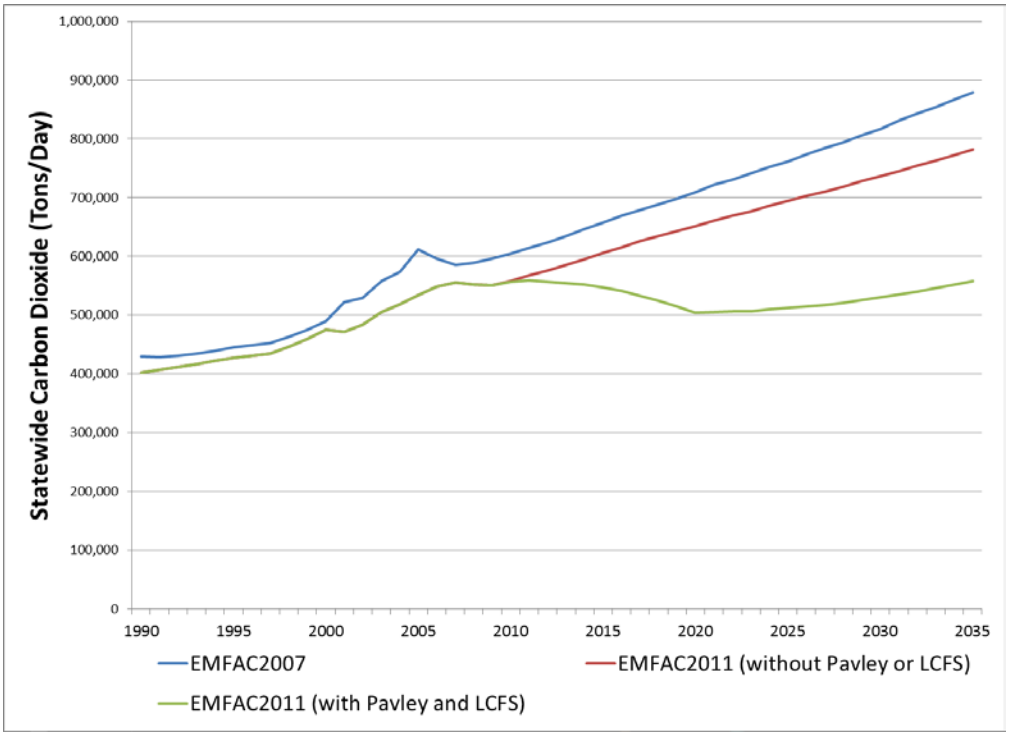

Figure 6-8. South Coast CO2 Emissions: EMFAC2011 vs EMFAC2007

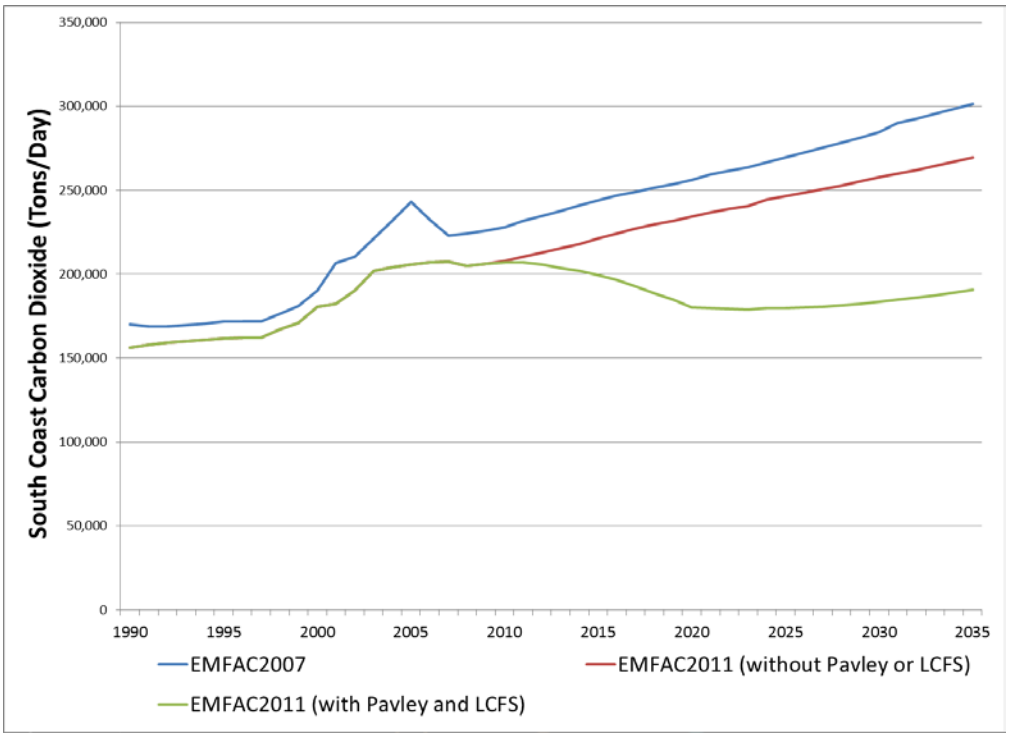

Figure 6-9. San Joaquin Valley CO2 Emissions: EMFAC2011 vs. EMFAC2007

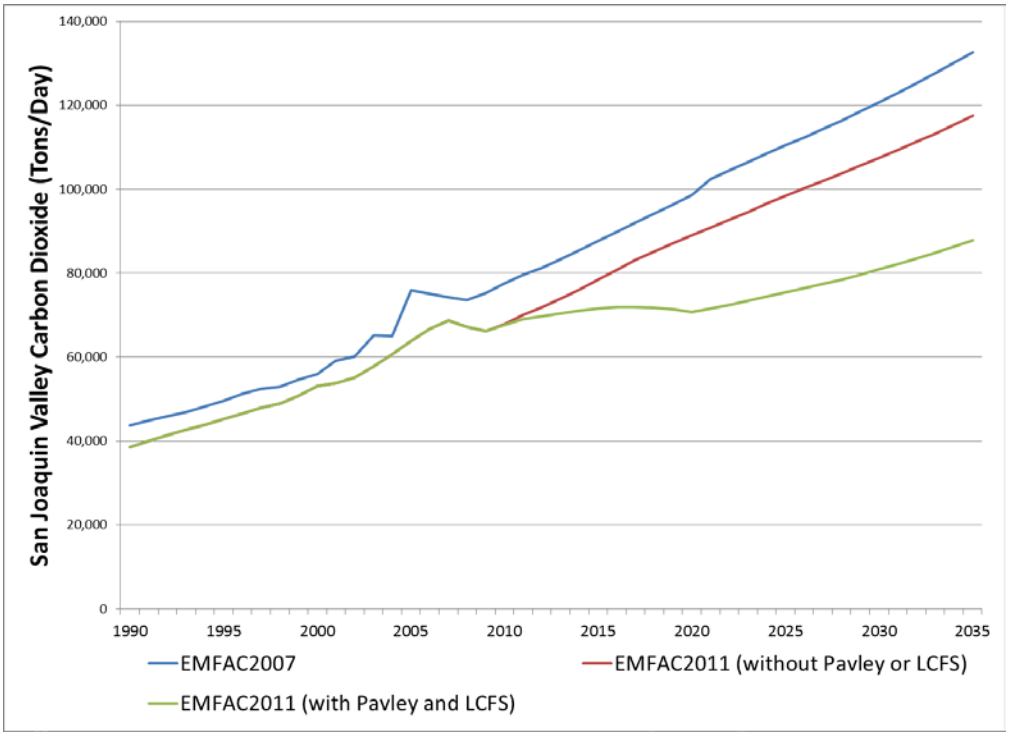

6.4 NOX AND ROG EMISSIONS

NOx and ROG emissions show the continuing downward trend caused by decades of ARB rules designed to reduce emissions from cars and trucks. Statewide results are shown in Figure 6-10 and Figure 6-11 below. Several trends are apparent. The NOx anomaly caused by heavy-duty truck population estimates in EMFAC2007 is corrected for EMFAC2011. NOx emissions are driven by trucks and are lower due in part to the impact of the recession on heavy-duty truck emissions, the impact of ARB rules designed to reduce NOx emissions from diesel trucks and buses, and the impact of reduced out-year forecasts for truck VMT. ROG emissions are driven by gasoline vehicles, and are marginally lower due to improvements in emission rates, updates to vehicle survival algorithms that have the impact of slightly increasing vehicle turnover, and updated temperature and relative humidity estimates. These changes are discussed in Sections 3.3.3.3, 3.3.3.4, 3.3.4.2, and 3.3.4.4.

Figure 6-10. Statewide NOx Emissions: EMFAC2011 vs. EMFAC2007

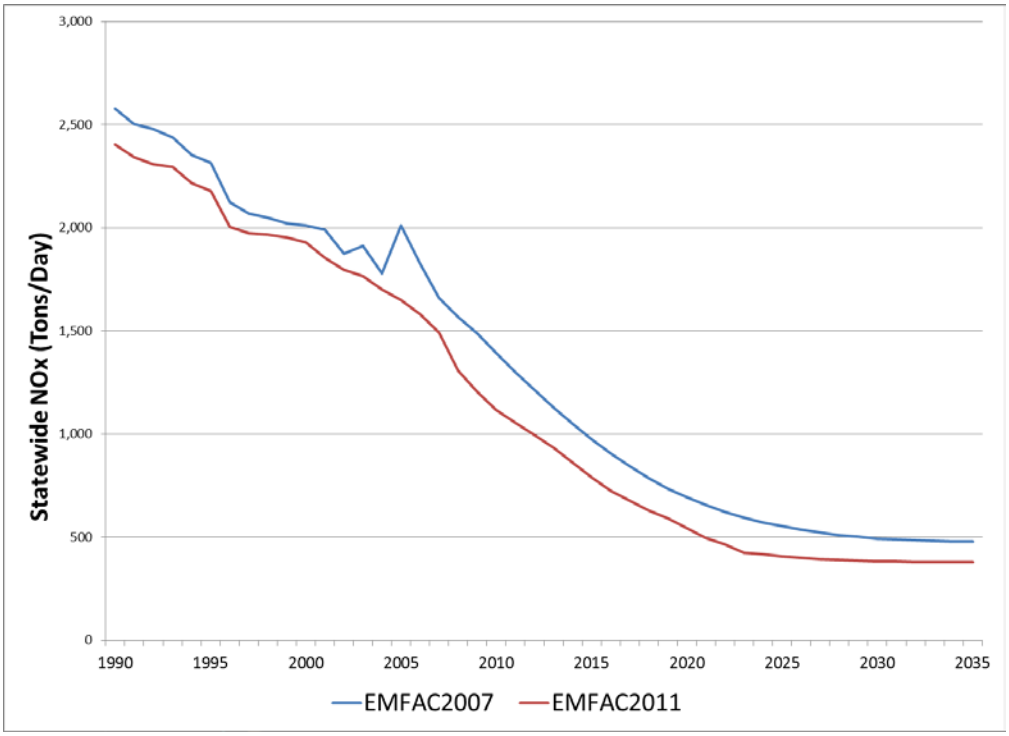

Figure 6-11. Statewide ROG Emissions: EMFAC2011 vs EMFAC2007

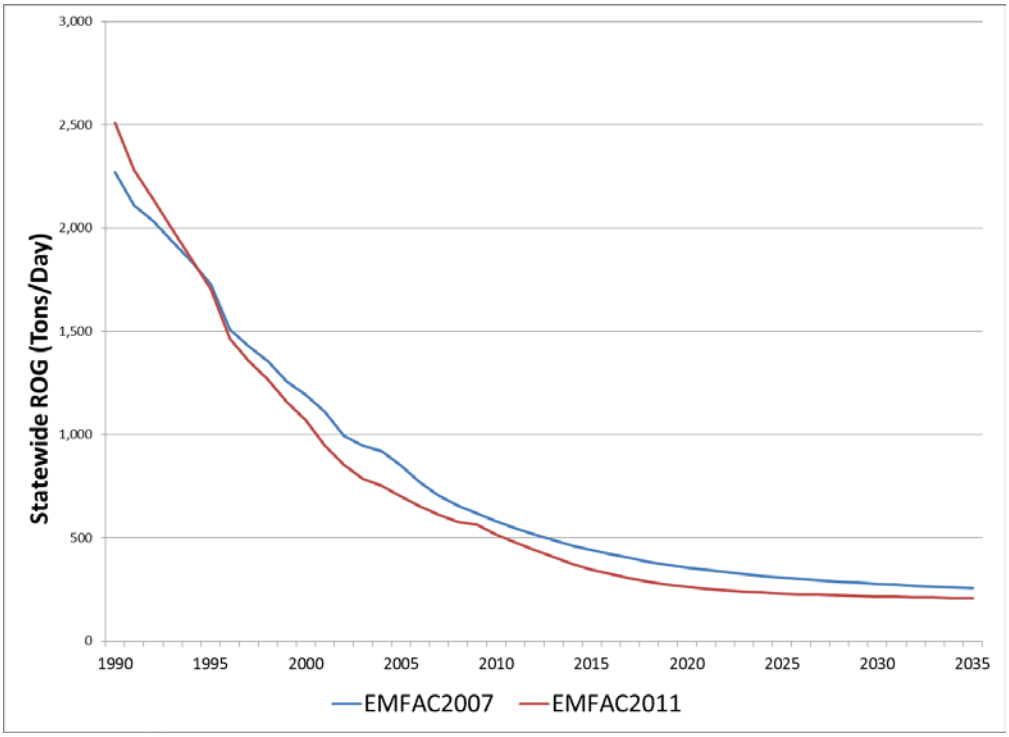

Results for the South Coast Air Basin are shown in Figure 6-12 and Figure 6-13. Results are very similar in the South Coast as on a Statewide basis, and differences between EMFAC2011 and EMFAC2007 are caused by the same factors discussed above.

Results for the San Joaquin Valley are shown in Figure 6-14 for NOx. In the figure NOx emissions are flat between 1990 and 2005, which is different than the trend seen Statewide or in the South Coast. These trends differ because the San Joaquin Valley is less densely populated and so historically cars, which used to have higher NOx emission rates but are today well controlled, played less of a role in overall San Joaquin Valley emissions than they did in South Coast or Statewide. NOx emissions are reduced in the San Joaquin Valley due to the penetration of newer trucks with cleaner technologies that is caused both by natural turnover and the Statewide Truck and Bus rule. Figure 6-15 shows ROG emissions in the San Joaquin Valley. ROG emissions are dominated by cars and so emissions in the San Joaquin Valley are much lower in total than in the South Coast. The reduction in emissions between EMFAC2011 and EMFAC2007 is caused by the same factors affecting differences in statewide ROG emissions.

Figure 6-12. South Coast NOx Emissions: EMFAC2011 vs EMFAC2007

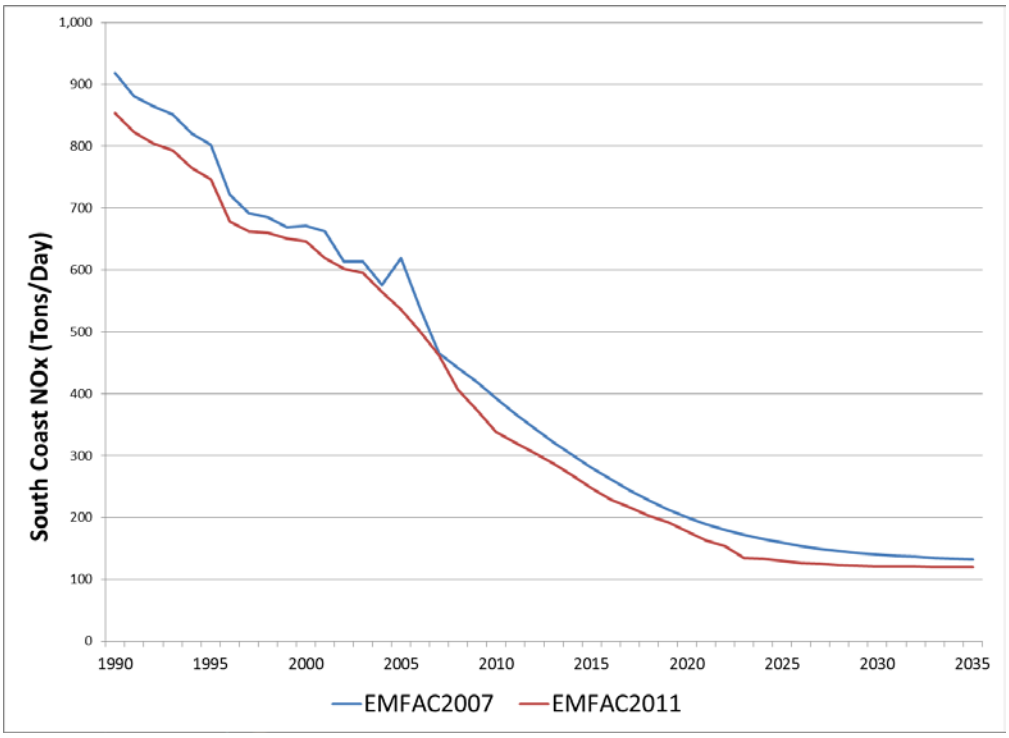

Figure 6-13. South Coast ROG Emissions: EMFAC2011 vs. EMFAC2007

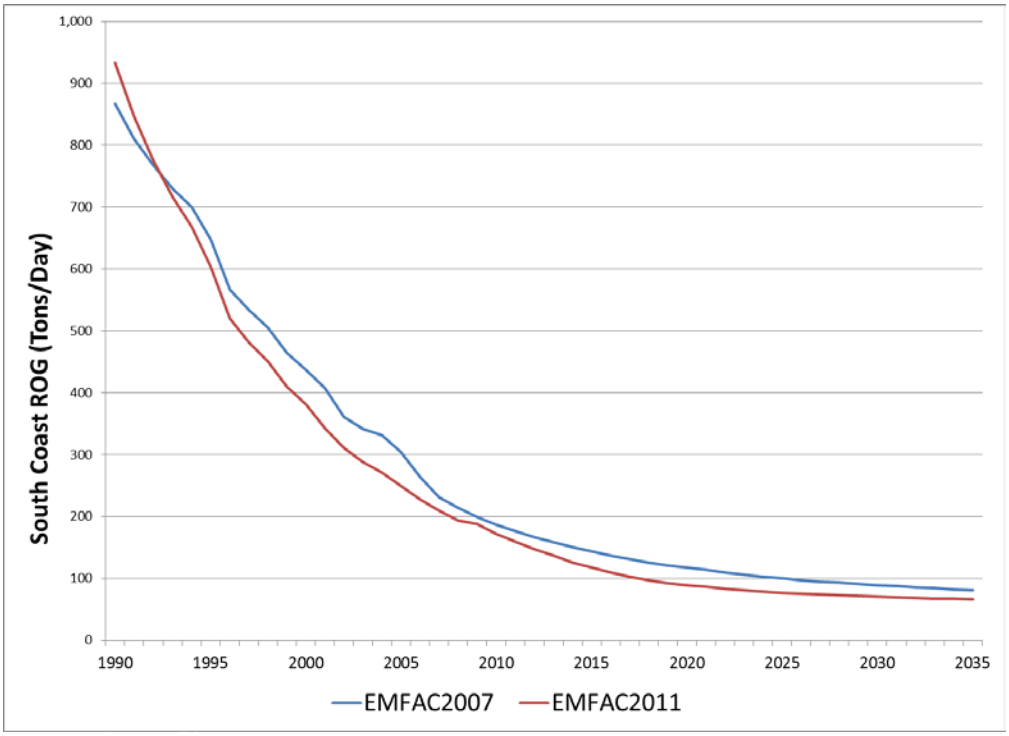

Figure 6-14. San Joaquin Valley NOx Emissions: EMFAC2011 vs. EMFAC2007

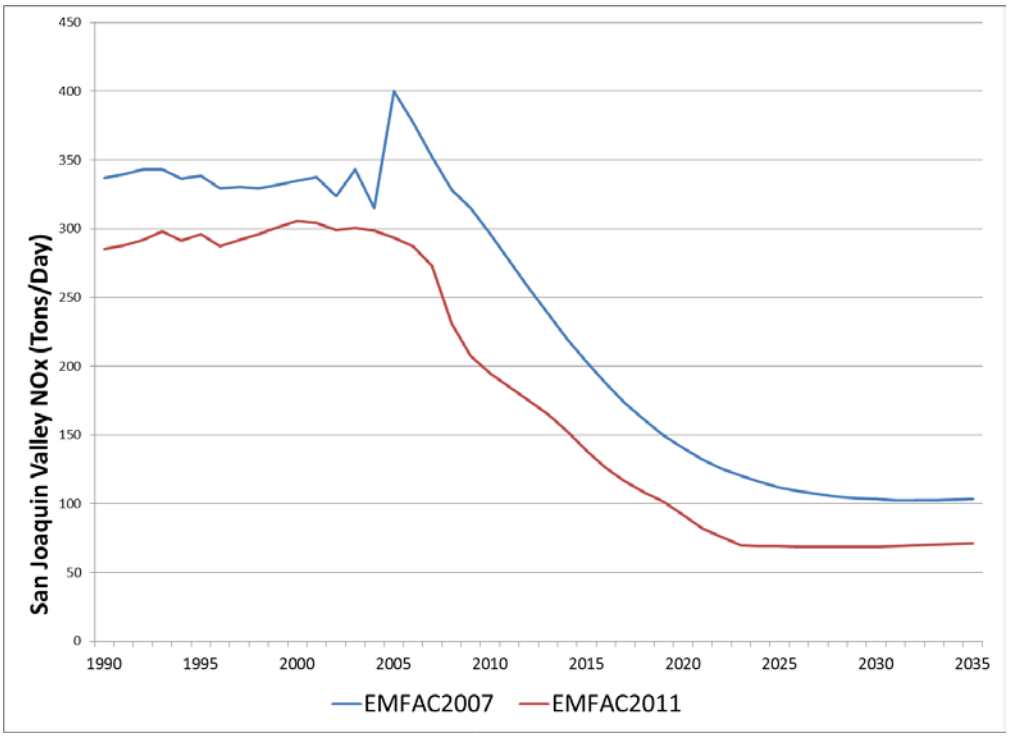

Figure 6-15. San Joaquin Valley ROG Emissions: EMFAC2011 vs. EMFAC2007

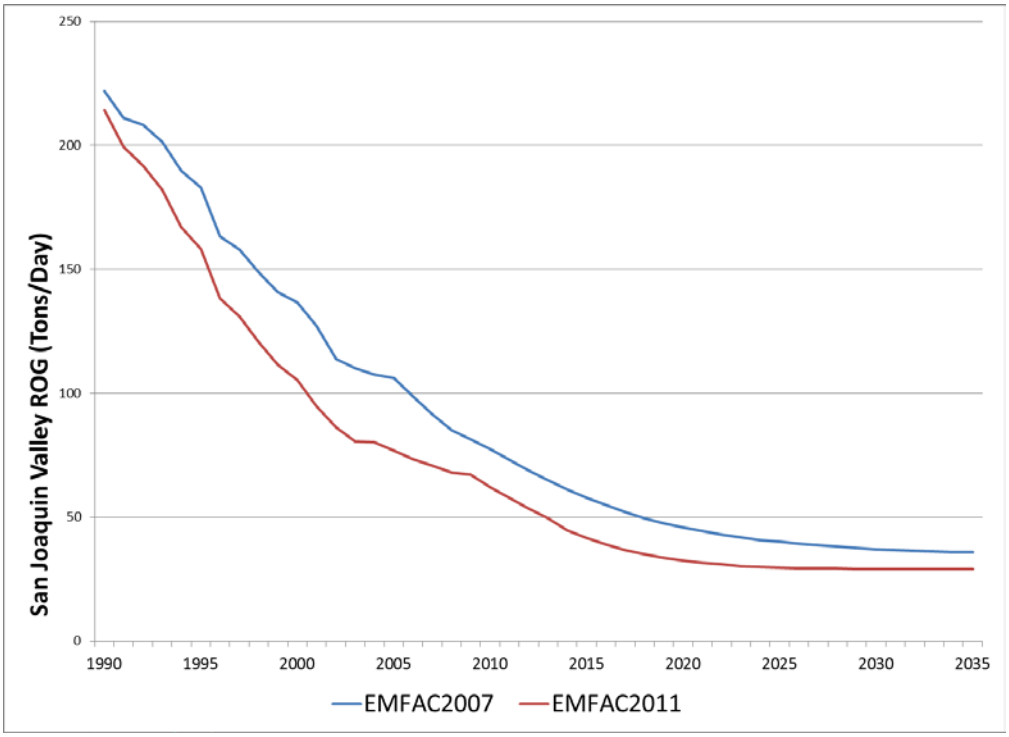

6.5 PM2.5 EMISSIONS

Statewide PM2.5 emissions are shown in Figure 6-16. Backcast emissions are higher because of new test data suggesting exhaust PM2.5 emission factors were higher for older vehicles historically than thought in EMFAC2007, which is discussed in Section 3.3.3.6. The anomaly in DMV population data led to an artificial increase in PM2.5 emissions in 2005 in EMFAC2007, which has been corrected in EMFAC2011. Forecast PM2.5 emissions are lower in EMFAC2011 than in EMFAC2007 because of the Statewide Truck and Bus Rule that drastically reduces diesel PM2.5 emissions from diesel trucks,and updates to future gasoline vehicle PM emission rates. Those decreases are partially offset by increases to brake wear PM emission rates.

Trends in South Coast, shown in Figure 6-17 are similar to those seen Statewide and caused by the same factors. Forecasted trends in the San Joaquin Valley, shown in Figure 6-18, are similar, however backcast emissions are lower in EMFAC2011 than in EMFAC2007 because EMFAC2011 assumes less total truck VMT than assumed in EMFAC2007, which has the effect of reducing PM2.5 emissions historically in the region.

Figure 6-16. Statewide PM2.5 Emissions: EMFAC2011 vs. EMFAC2007

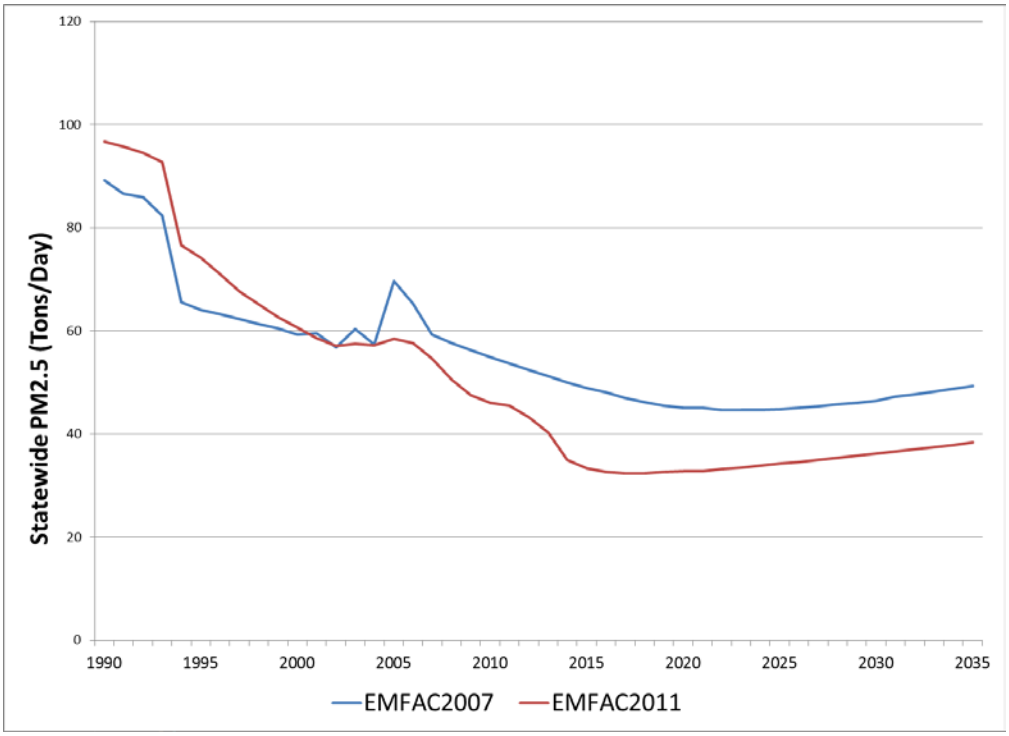

Figure 6-17. South Coast PM2.5 Emissions: EMFAC2011 vs. EMFAC2007

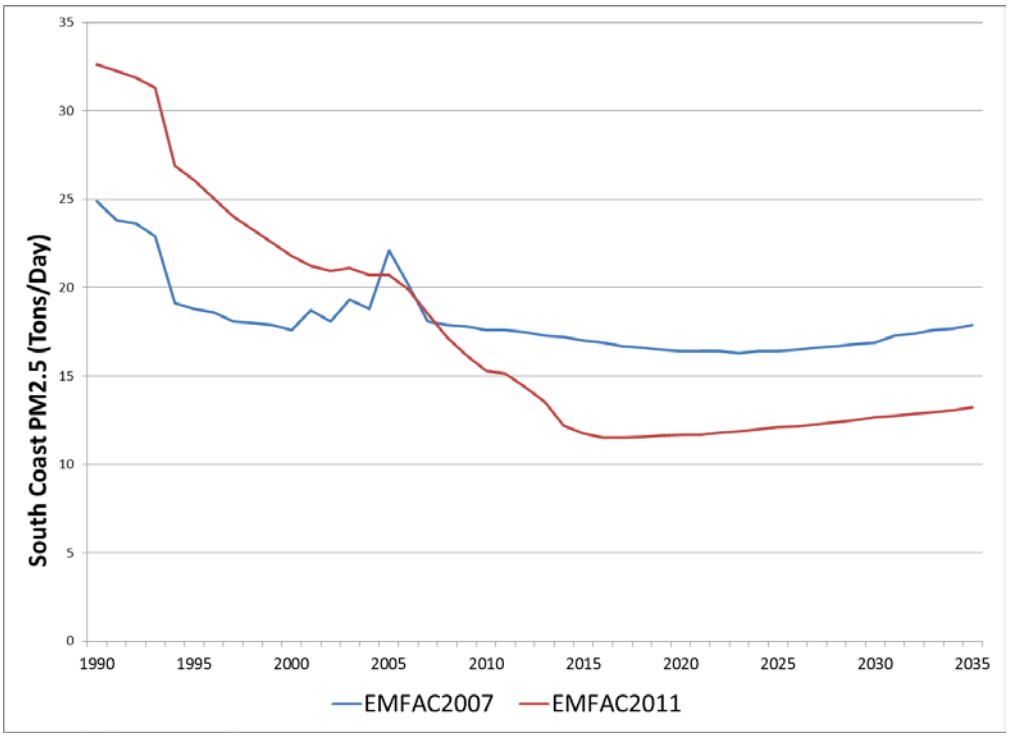

Figure 6-18. San Joaquin Valley PM2.5 Emissions: EMFAC2011 vs. EMFAC2007.

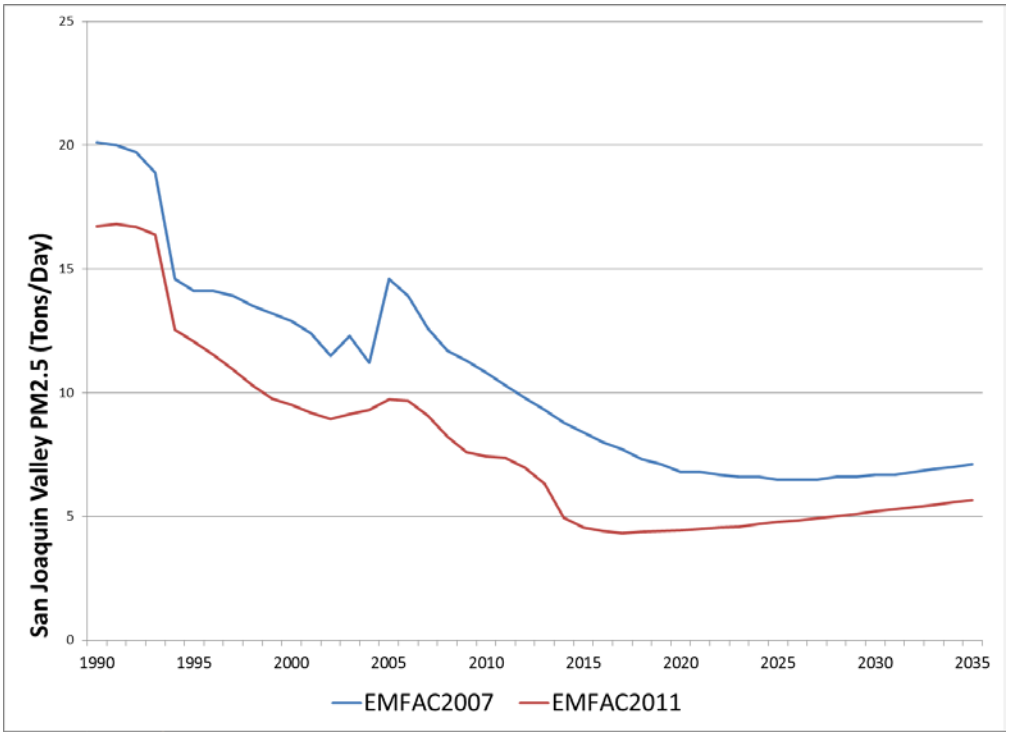

For detailed emissions impacts of each incremental change on selected air basins and calendar years of the State, see Section 12.

7 APPENDIX: UPDATING VEHICLE MILES TRAVELED AND SPEED DISTRIBUTIONS IN EMFAC2011

This section documents the final revisions to the motor vehicle activity data used EMFAC 2011. Vehicle miles traveled (VMT) and speed distributions were submitted by regional transportation planning agencies (RTPAs) in calendar year 2010 and early 2011 for five regions: South Coast region, the San Francisco Bay Area region, San Diego County, San Joaquin Valley region and Sacramento region. In addition to discussing the most recent activity data submitted by the TPAs, the memo recaps key information and issues from staff's review of TPA activity data submitted in 2010 and early 2011. Emissions impacts of the updated data are available in Sections 12.9 and 12.13.

ARB maintains EMFAC and periodically updates the model with new data. RTPAs are generally responsible for estimating vehicle miles and speed of travel in their respective regions. ARB relies on RTPAs, as well as the Department of Motor Vehicles (DMV), and the Bureau of Automotive Repair (BAR), for vehicle activity data in EMFAC. ARB solicited the data most recently adopted or proposed for adoption, prior to developing EMFAC 2011 model updates. In the absence of recent RTPA data, the model contains default speed distributions and estimated VMT as a function of vehicle population (from DMV) and mileage accrual rates (from BAR). Typically, for heavy-duty vehicles default speed distributions are based on instrumented vehicle studies. In some areas of the state, the VMT and speed distributions contained in EMFAC 2011 were carried forward from EMFAC 2007.

The years of VMT data provided by local RTPAs are summarized in Table 7-1. ARB processed base year vehicle population data from the California Department of Motor Vehicles (DMV) for year 2009. The model matched for 2009 population and VMT by allowing the accrual rate to float. The base years provided by RTPAs are also listed in Table 7-1.

Table 7-1. VMT and Speed Updated by Area

The RTPAs submitted VMT by speed bin by period of the day for selected calendar years. There are 14 speed bins from 5 to 70 miles per hour in 5 miles increment. Each RTPA may have different definitions of period ranging from daily, where the same speed distribution applies throughout the day, to hourly where distributions vary. However, most RTPAs submitted VMT by speed bin for morning peak (AMPK), afternoon peak (PMPK) and one or two off-peak periods. Table 7-2 summarizes the period definitions by area and calendar years provided by RTPAs. EMFAC coding requires six time periods: AMPK, Noon, Mid-day, PMPK and 2 Night periods, and staff matched the time periods provided by RTPAs to one of the six time periods in EMFAC as described in the regional submittal tables. For each region and time period, ARB staff developed the speed distribution using the VMT in the speed bins and the total VMT from all speed bins. ARB did not interpolate or extrapolate speed distributions, but applied the speed distribution for the next future year to interim years. The Southern California Association of Governments (SCAG) submitted separate VMTs for light-duty vehicles (LDV) and heavy-duty trucks (HDT). For all other regions, ARB default HDT speeds were used. In the absence of recent RTPA data, submittals for EMFAC2007 development were carried forward.

Staff evaluated speed data submitted by each RTPA, looking to make sure data were consistent and that generally in most cases peak speeds in urban areas declined with time, that peak speeds in growing rural areas were declining with time, that nighttime speeds were flat, and that peak speeds in rural non-growing areas were relatively high and flat over time. Speed data appeared reasonable in all cases and so were input to the model. Table 7-2 summarizes the period definitions by area and shows some differences from ARB's period definitions.

Table 7-2. Time Period Definitions for EMFAC 2011

SCAG Region

The Southern California Association of Governments (SCAG) has submitted the latest motor vehicle activity for light-duty vehicles (LDV) and heavy-duty trucks (HDT). The submittal includes both vehicle miles traveled (VMT) and speed distributions for the CYs 2003, 2008, 2009, 2010, 2012, 2014, 2018, 2020, 2023, 2030, 2035. ARB staff reviewed the data for anomalies and compared the VMT and speed trends to SCAG 2009 submittals, EMFAC 2007, MVSTAFF and human population. Table 7-3 describes the VMT and speed distribution data submitted by SCAG. Table 7-4 and Table 7-5 summarize the latest SCAG submittal for LDV+MDV and HDT respectively.

Table 7-3. SCAG Submittal

Traffic Model Citation:	The adopted 2008 RTP					
Date of Submittal:	October 12, 2010					
Years Provided:	2003, 2008, 2009, 2010, 2012, 2014, 2018, 2020, 2023, 2030, 2035.					
VMT Vehicle Classes:	SCAG provided LDV VMT totals for light- and medium-duty vehicles plus motorcycles combined and HDT VMT totals for heavy-duty trucks combined. (No data for buses or motor homes.) ARB will match SCAG total VMT for all vehicle classes except buses and motorhomes by sub-area and distribute VMT by vehicle class based on updated DMV/Smog Check data. The HD diesel truck, other buses (diesel) and school buses (diesel) VMT by vehicle class are from ARB's EMFAC2011-HD truck model and updated DMV and mileage accrual rate data. ARB will add VMT for remaining classes bus and motor homes using DMV data.					
Speed Vehicle Classes:	Speeds were provided for light- and medium-duty vehicles combined and separate speeds for heavy-duty trucks derived from SCAG's truck model.					
Speed Distributions by Periods:	SCAG provided speed distributions for AM Peak (period 2), PM Peak (period 5), Mid-day (periods 3 and 4), and Night (periods 1 and 6)

Staff reviewed VMT and speed data submitted by SCAG for the South Coast region, comparing growth rates to human population growth trends, and comparing submitted data to the following data sources:

- SCAG 2010 submittal (October 2010).
- EMFAC 2007, Version 2.6 (Nov 06).
- SCAG 2009 submittal (April 2009).
- California Motor Vehicle Stock, Travel and Fuel Forecast, May 2008 (MVSTAFF)
- Human Population, State of California, Department of Finance, Population Projections for California and Its Counties 2000-2050, Sacramento, California, July 2007.

Figure 7-1 compares the SCAG region VMT from the different data sources. The October 2010 submittal follows a similar trend to SCAG 2009 and EMFAC2007. Figure 7-2 illustrates the growth rate of VMT and human population from the different sources. The split between the light-duty and heavy-duty vehicles and the growth rate of these vehicle classes are shown in Figure 7-3. Both SCAG 2010 VMT and human population grow at a similar rate of 1.29% and 1.25% per annum respectively. SCAG's 2010 LDV VMT growth rate at 1.22% and HDT growth rate at 2.27% per annum are similar to the EMFAC2007 LDV VMT growth rate of 1.01% and HDT growth rate of 2.43%. While VMT and human population growth rates are much lower in the SCAG data than MVSTAFF, staff places little weight on MVSTAFF estimates in this area. The SCAG model does not estimate VMT for buses or motor homes. ARB provides the estimates for these vehicle classes based on updated DMV data and mileage accrual rates. In EMFAC2011, other buses (diesel) and school buses (diesel) are based on the ARB's EMFAC2011-HD truck model. Long term heavy duty vehicle VMT forecasts developed by SCAG are similar to those developed for the Statewide Truck and Bus Rule; however short term estimates do not appear to reflect the downturn in the economic cycle.

Figure 7-1. VMT in the SCAG Region

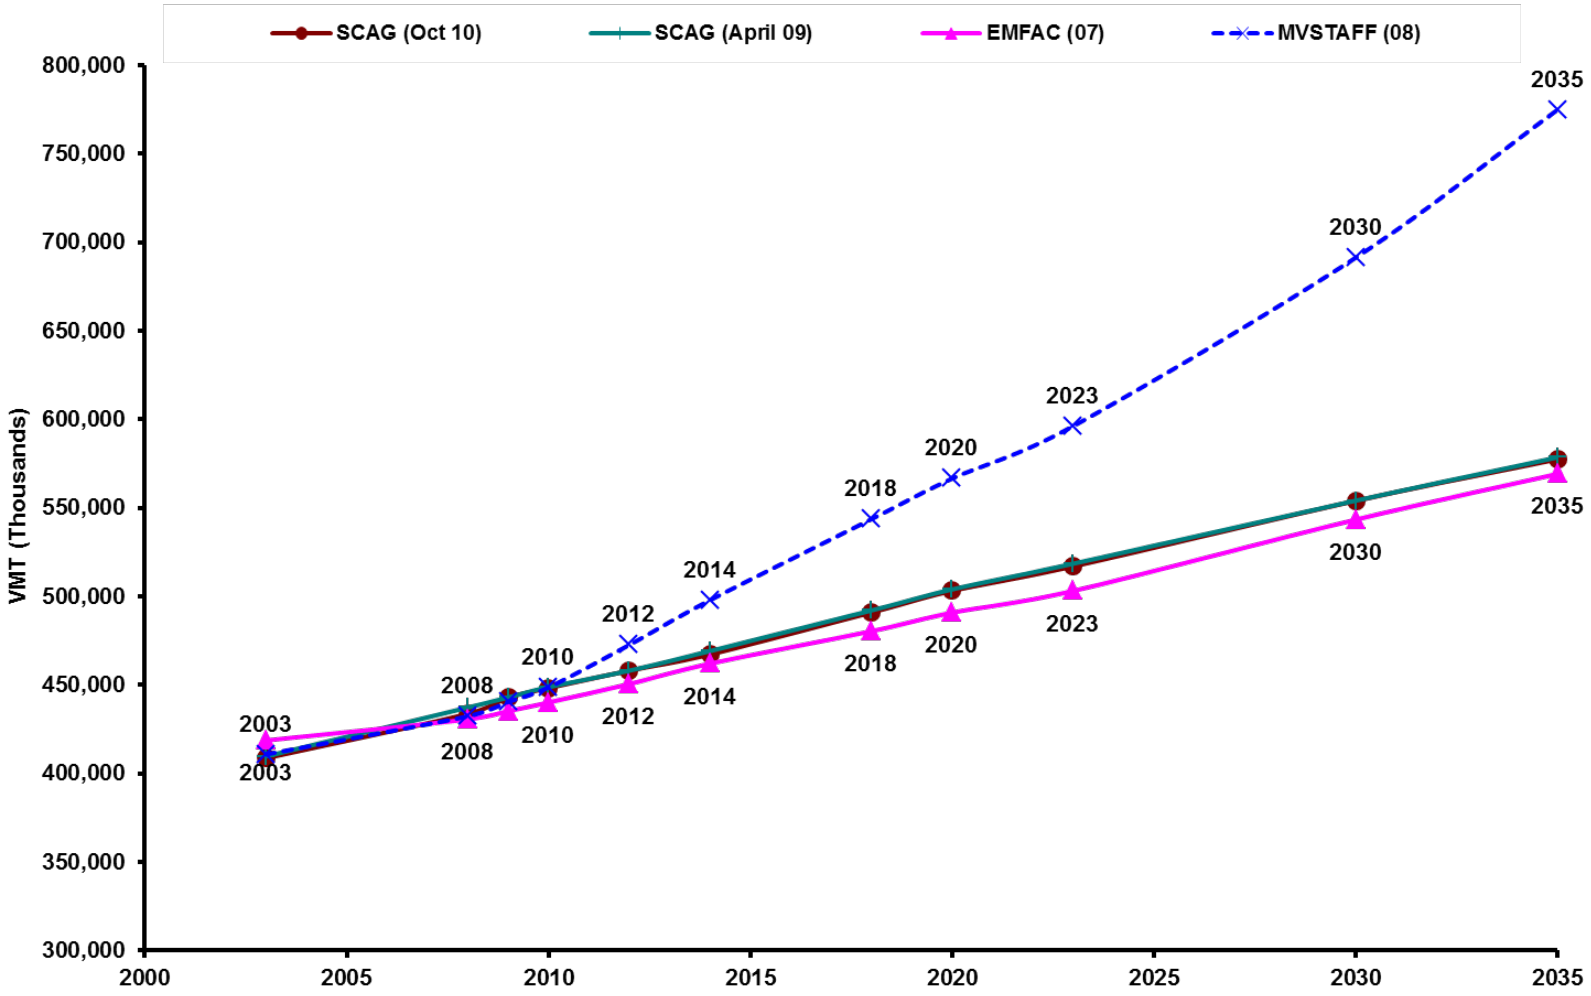

Figure 7-2. VMT and Human Population Growth in the SCAG Region

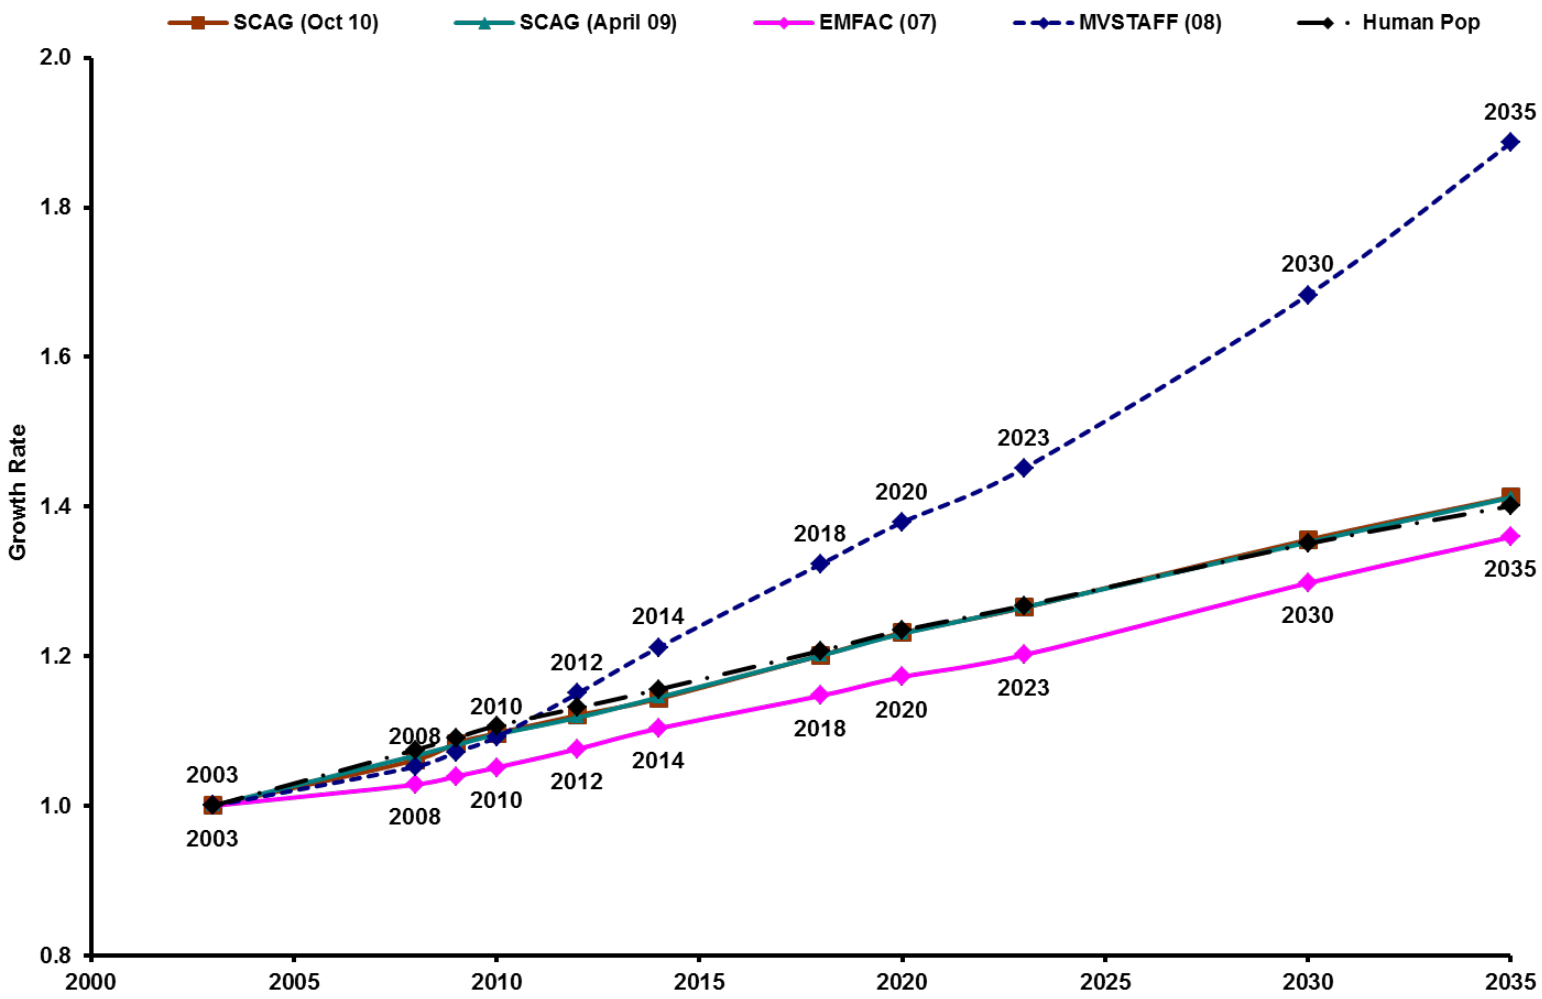

Figure 7-3. Light-Duty vs Heavy-Duty VMT Growth Rates in the SCAG Region

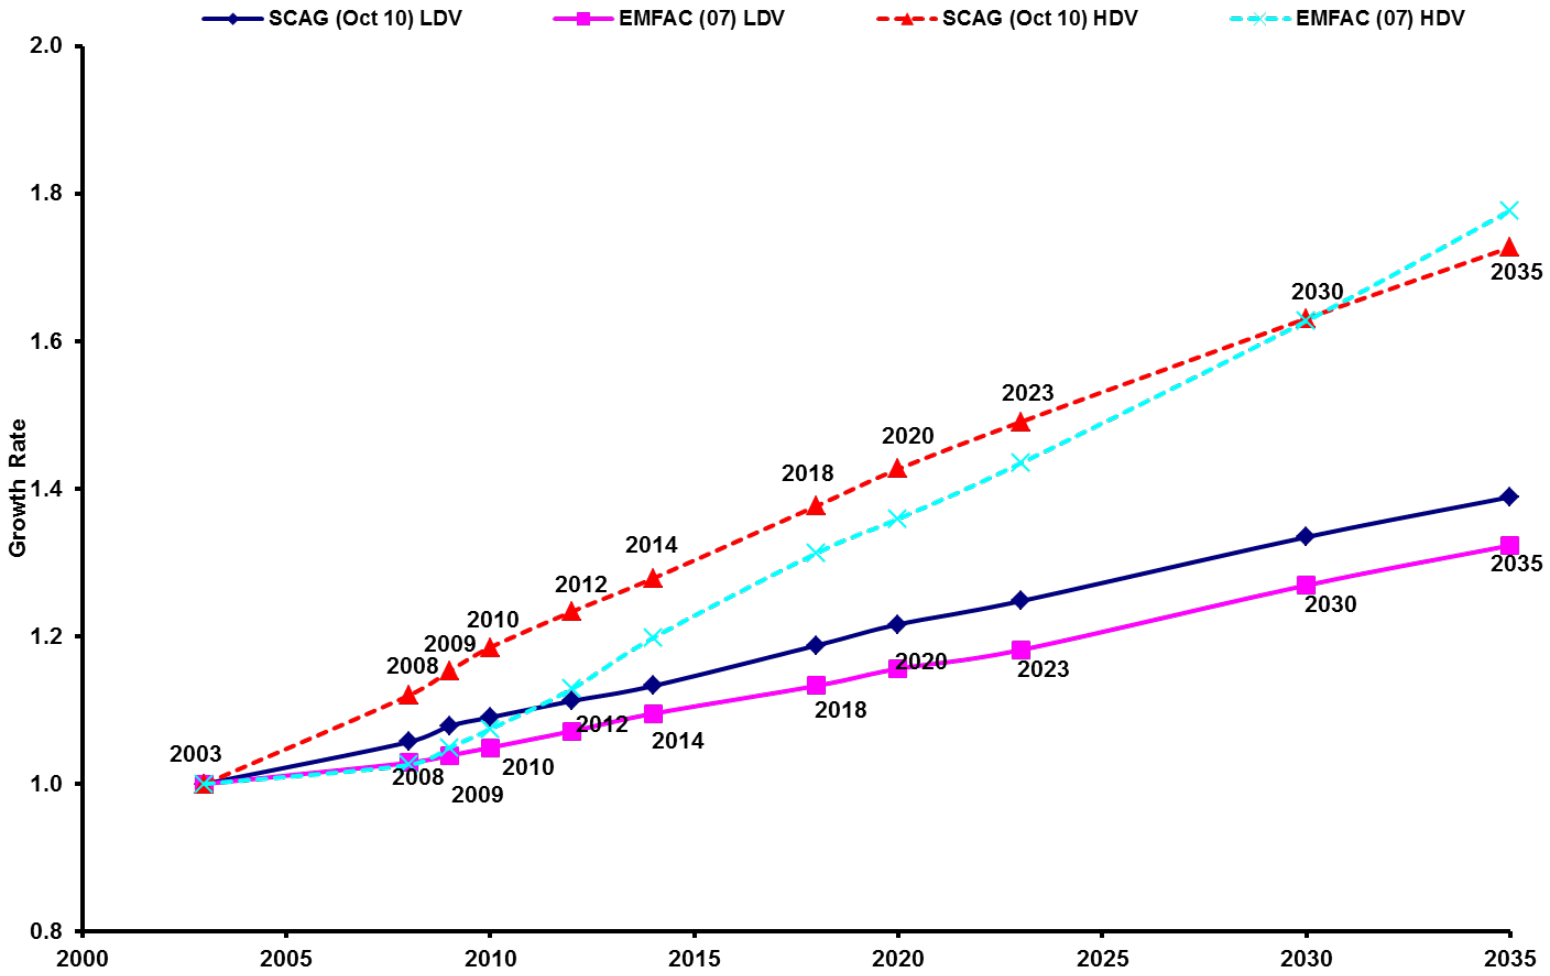

SAN DIEGO REGION

The San Diego Association of Governments (SANDAG) submitted vehicle activity data in October 2011. Table 7-6 provides details on the SANDAG submittal.

Table 7-6. SANDAG Data Submittal Summary

Traffic Model Citation:	**The adopted 2007 RTP.**					
Date of Submittal:	October 2010					
Years Provided:	2008, 2010, 2020, and 2030					
VMT Vehicle Classes:	VMT totals represent all vehicle classes. SANDAG provided VMT by vehicle class and by period; however, EMFAC 2011 reflects VMT distribution over the vehicle classes based on DMV data and ARB EMFAC2011-HD truck model.					
Speed Vehicle Classes:	Speed distributions were provided by vehicle class; however, only distribution for light duty vehicles was used because SANDAG has no heavy duty truck model.					
Speed Distributions by Periods:	Speed distributions were provided hourly and converted to AM Peak (period 2), PM Peak (period 5), Mid-day (periods 3 and 4), and Night (periods 1 and 6).					
Period Definitions	**Period 1**	**Period 2**	**Period 3**	**Period 4**	**Period 5**	**Period 6**
	Hours 0-5	6-8	9-11	12-14	15-17	18-23

Similar to the South Coast data review, ARB staff reviewed the activity data received from SANDAG and compared VMT trends for CYs 2008 through 2030 to other data sources including:

- SANDAG Activity Data Submitted to ARB in October 2010
- EMFAC 2007, Version 2.3 (Nov 2006)
- SANDAG Activity Data Submitted to ARB in 2008
- California Motor Vehicle Stock, Travel and Fuel Forecast, May 2008 (MVSTAFF)
- Human Population, State of California, Department of Finance, Population Projections for California and Its Counties 2000-2050, Sacramento, California, July 2007.

SANDAG provided VMT and speeds by vehicle class; however, because of ARB's recent efforts to update vehicle population and redistribute statewide VMT for heavy-duty trucks, ARB preferred to use SANDAG total VMT for the fleet as a whole but with ARB VMT distributions by vehicle class. The heavy heavy-duty truck VMT was updated to agree with ARB's EMFAC2011-HD truck model redistribution. DMV data was used to distribute the light-duty vehicles. Similarly, SANDAG agreed to use ARB default speed distributions for heavy-duty vehicles. EMFAC 2011 reflects SANDAG speed distributions for light-duty cars and trucks plus motorcycles. Figure 7-4 compares the SANDAG region VMT from different data sources. Figure 7-5 illustrates the growth rate of VMT and human population from the different sources. The October 2010 submittal follows a similar trend to SANDAG 2008 and EMFAC2007. However, it is about 7-10% lower than their previous submittal. Thought the total EMFAC2007 VMT is higher than the SANDAG 2010 submittal VMT, the annual growth rate is lower.

Figure 7-4. VMT in the San Diego Region

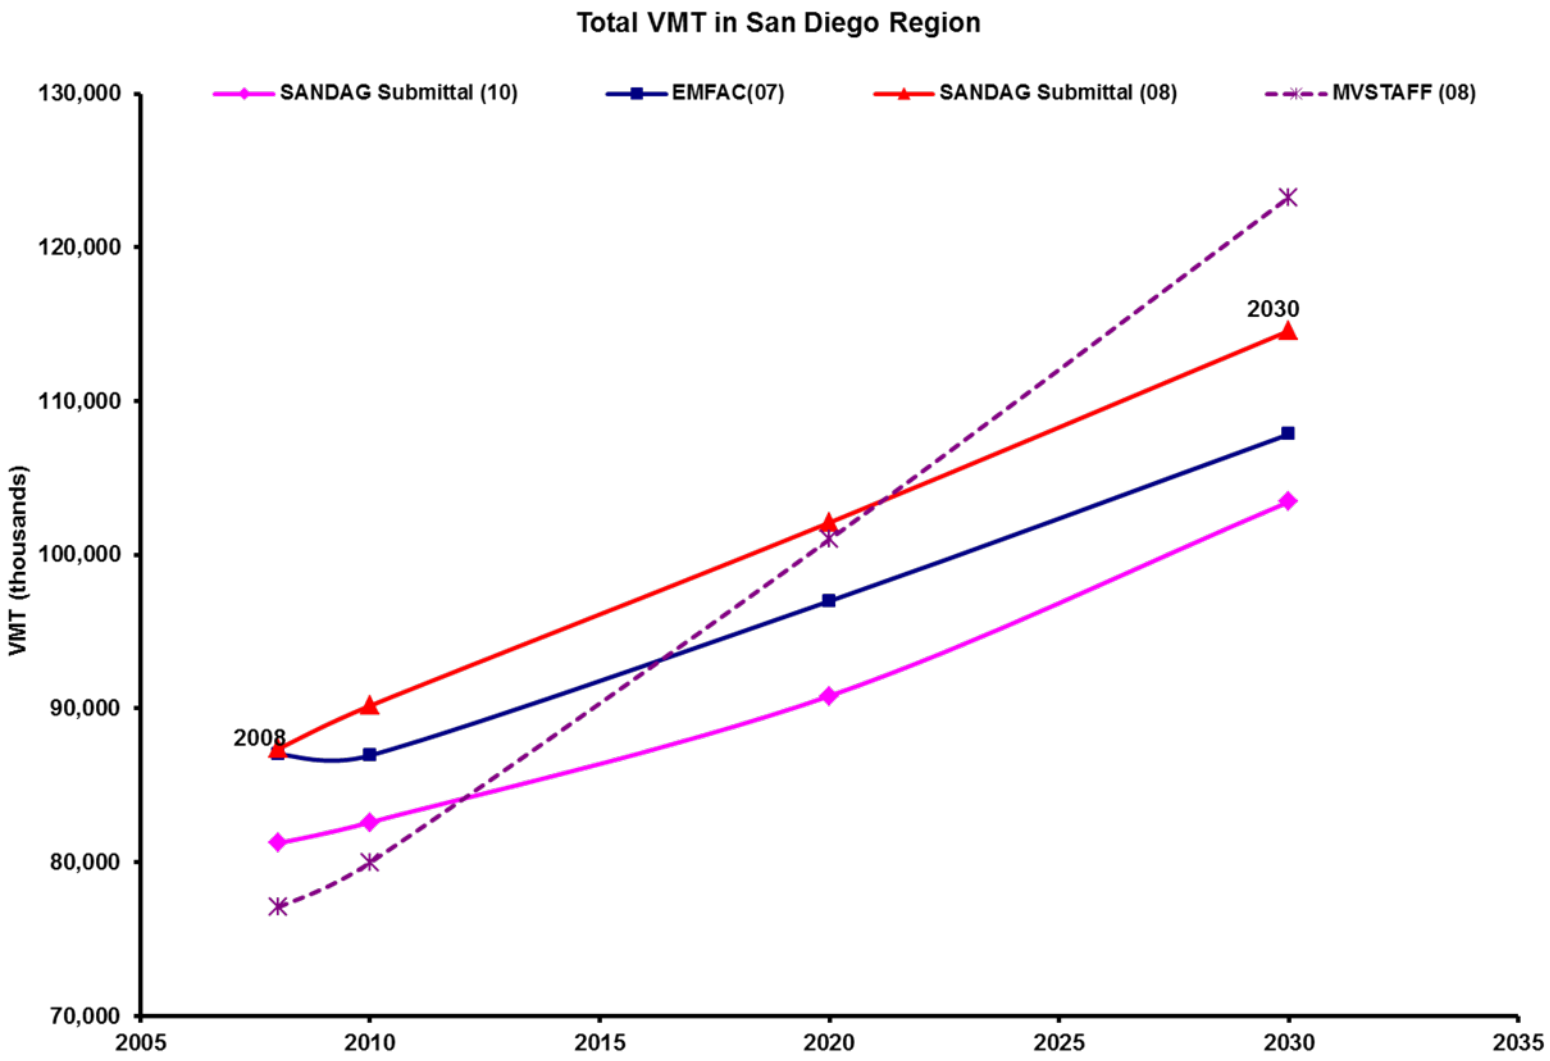

Figure 7-5. VMT and Human Population Growth in the San Diego Region

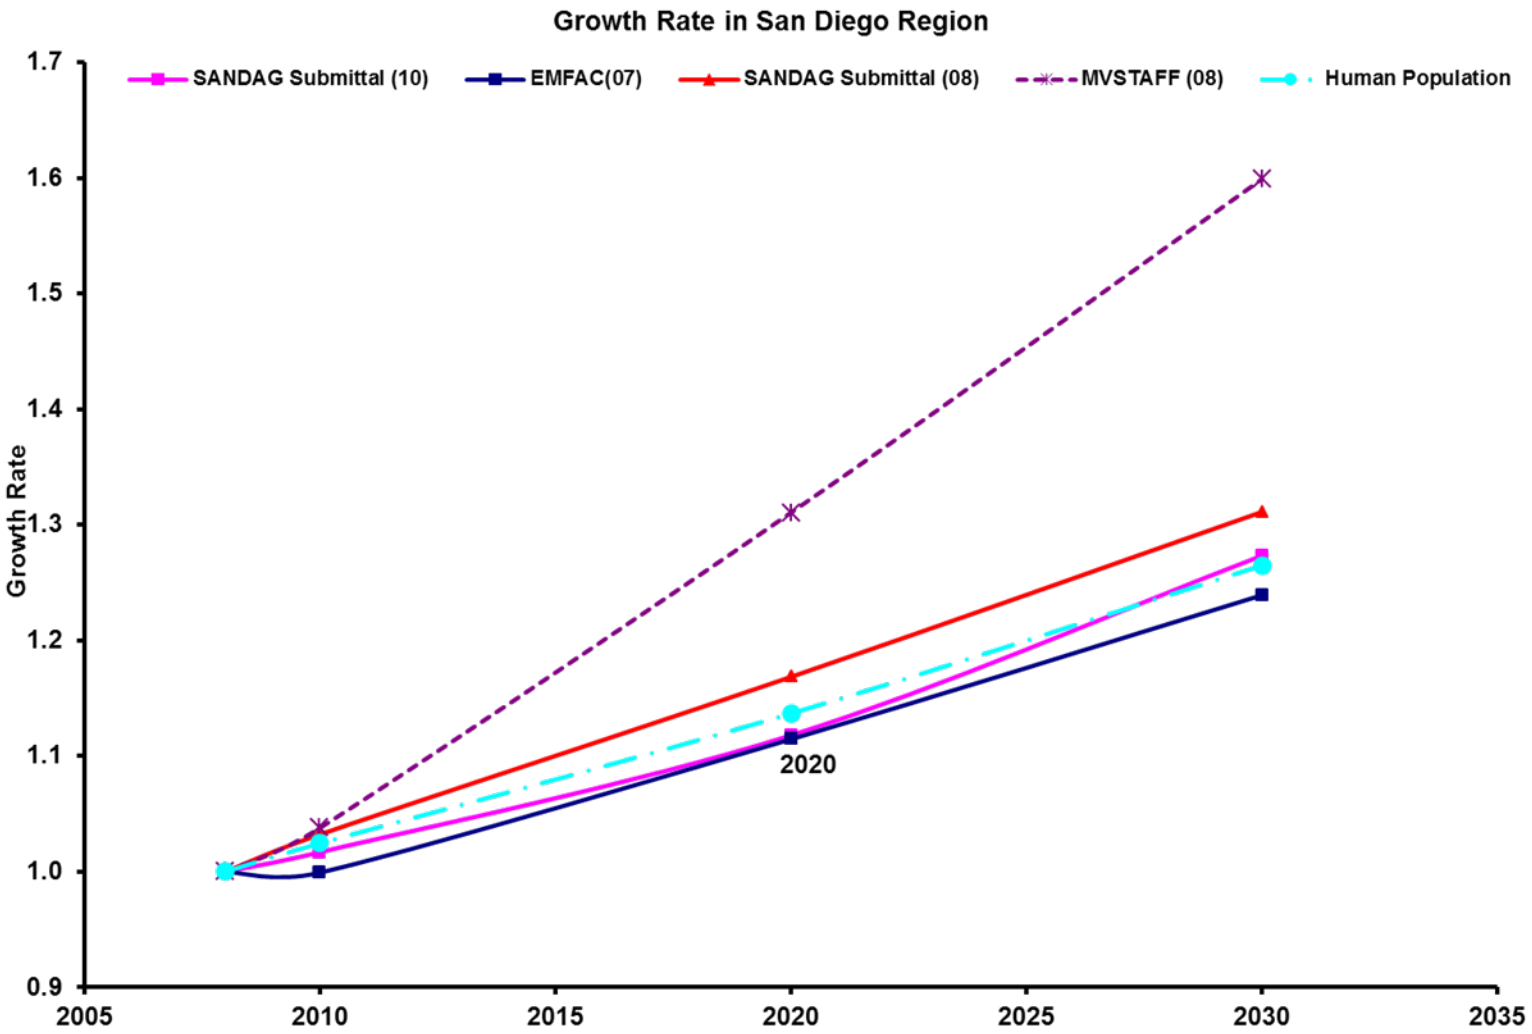

SAN FRANCISCO BAY AREA

The Metropolitan Transportation Commission (MTC) provided updated activity data in January 2011. Table 7-7 describes the VMT and speed distribution data submitted by MTC.

Table 7-7. Data Submittal from MTC

Traffic Model Citation:	Travel Model One (activity based model) using ABAG's Projections 2009 demographic/socio-economic/land forecast developed and adopted by ABAG in March 2009.					
Date of Submittal:	January 2011					
Years Provided:	2000, 2005, 2035					
VMT Vehicle Classes:	VMT totals represent all vehicle classes. EMFAC 2011 reflects VMT distribution over the vehicle classes based on DMV data and ARB EMFAC2011-HD truck model.					
Speed Vehicle Classes:	Apply to light-duty cars and trucks, medium-duty vehicles, and motorcycles. ARB default speeds to be used for all heavy-duty vehicles.					
Speed Distributions and Periods:	MTC submitted their speed distribution in 7 periods, which staff converted into 6 periods: AM Peak (period 2), PM Peak (period 5), Midday (periods 3 and 4), and Night (periods 1 and 6).					
Period Definitions	**Period 1**	**Period 2**	**Period 3**	**Period 4**	**Period 5**	**Period 6**
	Hours 3-5	6-9	10-11	12-14	15-18	19-2

Similar to the South Coast QA process, ARB staff reviewed MTC's VMT and speed distributions. ARB compared MTC's VMT and growth rates by county, CYs 2005 and 2035 to the following data sources:

- MTC Activity Data Submitted to ARB (Jan 2011)
- EMFAC 2007, Version 2.3 (Nov 2006)
- EMFAC 2011 (applied MTC growth rate for future years)
- California Motor Vehicle Stock, Travel and Fuel Forecast, May 2008 (MVSTAFF)
- Human Population, State of California, Department of Finance, Population Projections for California and Its Counties 2000-2050, Sacramento, California, July 2007.

Table 7-8 shows Daily VMT by County in the MTC region by calendar year.

Table 7-8. MTC Daily VMT by County

MTC	2000	2005	2035
Alameda	36,924,303	36,991,842	46,805,997
Contra Costa	19,947,507	21,437,898	26,777,372
Marin	6,064,389	6,186,610	6,962,727
Napa	2,611,517	3,045,574	3,513,033
San Francisco	8,724,235	8,699,284	10,568,527
San Mateo	15,543,143	14,841,629	18,518,543
Santa Clara	38,572,183	37,645,288	49,766,067
So. Solano	6,291,308	6,923,862	8,190,946
So. Sonoma	7,934,749	8,242,240	9,664,187
No. Solano	4,276,033	4,502,751	5,326,765
No. Sonoma	1,854,636	2,118,420	2,483,889
Total	148,744,003	150,635,398	188,578,053

For EMFAC2011, MTC VMT growth rates were applied to the default CY 2000 base year VMT in EMFAC 2011 to estimate the MTC CY 2005 and 2035 VMT. VMT comparison and growth rates for the San Francisco Air Basin are shown in Figure 7-6 and Figure 7-7. The EMFAC 2011 VMT is about 11 – 25% higher than the MTC 2011 VMT. Both MTC 2011 VMT and human population grow at a similar rate of 0.8% and 0.9% per annum respectively.

One important issue discussed during the QA process on MTC's data was VMT estimates for base year 2000. Prior investigations as well as the current analysis by ARB showed that MTC VMT estimates were significantly lower than those based on the DMV vehicle populations plus mileage accrual rates determined from California's Smog Check Program. In an effort to be fully protective of air quality, ARB, MTC, and the Bay Area Air Quality Management District (BAAQMD) determined that it would be better to have VMT forecasts that err on the side of being too high rather than too low. Therefore, these agencies agreed to adjust Bay Area VMT before using it in air quality plans or in the EMFAC model pending future efforts to determine the reasons for VMT discrepancies among independent sources of data.

Figure 7-6. VMT in the San Francisco Bay Area

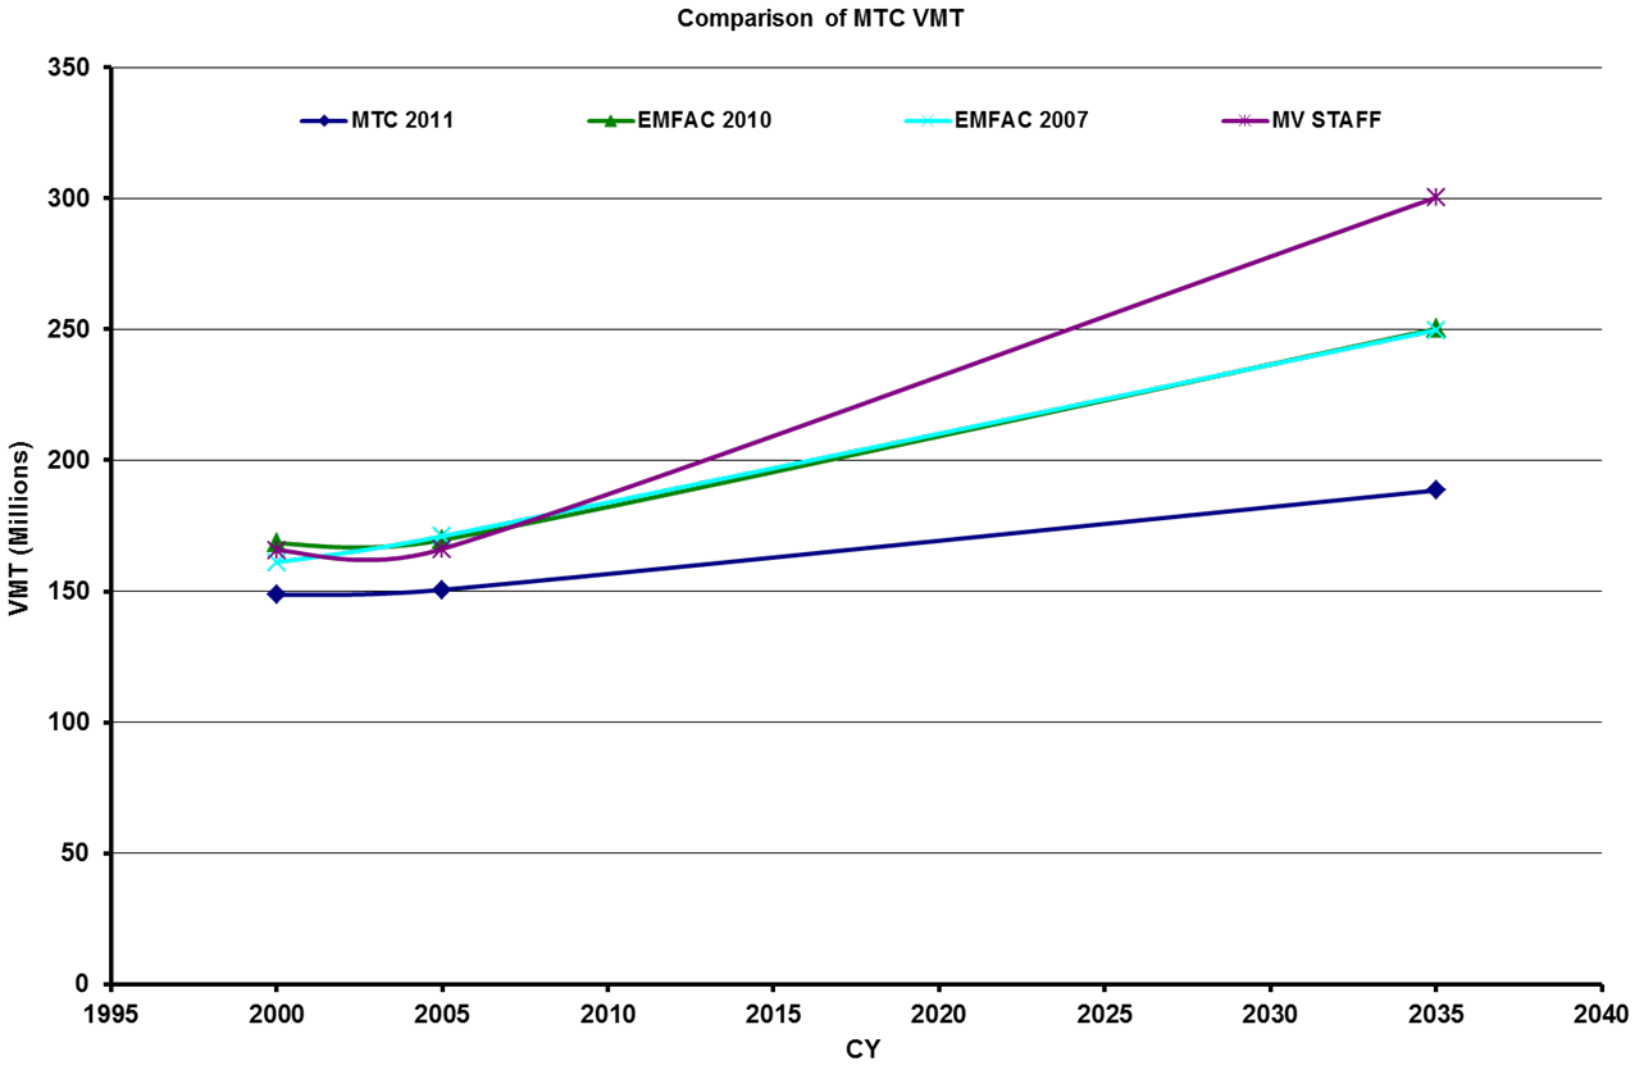

Figure 7-7. VMT and Human Population Growth in the San Francisco Bay Area

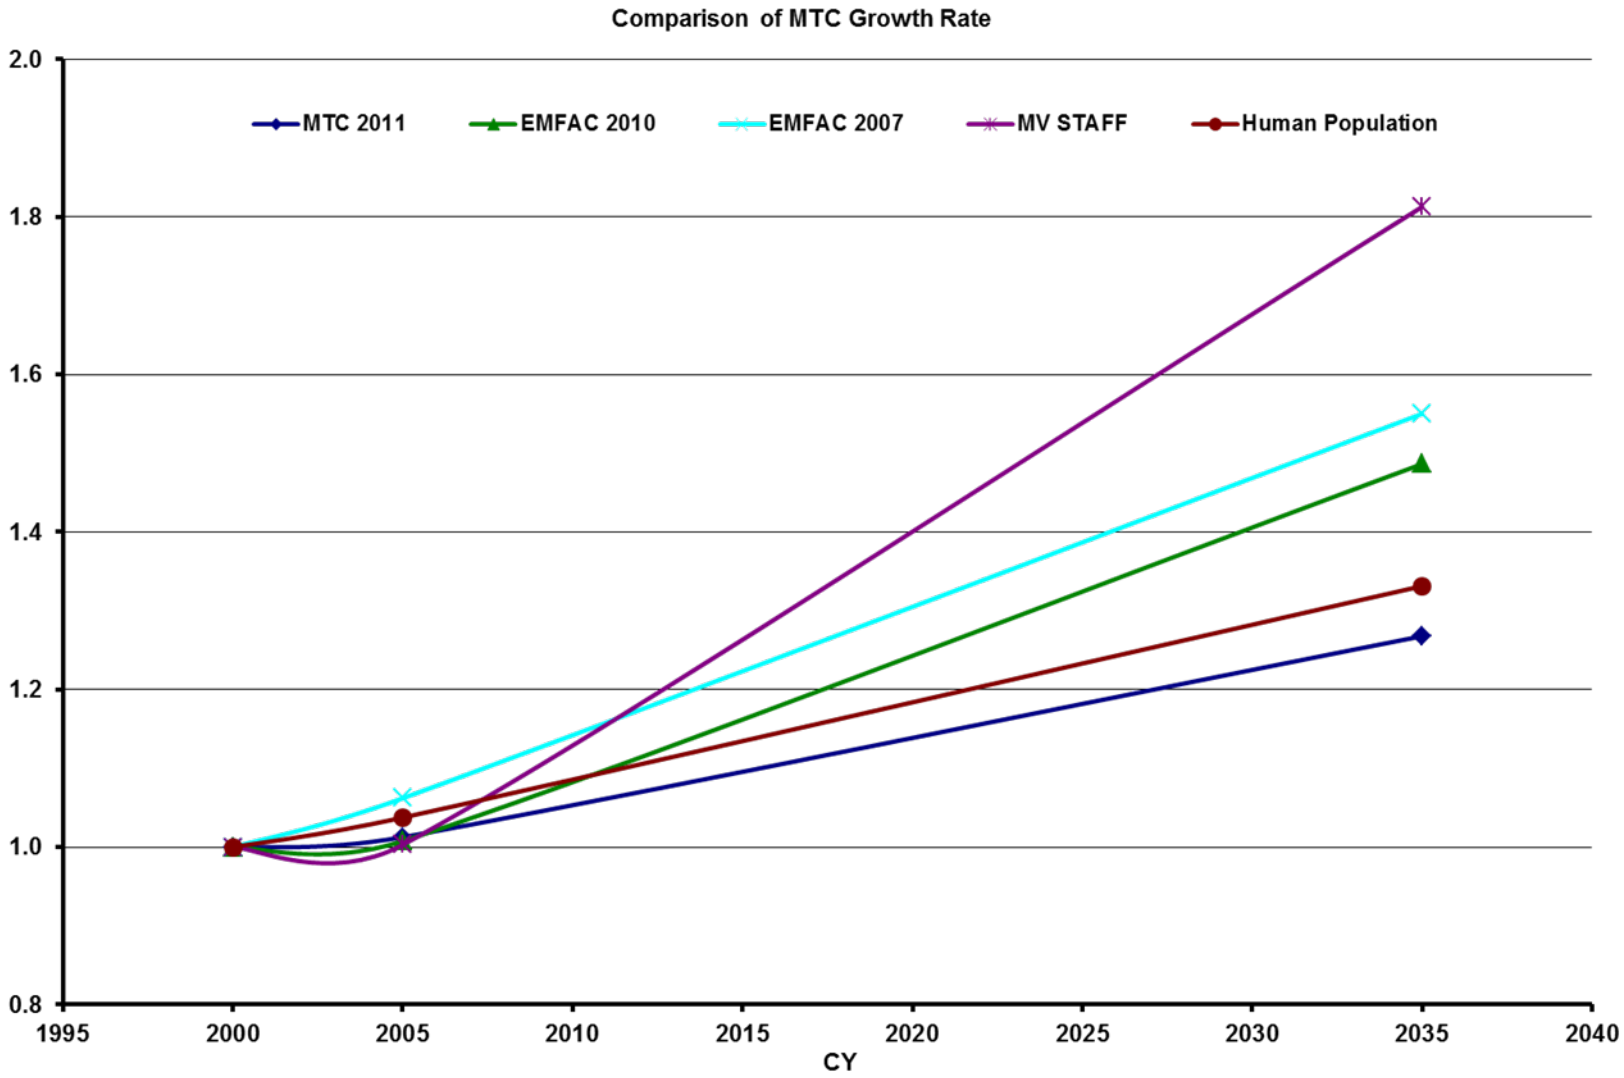

SACRAMENTO METROPOLITAN AREA

Sacramento Area Council of Governments (SACOG) provided ARB with VMT and speed distributions in February 2011. Table 7-9 illustrates the VMT and speed distribution data submitted by SACOG.

Table 7-9. SACOG Submittal

Traffic Model Citation:	The adopted Metropolitan Transportation Plan 2035.					
Date of Submittal:	February 2011					
Years Provided:	2005, 2018, and 2035					
VMT Vehicle Classes:	VMT totals represent all vehicle classes. EMFAC 2011 reflects VMT distribution over the vehicle classes based on DMV data and ARB truck model.					
Speed Vehicle Classes:	Apply to light-duty cars and trucks, medium-duty vehicles, and motorcycles. ARB default speeds to be used for all heavy-duty vehicles.					
Speed Distributions and Periods:	SACOG provided four speed distributions -- AM peak (period 2), PM peak (period 5), Noon (periods 3 and 4) and Night (periods 1 and 6)					
Period Definitions	**Period 1**	**Period 2**	**Period 3**	**Period 4**	**Period 5**	**Period 6**
	Hours 0-5	6-8	9-11	12-14	15-17	18-23

ARB staff reviewed SACOG's VMT and speed distributions. Table 9 shows the daily VMT provided by SACOG. ARB compared SACOG's VMT and growth rates by county to the following data sources:

- SACOG Activity Data Submitted to ARB (Feb 2011)
- EMFAC 2007, Version 2.3 (Nov 2006)
- SACOG Activity Data Submitted to ARB (2007)
- California Motor Vehicle Stock, Travel and Fuel Forecast, May 2008 (MVSTAFF)
- Human Population, State of California, Department of Finance, Population Projections for California and Its Counties 2000-2050, Sacramento, California, July 2007.

Table 7-10. SACOG Daily VMT by County

SACOG	Area	2005 (EMFAC)	2005 (SACOG07)	2005 (SACOG11)	2018 (EMFAC)	2018 (SACOG07)	2018 (SACOG11)	2035 (EMFAC)	2035 (SACOG07)	2035 (SACOG11)

Total Region		55,936,000	54,024,286	55,639,250	65,001,000	67,513,953	69,436,829	82,151,000	82,329,900	83,089,255

SACOG provided VMT and speeds by vehicle class and by county. ARB used DMV population and EMFAC2011-HD truck model redistribution to update vehicle population. SACOG agreed to use ARB default speed distributions for heavy-duty vehicles. EMFAC 2011 reflects SACOG's speed distributions for light-duty cars and trucks plus motorcycles. The Sacramento Metropolitan Area VMT comparison and growth rates are shown in Figure 7-8 and Figure 7-9. SACOG 2011 has same VMT as in their previous submittal except less than 1% difference in their base year.

Figure 7-8. Sacramento Region VMT

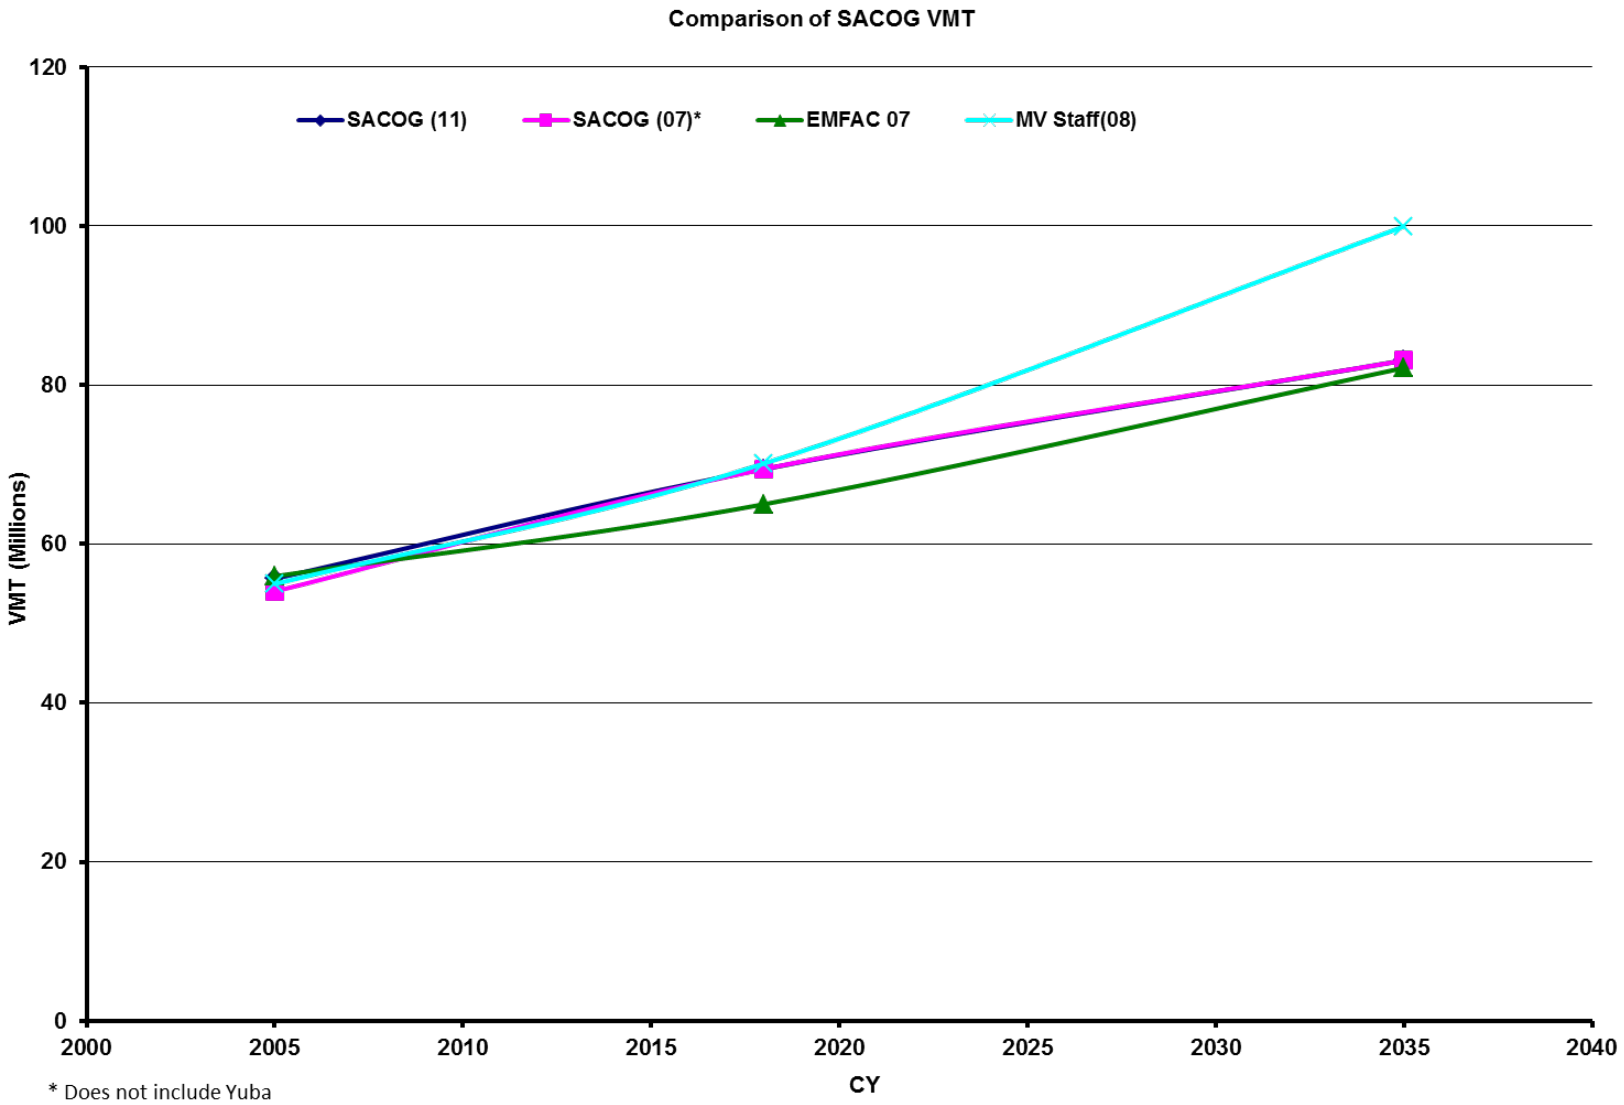

Figure 7-9. VMT and Human Population Growth in the Sacramento Region

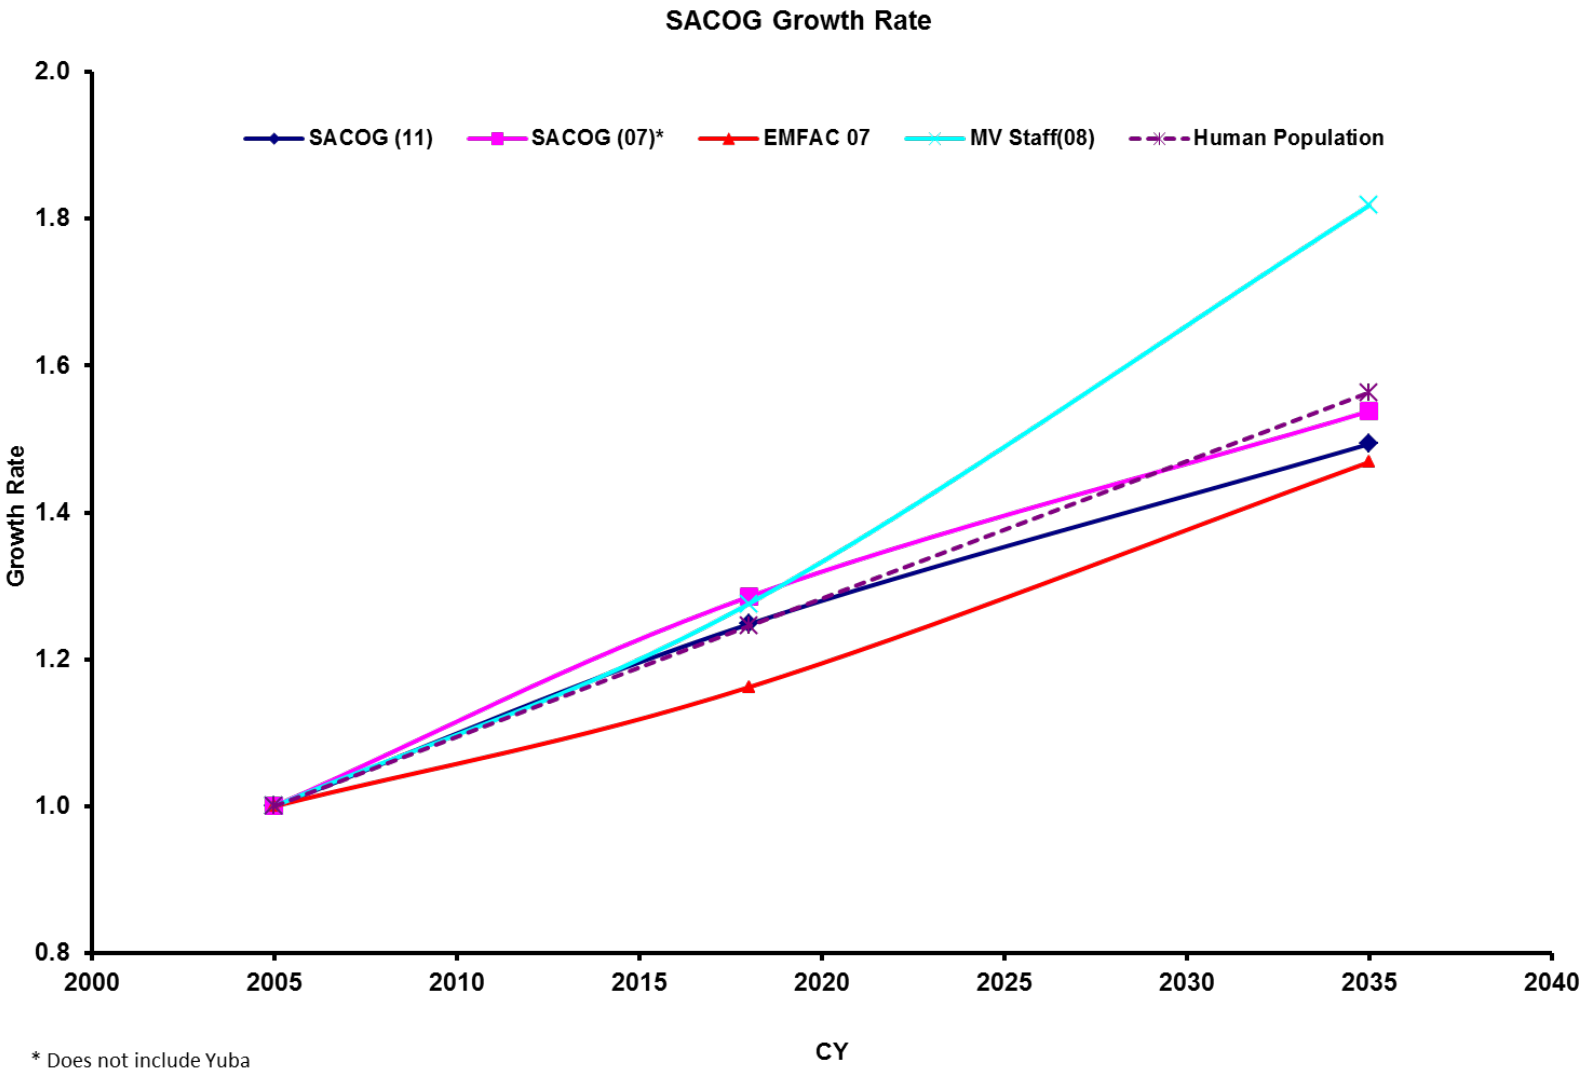

SAN JOAQUIN VALLEY

There are eight COGs (Council of Governments) in the San Joaquin Valley (SJV) including Fresno, Kern, Kings, Madera, Merced, San Joaquin, Stanislaus, and Tulare. All the COGs in SJV region have submitted vehicle activity data in October 2011. Table 7-11 provides details on the SJV submittal.

Table 7-11. San Joaquin Valley Submittal

Traffic Model Citation:	Activity data is based 2011 TIP and RTP currently pending state and federal approval					
Date of Submittal:	October 2010					
Base Years Provided:	Fresno - 2003, Kern - 2006, Kings - 2005, Madera - 2000, Merced - 2000, San Joaquin - 2005, Stanislaus - 2006, and Tulare - 2007.					
Future Years Provided:	2011, 2012, 2014, 2017, 2020, 2023, 2025, 2035					
VMT Vehicle Classes:	VMT totals represent all vehicle classes. EMFAC 2011 reflects VMT distribution over the vehicle classes based on DMV data and ARB truck model.					
Speed Vehicle Classes:	Apply to light-duty cars and trucks, medium-duty vehicles, and motorcycles. ARB default speeds to be used for all heavy-duty vehicles.					
Speed Distributions and Periods:	Fresno, Kern, San Joaquin, Stanislaus and Tulare COGs provided speed distribution for three periods: AM peak (period 2); PM peak (period 5); and off-peak (periods 1, 3, 4, and 6). Kings, Madera and Merced COGs provided daily speed distribution.					
Period Definitions	**Period 1**	**Period 2**	**Period 3**	**Period 4**	**Period 5**	**Period 6**
	Hours 0-5	6-8	9-11	12-14	15-17	18-23
Period Definitions	Daily, same distribution for all periods.					

ARB staff reviewed the activity data received from SJV COGs and compared VMT trends for CYs 2000 through 2035 to other data sources:

- SJV Activity Data Submitted to ARB in October 2010
- EMFAC 2007, Version 2.3 (Nov 2006)
- SJV Activity Data Submitted to ARB in 2009
- California Motor Vehicle Stock, Travel and Fuel Forecast, May 2008 (MVSTAFF)
- Human Population, State of California, Department of Finance, Population Projections for California and Its Counties 2000-2050, Sacramento, California, July 2007.

SJV COGs provided total VMT and one speed distribution for all vehicle classes. The heavy heavy-duty truck VMT was updated to agree with ARB's EMFAC2011-HD truck model redistribution. Similarly, SJV COGs agreed to use ARB default speed distributions for heavy-duty vehicles. EMFAC2011 reflects SJV COGs speed distributions for light-duty cars and trucks plus motorcycles.

The SJV COGs total VMT comparison and growth rates (excluding the portion of Kern County located in the Mojave Desert Air Basin) are shown in Figure 7-10 and Figure 7-11. Figure 7-12 and Figure 7-13 show the VMT and growth rate comparisons for Kern County in the Mojave Desert Air Basin.

Figure 7-10. VMT in the San Joaquin Valley (Excluding Portions of Kern County Located in the Mojave Desert Air Basin)

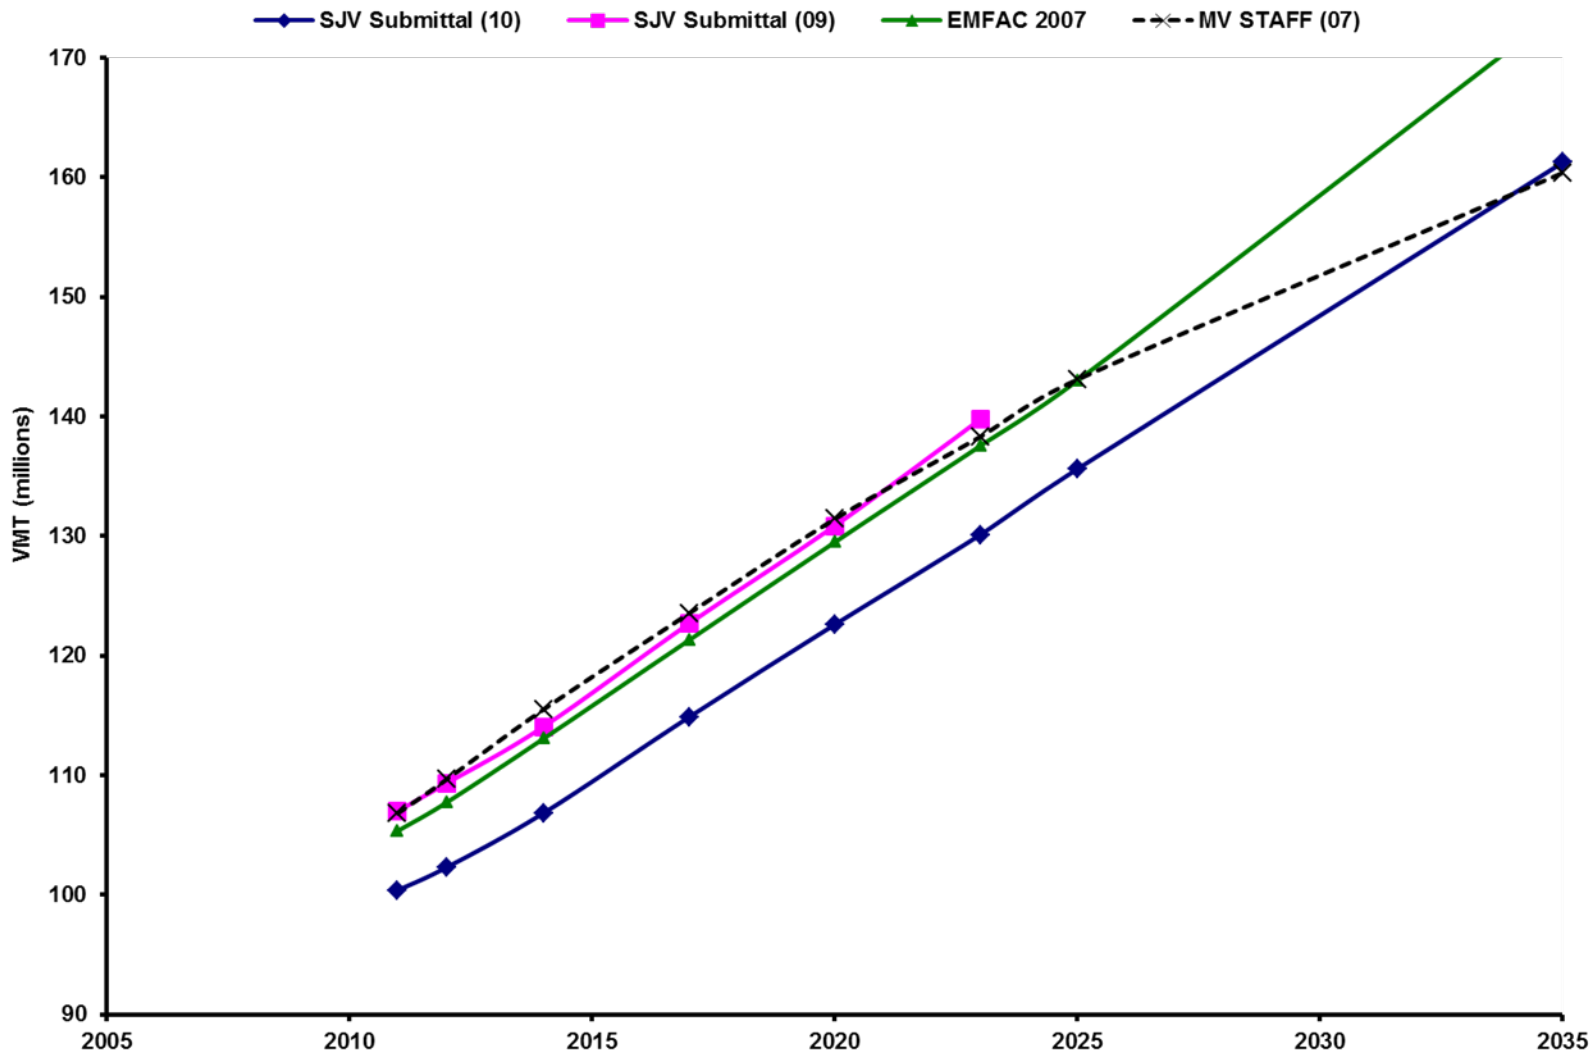

Figure 7-11. VMT and Human Population Growth in the San Joaquin Valley

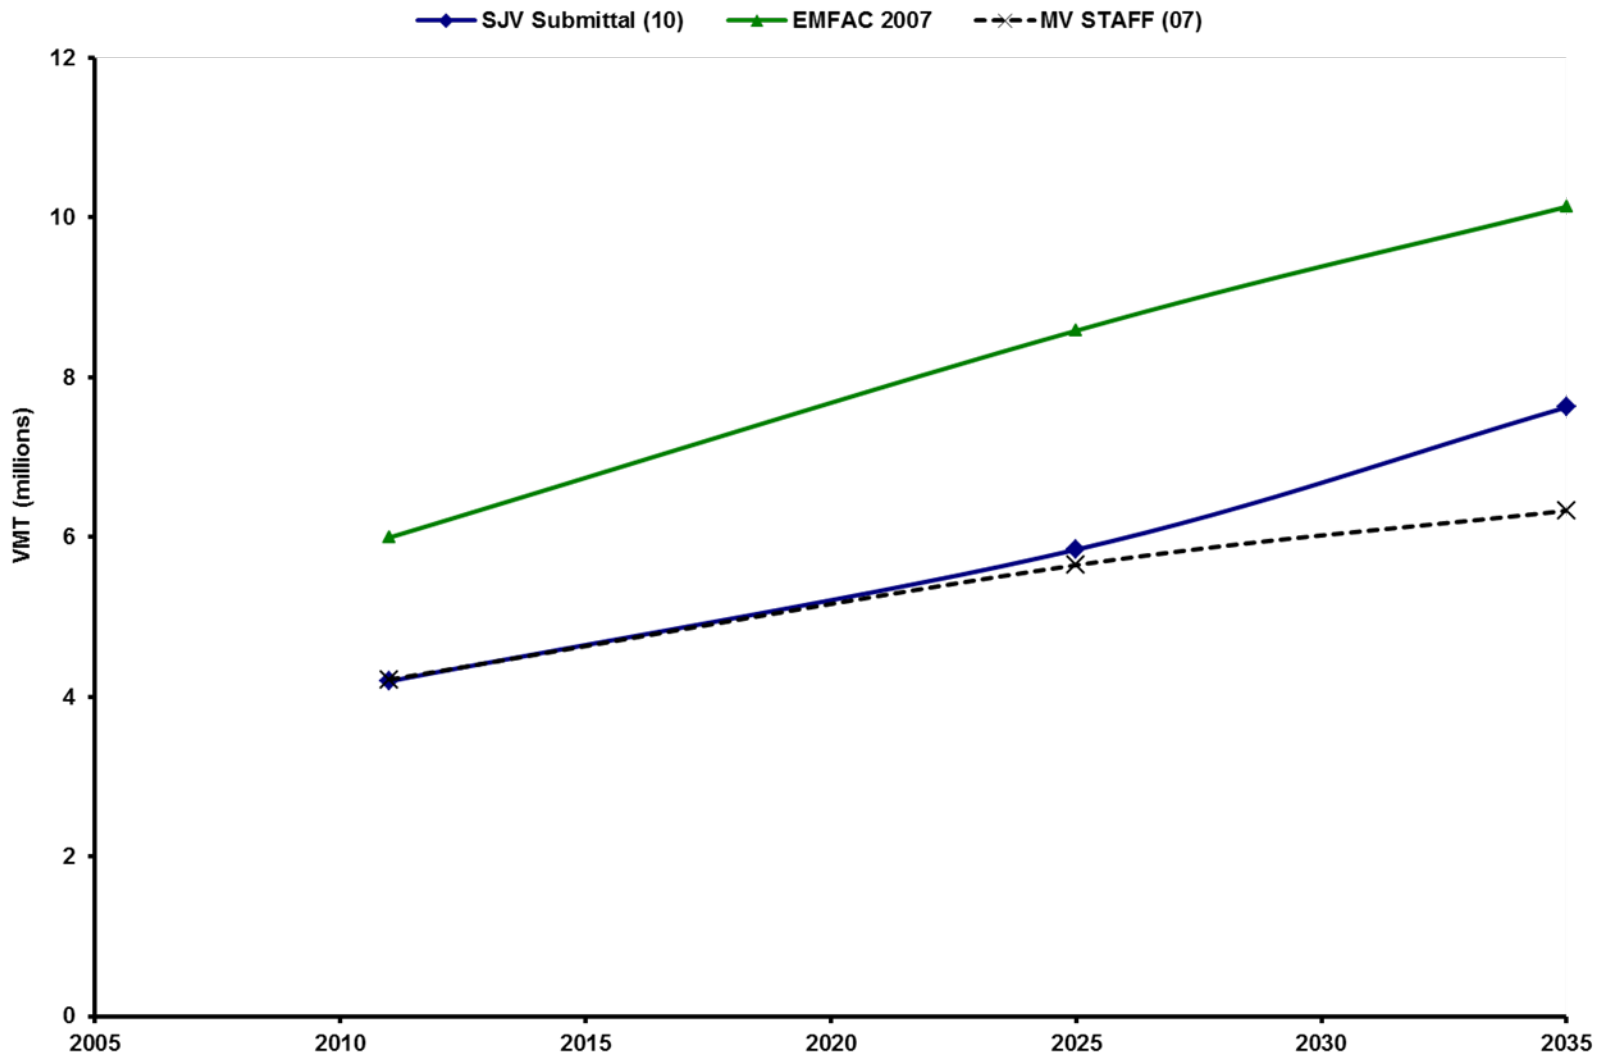

Figure 7-13. VMT and Human Population in Kern County, Mojave Desert Air Basin

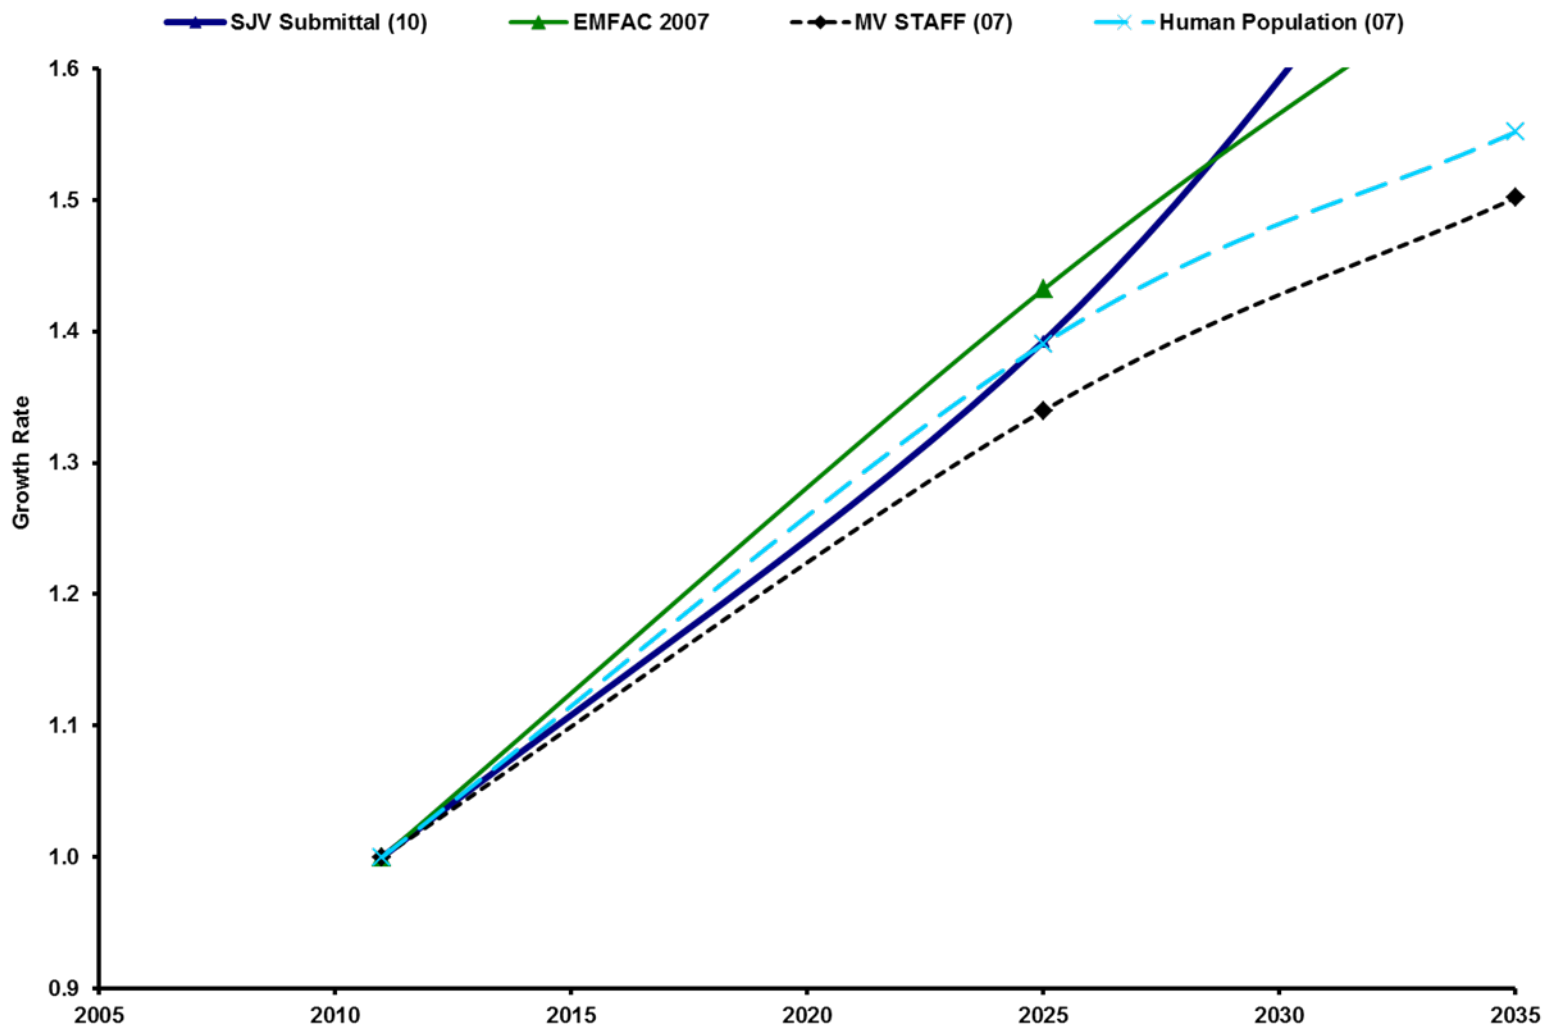

8 APPENDIX: CARBON DIOXIDE EMISSION RATE UPDATES

The official greenhouse gas emissions inventory representing the transportation economic sector is developed using top-down methods based upon statewide fuel sales data and published at **http://www.arb.ca.gov/cc/inventory/inventory.htm**.

EMFAC2011 outputs carbon dioxide emissions and fuel consumption through the EMFAC2011-LDV and EMFAC2011-HD modules using a bottom-up emissions inventory calculation based on population, activity, and emission rates. The two approaches provide marginally different results. The top-down method is considered a more accurate assessment of fuel use and carbon dioxide emissions because fuel use is measured through tax receipts by the California State Board of Equalization. The bottom-up method used by EMFAC provides information the top-down method cannot provide, such as a breakdown of estimated fuel use and emissions by vehicle class, for different engine technologies, different model years of vehicles and other factors.

Since EMFAC2000 the model has output carbon dioxide emissions and estimated fuel consumption based on carbon balance. The estimates of carbon dioxide (CO_2) emissions in the EMFAC model come from direct chassis dynamometer exhaust tests. This section analyzes the effect of introduction of oxygenated fuels, and updates the previous (2000) analysis with recent dynamometer test data collected on the Unified Cycle. The methods of estimating fuel consumption from CO_2 emissions and carbon balance are explored as a function of oxygenate content. The forecasted CO_2 emissions estimates provided in EMFAC2011 assume implementation of the Pavley (AB1432) greenhouse gas emission limits; however these benefits are calculated in EMFAC2011-SG, and not in EMFAC2011-LDV; as a result the changes discussed here only reflect changes based on driving cycle and oxygenate content.

A summary of the emissions effects of these changes for various areas in the State is shown in Section 12. Table 8-1 shows the effect on criteria pollutants and CO2 for the year 2007. The proposed changes lower the CO2 emissions by about 2% in 2007, mostly due to slightly different results from the vehicle surveillance programs.

Table 8-1. Summary of Emissions Changes due to Revised Greenhouse Gas Emission Factors, Calendar Year 2007

Air Basin	CO2 Emission Changes (tons per day)
Statewide	-6,446
South Coast	-2,092
San Joaquin Valley	-596
Sacramento Valley	-476
San Diego	-502
San Francisco Bay Area	-1,673

We determine carbon dioxide emissions from vehicles by measuring the exhaust concentration of carbon dioxide while running a specified driving cycle with the car situated on a dynamometer. In this case we evaluated two driving cycles: the Federal Test Procedure (FTP) and Unified Cycle (UC). The FTP is used for emission certification of new vehicles, and is modeled after suburban driving around Los Angeles in 1977. The FTP is not considered to be representative of actual driving conditions as it reflects 30-year old traffic conditions, has no or little freeway driving, and measured acceleration rates were reduced in the development of the cycle to accommodate older technology dynamometers. In the EMFAC model, base emissions are estimated using the UC driving this cycle because it is intended to be representative of average driving. It was developed from California-specific chase-car studies completed in the early 90's. It reflects driving on freeways; therefore, has higher speeds and acceleration rates than the FTP cycle.

The CO_2 emissions data in the EMFAC2007 model date from EMFAC2000, and are based on testing of cars during the 1990s. Table 8-2 shows the sources of the FTP data analyzed for EMFAC2000 and for this update.

Table 8-3 shows the sources of UC data. The projects with "S" in the name are surveillances. The projects with "R" in the name are research projects. The middle digits (positions 3 and 4 from the left) are the year that the project was begun. The three surveillances listed in the last three lines of the table are new (since the EMFAC2000 work), and are the basis for this model revision.

* In these projects light duty trucks were not separated by class I and 2. They are combined.

The term “Phase 2” in Table 2 refers to Phase 2 Reformulated Gasoline. In 1995 vehicles being tested at the ARB Haagen-Smit Laboratory in El Monte started to be performed with commercial Phase 2 reformulated gasoline (RFG), which contained 10% MtBE (methyl t-butyl ether) at the time. We segregated the 1990’s data into Phase 1 and Phase 2 RFG. We combined the recent surveillance data (from 2000 to 2007). We compiled the results for the three bags (test phases) of the FTP, as well as new UC results. The results of the data compilation for passenger cars are shown in Table 8-4 through Table 8-7 for the FTP and Table 8-8 through Table 8-11 for the UC. The new composite results are remarkably close to the EMFAC 2000 results. Segregating the light trucks into the separate LT1 and LT2 categories shows that the LT1s and PCs have similar CO_2 emission rates.

In EMFAC2007, fuel usage estimates are determined by carbon balance, which means that the emissions results for carbon containing species (carbon dioxide, carbon monoxide, and total hydrocarbons or volatile organic compounds) are used to determine the amount of fuel combusted. For EMFAC2011 the carbon balance methodology has been improved by accounting for oxygenated reformulated gasolines.

The carbon balance equation (for gasoline) as described in the EMFAC2000 Technical Support Document is as follows:

$$\text{gal/d} = 375 \text{ gal/ton C} * (0.273*CO_2 \text{ tpd} + 0.429*\text{CO tpd} + 0.866*\text{HC tpd})$$

The quantity in parentheses is the mass of carbon in the emission gases. The coefficients of the CO_2, CO and HC terms (0.273, 0.429, 0,866) are the weight fractions of carbon in those quantities. The first factor in the equation (375 gal/ton C) is the only one that would be affected by the presence of oxygen in gasoline. It is calculated from:

$$\text{gal/ton C} = 2000 \text{ lb/ton} / \text{wt frac C} / \rho_{gaso} \text{ lb/gal}$$

where ρ_{gaso} is the density of liquid gasoline, lb/gal

Properties of gasoline as well as MtBE and Ethanol gasoline blends are provided in Table 8-12.

E85 (85E 15I)	57.0	13.1	29.8	6.54	537

(M10 is 10% MtBE and 90% Gasoline; E10 is 10% Ethanol, 90% Gasoline)

Prior to 1994, gasoline sold in California was non-oxygenated, with the exception of gasoline sold in the South Coast Air Quality Management District. Beginning in 1996, California required reformulated gasoline, which was formulated using 10% MtBE. In 2004, California banned the use of MtBE as a fuel oxygenate, requiring instead that ethanol be used at 6% by weight (E6). Beginning in 2010, petroleum marketers began selling a 10% ethanol gasoline blend (E10). Gasoline exceeding 10% ethanol can be sold in California but may only be used in flex-fuel vehicles, which is currently a very small proportion of the vehicle fleet in California.

The impact of this change on the emissions inventory is relatively minor, and caused by both the updated base emission rates using updated information and the UC, and the impact of the inclusion of oxygenated fuels. Table 8-13 compares running CO2 emission rates by model year between EMFAC2007 and EMFAC2011. Passenger car emission rates are about 5% lower than in EMFAC2007 than in EMFAC2011, and Light Duty Trucks (Class I) are 6% lower in EMFAC2011 than EMFAC2007. Light Duty Trucks (Class 2) and Medium Duty Trucks are about 6% higher in EMFAC2011 than assumed in EMFAC2007. The effect on CO2 emissions statewide is shown in Table 8-14. Overall the emission rate update had a minor effect on emissions which differs by calendar year and is about a 2% reduction in estimated emissions into the future.

The calculation of CO2 emissions is dependent on fuel carbon content. Table 8-15 compares estimated fuel use using the EMFAC2011 (accounting for fuel oxygenate content) and EMFAC2007 (no accounting for fuel oxygenates) approaches. Results show estimated fuel use is 3%-4% higher in EMFAC2011 than in EMFAC2007.

9 APPENDIX: BRAKE WEAR PARTICULATE MATTER EMISSIONS UPDATE

EMFAC2011 estimates the directly emitted emissions of total particulate matter (PM) for exhaust, tire wear, and brake wear. EMFAC2007 used an emission factor of 12.8 milligrams per mile (12.8 mg/mi PM) to estimate the amount of airborne dust attributable to brake wear. This emission factor, based on twenty-year-old tests of asbestos friction-materials from automobile disc brakes, was applied to all vehicles. Two studies were performed on modern asbestos-replacement friction materials over the past 10 years. Staff correlated results from these studies with wheel load, braking speed and material. The results were applied to the braking events of the Unified Cycle (UC), and the Transient and Cruise cycles for medium heavy-duty and heavy heavy-duty trucks, taking into account that heavy heavy-duty trucks have eight rear and two front brakes compared to four brakes on cars. This information was used to update brake wear emissions estimates in EMFAC2011.

Updated per-mile braking emission rates are, in general, about 2.5 times greater in EMFAC2011 than in EMFAC2007. This is increase is caused by modern brake pad materials that are more friable but less toxic than older asbestos based technologies. Staff analysis also found that the speed at which braking occurs, the weight of the vehicle, and, most importantly, the fraction of stop-and-go driving affects the per-mile airborne brake wear rate. A summary of the increases for various areas in the State is shown in Table 9-1 below. Implementation of the proposed modification results in an increase in the PM inventory of about 30 tons per day statewide in 2007. This is a more than tripling of the brakewear emissions and a 50% increase in total PM emissions. The increase in PM2.5 is less than for PM due to the relatively small fraction of brake wear PM in the PM2.5 size fraction.

Table 9-1. PM10 Emissions Increase Due to Brake Wear Method Improvement

Air Basin	PM10 Emissions Increase (Tons per Day)	
	2007	2023
Statewide	29.95	37.34
South Coast	11.65	13.55
San Joaquin Valley	3.32	4.69
Sacramento Valley	2.25	3.09
San Diego	2.77	3.17
San Francisco Bay Area	5.5	6.68

EMFAC2007 brake wear emission factors were, carried over from earlier versions of the U.S. EPA Mobile model. The U.S. EPA in turn derived the 13 mg/vehicle-mile estimate from a 1983 paper by Cha et al.[2] (U.S. EPA and Northrop). That work collected particles generated from operating a disc brake dynamometer with asbestos friction

[2] Cha, S, P. Carter, and R. Bradow. 1983. Simulation of Automobile Brake Wear Dynamics and Estimation of Emissions. SAE Paper 831036. Society of Automotive Engineers, Warrendale, PA.

materials on a schedule of braking events typical of Raleigh City driving. The original result of 12.8 mg/mile was calculated from the following equation:

(2 x 2.43 mg/application front disc + 2 x 1.68 mg/application rear) x 31% airborne x 5.1 applications/mi.

Cha et al estimated 0.75 mg PM / application airborne (out of a total brake pad weight loss of 2.43 mg/application) for one disc brake. So, when calculating brake wear emissions there are a number of variables of interest including (a) the number of brakes per vehicle; (b) dust emissions per brake application; (c) the fraction of dust that becomes airborne in various size fractions; and (d) the number of brake applications per mile. The amount of dust generated per brake application is a function of the type of friction material, the type of brake, the deceleration rate, the vehicle weight, and the brake pad size. In many studies, the experimental method used provides only the airborne dust per application (the product of the gross dust emissions per application and the fraction of dust airborne), so the variables of dust emission per application and fraction of dust airborne are in some cases not reported separately.

Two new studies over the past 10 years have characterized particulate matter emission from braking events using modern materials: Garg et al[34] from General Motors and Sanders et al[56] from Ford. Garg gave the breakdown of the sales of friction materials in 1998, shown below in Table 9-2. The trucks in this table are pickups and full-size sport utility vehicles. All vehicles were equipped with disc brakes unless otherwise noted. 1998 was the last year for asbestos-containing materials in OEM brake pads.

Table 9-2. Sales of Brake Pad Materials in 1998 (Garg et al., 2000a)

		Semi-Metallic	Low-Metallic	Non-Asbestos Organic	Asbestos Organic
Front Brakes	**Automobile**	70%	15%	15%	
	Truck	75%	25%		
Rear Brakes	**Automobile**	50%	12%	16%	22% (drum)
	Truck	75% (drum)	15%	10%

In the Garg and Sanders studies, researchers tested brake pads with different friction materials on a shrouded brake dynamometer, sampled dusts generated by each braking event, and measured the breakdown of emissions by particle size. Results are shown in Table 9-3.

Table 9-3. Airborne Dust Emissions per Brake Application

Material	Source	Average Brake Speed (mph)	Dust (mg/stop)	Wheel Load (pounds)	Wind Speed (mph)	Brake Drag (pounds)
Low-Metallic	Sanders	15	6	1070	8	120
		15	4	1070	8	120
		31	21.5	1070	8	856
		15	9	1070	7	120
		30	24.5	1070	7	196
		30	21	1070	40	196
Semi-Metallic	Sanders	15	1.5	1447	8	160
		31	20	1447	8	1160
		15	1.5	1447	7	160
	Garg	16	3.9	1984	2-13	586
		16	1.7	1616	2-13	469
Non Asbestos Organic	Sanders	15	0.9	1070	8	120
		31	11.5	1070	8	856
		15	1.4	1076	7	120
	Garg	16	4.6	1376	2-13	407
		16	1.9	1671	2-13	500
		16	3	1577	2-13	469
		16	2.1	592	2-13	167
		16	6.5	1434	2-13	430

Results shown in Table 9-3 are corrected to a wheel-installed basis and 50% airborne sampling efficiency. Other characteristics of the tests varied. For example, while both studies measured emissions from full stops, Garg et al. used repeated stops from 32 miles per hour at a 6.5 miles/hour-sec deceleration rate. In contrast, Sanders et al., used several braking programs including a series of 24 stops from various speeds (22-55 mph) at variable deceleration rates (1.3-3.4 mph/second); a series of 10 stops from 62 miles per hour at 17.7 mph/second; and a series of stops from 60 miles per hour at 4 mph/second. Sanders et al found a 50% airborne fraction using a wind tunnel at 40 miles per hour. While this is higher than the 31% previously assumed, the Sanders study is more representative of real-world driving and as a result the 50% factor is used in this analysis.

The frequency and intensity of braking events is depending on real-world driving conditions. EMFAC2007 and previous versions of EMFAC assumed a PM emissions factor that was based on a statistical analysis of Raleigh city driving (Cha, 1983) which assumed 5.1 brake applications per mile, 69% on average of a full stop with an initial braking even velocity of 22 mph. The fraction of a full stop was defined as the initial velocity squared minus final velocity squared all divided by initial velocity squared - this is the ratio of the actual kinetic energy change to the absolute kinetic energy.

In this analysis we updated our assumptions about the frequency and intensity of braking events. We used the Unified Cycle (LA 92) for passenger cars and SUVs, which is the same driving cycle upon which emission factors are based for all pollutants in EMFAC. For medium heavy-duty trucks, we used the ARB MHD cycle developed for the CRC E55/59 testing. The cruise, low-speed transient, and high-speed transient cycles were weighted according to their activity. For heavy heavy-duty trucks, the ARB HHD cycles were used, and weighted according to their activity. Heavy-duty truck activity is dominated by high speed cruising (interstate travel). Thus the braking cycle for them has few applications per mile and the events are shallow (low-energy). For urban buses we used the OCTA (Orange County Transit Authority) cycle. This was developed from actual tracking of buses in Orange County, and has more 40 mi/h cruising than the New York City Cycle or the SAE Central Business District cycle. The severity, frequency and average speed of braking for each vehicle type is shown in Table 9-4, and is compared to the assumptions in EMFAC2007 based on Cha et al.

Table 9-4. Assumed Braking Attributes by Vehicle Type

Vehicle Type	Braking Cycle	Braking Frequency (Applications/mile)	Initial Velocity (mph)	Fraction Full Stop
Passenger Cars and SUVs	UC	4.0	27.1	61%
Medium-Heavy Duty Trucks	ARB-MHD	3.0	29.1	49%
Heavy Heavy-Duty Trucks	ARB-HD	1.2	31.5	8%
Urban Transit Buses	OCTA	8.2	21.2	73%
School Buses	MHD-LS Transient	14	12.7	79%
All (EMFAC2007) from Cha et al. (1983)	Raleigh City	5.1	22.1	69%

To develop a model of brake wear emissions, staff combined data by material and evaluated the results. Figure 9-1 and Figure 9-2 show modeled results for non-asbestos organic materials and semi-metallic materials respectively. The slope of the emissions vs wheel load was taken in both cases from the 15 and 16 mph results. The same slope was assumed for the 31 mph results. These slopes were used to scale the automotive data to truck applications. Representative loads are shown in Table 9-5.

Figure 9-1. Modeled Brake Dust Emissions: Non-Asbestos Organic Materials

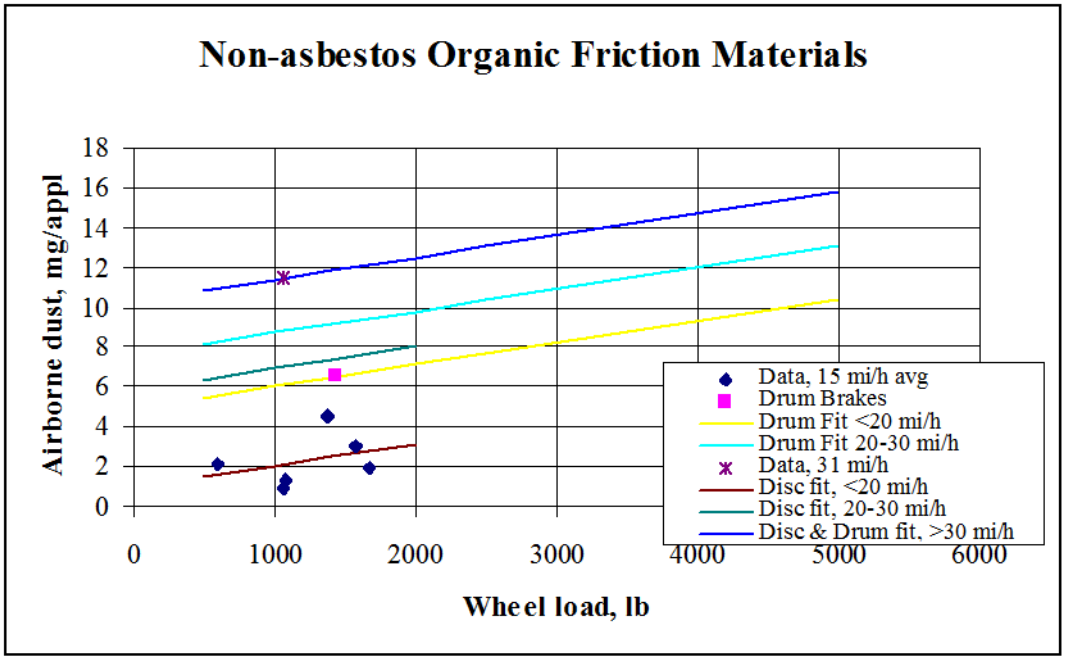

Figure 9-2. Modeled Brake Dust Emissions: Semi-Metallic Materials

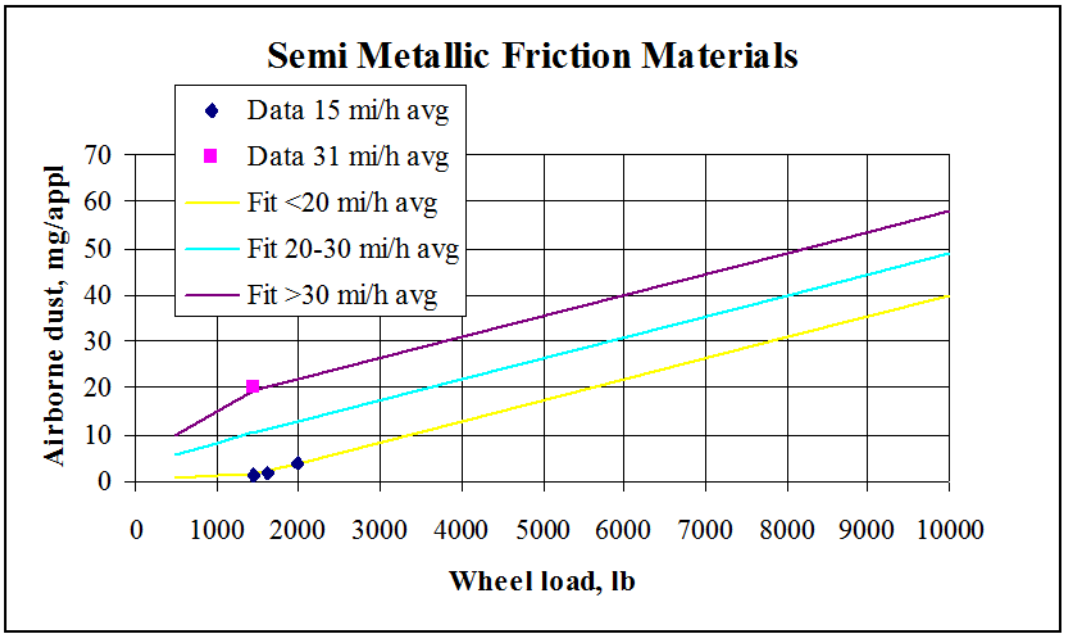

Table 9-5. Assumed Wheel Braking Loads

	Assumed Gross Vehicle Weight (pounds)	Front (pounds/wheel)	Rear (pounds/wheel)	Rear Trailer (pounds/wheel)
Car	3100	1100	450	
SUV	6000	2100	900	
Medium Heavy Truck	20000	7000	3000	
Heavy Heavy-Duty Truck	52000	9000	4600	3900
Urban Bus	42000	14700	6300	

The figures show a correlation between average brake event speed (average of beginning and ending speed in the braking event) and emissions. In general, emissions are higher as a function of wheel load (brake inertia weight). The newer asbestos-free braking materials were found to have much higher emissions than asbestos friction materials. The (Cha,1983) result was about 0.75 mg airborne dust per application for an automotive front brake.

Brakes with the wheel loads in Table 9-5 were modeled as being operated on braking cycles derived from typical driving based on the test cycles described in Table 9-4. Emission factors were estimated by friction material and scaled by wheel load by average braking speed (average of initial and final speeds). Braking event emissions for partial stops were scaled by the kinetic energy change (difference of final speed squared and initial speed squared).

Results of this calculation for several vehicle types are shown in Table 9-6 and Table 9-7. The predicted value for passenger cars is about 34 mg/mi, about two and a half times the value of Cha et al (1983). This is largely due to the fact that the new asbestos-free friction materials give off more dust during braking than did the old asbestos-containing materials.

10 APPENDIX: GASOLINE PM EMISSION FACTOR UPDATES

UPDATE

The current exhaust emissions standard for PM from automobiles is 10 mg/mile. As shown in Table 9-6 above, passenger vehicles emit between 30 and 60 mg PM / mile from brake wear alone. Passenger vehicles manufactured since 1996 have met and exceeded the current exhaust emissions standard, and today 85 – 90% of particulate matter emitted from passenger vehicles is dust from tire and break wear emissions.

Gasoline PM emission factor updates in EMFAC2011 for 2004 and newer port fuel injected (PFI) and gasoline direct injected (GDI) engines were developed using tests results from 40 vehicles on the Federal Test Procedure (FTP) driving cycle, and 10 vehicles on the Unified Cycle (UC). FTP results appeared to show a statistically significant difference between newer technology PFI engines and newer technology GDI engines. This difference is described in this section and integrated into EMFAC2011.

In August 2011 staff received new testing data from U.S. EPA on 15 PFI and 2 GDI vehicles. These vehicles were tested by USEPA on the FTP and the US06 which is an aggressive driving cycle designed to identify off FTP cycle emissions. These data cast the assumptions developed for EMFAC2011 into question. Results from analysis of the USEPA data suggested that under FTP driving conditions emission rates for most PFI vehicles are very clean, and potentially cleaner than GDI vehicles. However, some newer PFI vehicles may burn oil through engine deterioration, and that could lead to higher emissions that could meet or exceed PM emission rates from current GDI technologies. At the same time testing on the US06 driving cycle was suggestive, although not conclusive, that PFI engines may have less precise engine control under aggressive conditions than GDI vehicles, leading to potential off-cycle PM emissions in excess of those expected under the FTP.

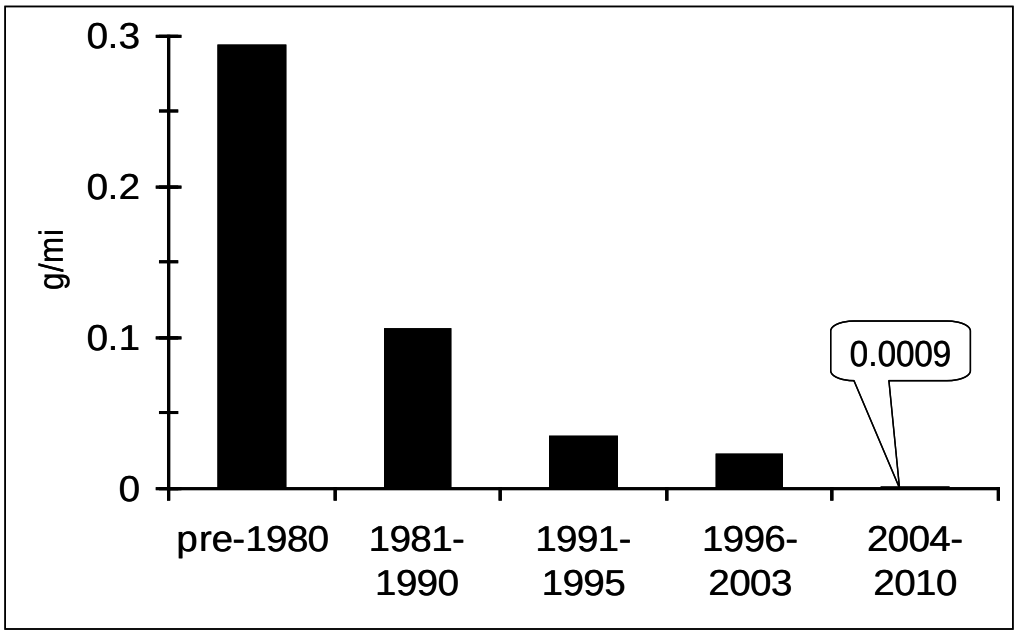
An overall analysis of the available data at this time suggests that while it is clear both GDI and PFI technologies emit at levels far below the current emissions standard of 10 mg/mile, it is not clear that 2004 and newer GDI technologies are cleaner than 2004 and newer GDI technologies.

The net impact on the inventory of this uncertainty is minimal, because the vast majority of fine particulate matter emitted by passenger vehicles is generated by tire and break wear. Statewide, gasoline vehicle particulate matter emissions from exhaust, tire wear, and brake wear represent around 3% of all PM2.5 emitted in California. Of that, only about 10-15% of that 3%, or 0.5% of the total is emitted from passenger vehicle exhaust.

These assumptions are continuing to be refined and will be discussed in greater detail through the Advanced Clean Car Rulemaking currently scheduled for December, 2011.

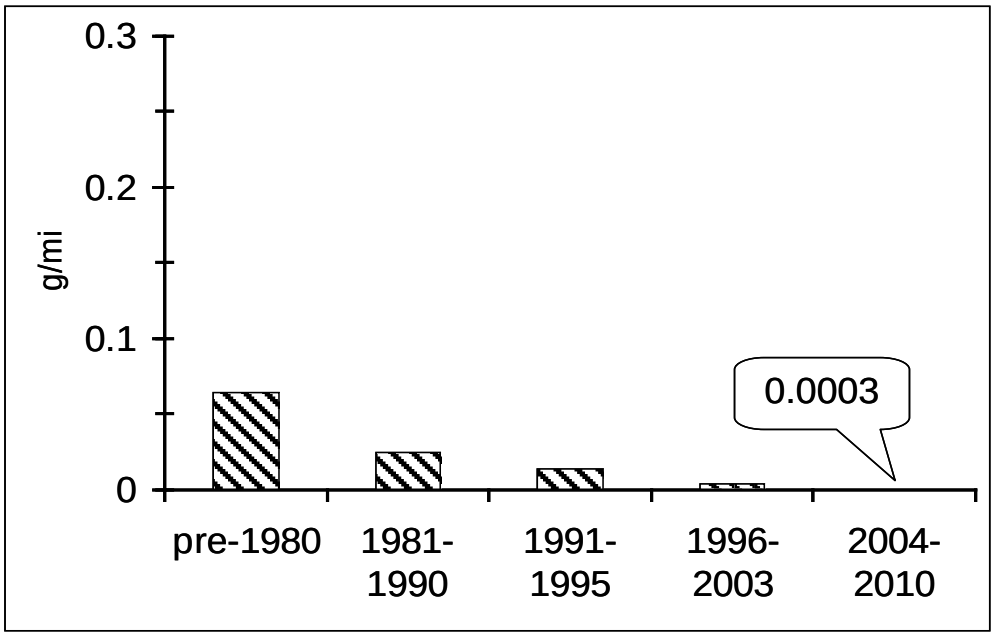
Basic emission rates for light duty gasoline vehicles have been updated using data from the Kansas City PM Characterization Study[7] (E-69). Those vehicles were certified to Federal Standards. Emissions data were collected under conditions prescribed in the Federal Test Procedures, and vehicles were operated over the LA92 Unified Driving Cycle. Figure 10-1 shows Kansas City Study $PM_{2.5}$ emission factors for cold start (Bag 1), and Figure 10-2 shows $PM_{2.5}$ hot running exhaust (Bag 2) by model year group through 2003. Measurements for newer vehicles (2004-2010) are from tests of in-use PFI vehicles over the same cycles and conditions but conducted at ARB's Haagen Smit Laboratory.

Figure 10-1. PM2.5 Emission Factor: Cold Start Exhaust (Bag 1)



[7] Kansas City PM Characterization Study, EPA420-R-08-009, April 2008

Figure 10-2. PM2.5 Emission Factor: Hot Stabilized Exhaust (Bag2)



We expect the percentage of gasoline direct injection (GDI) engines to increase from current levels in order to meet the GHG emission targets. We assumed that current wall-guided GDI engines will penetrate the fleet first, followed by cleaner center-walled technology in the future. The anticipated fleet penetration of GDI technology and its impact on $PM_{2.5}$ emission for both Bag 1 and Bag 2 are shown in Figure 10-3 and Figure 10-4, based on ARB testing of wall-guided technology GDI vehicles.

Figure 10-3. GDI Fleet Penetration and Cold Start Exhaust (grams per mile)

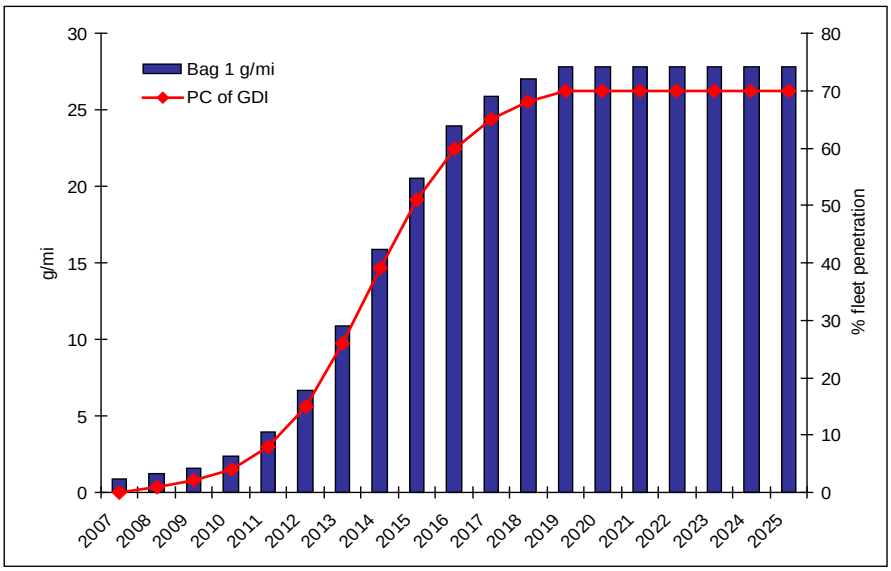


Figure 10-4. GDI Fleet Penetration and Hot Stabilized Exhaust (grams per mile)

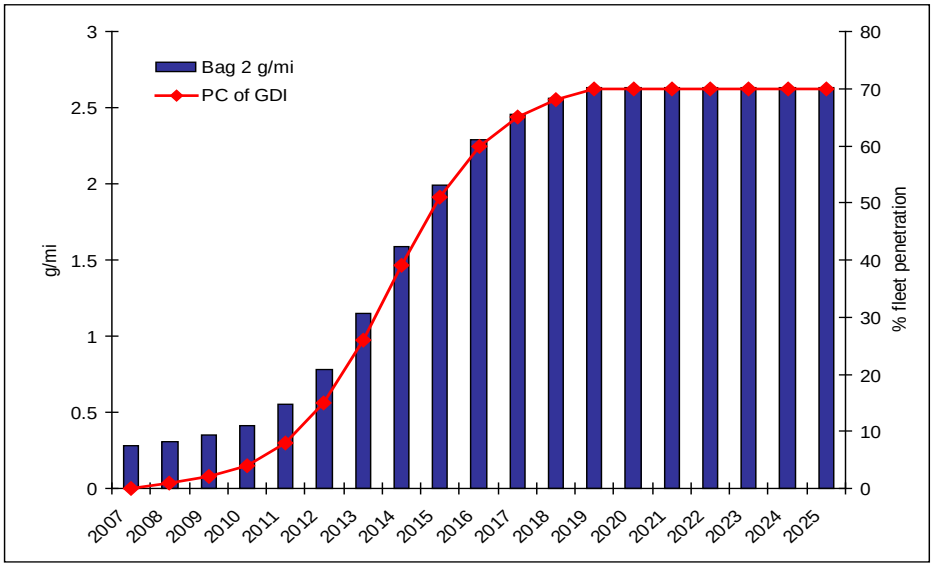

The current LEV II standard for PM is 10 mg/mi and will be in effect until 2016. As these standards are further reduced we expect technological improvements in GDI engines will result in substantial PM reductions over the present GDI. Our test results of one center-guided GDI engine showed about ⅓ of the PM emissions from wall-guided GDI engines. We assume that in the future these low PM emitting center-guided GDI engines will be the dominant technology. Figure 10-5 shows how technology is expected to change and the expected emissions.

Figure 10-5. Forecasted Light Duty Vehicle Technology Mix: 2007-2025.

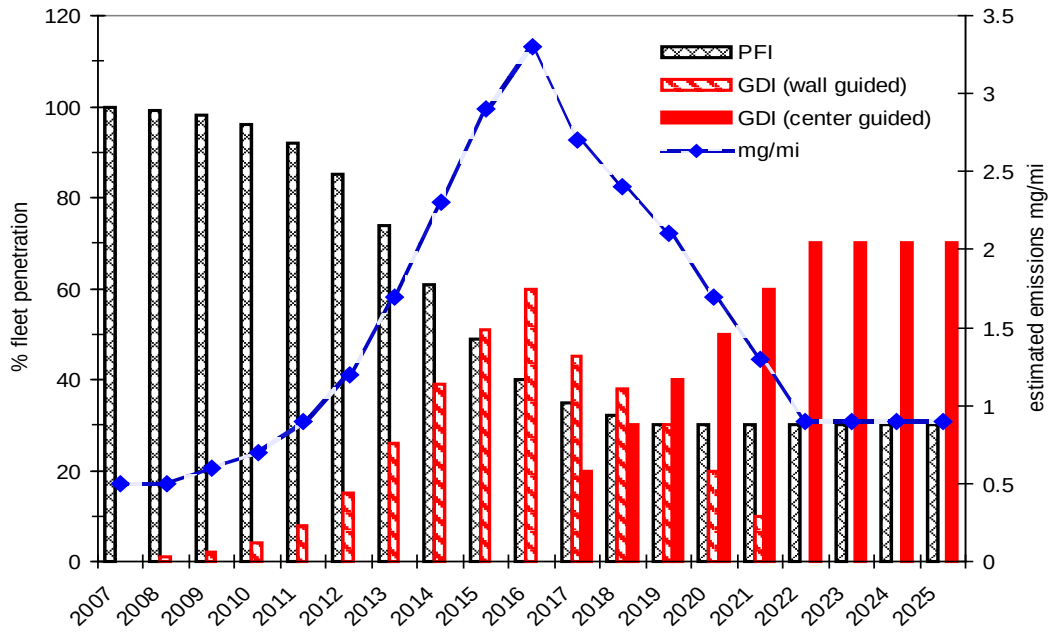

Table 10-1 below shows the reductions in emissions of PM from light duty gasoline vehicles with improved technology. We estimate there will be an approximately two ton per day reduction in PM emissions from light duty gasoline vehicles in 2040 caused by the penetration of GDI technology.

Table 10-1. Statewide Light Duty Gasoline PM Emissions (Tons per Day)

Year	Baseline (tons/day)	With Improved Technology (tons/day)
2014	3.6	3.6
2017	3.3	3.3
2018	3.3	3.2
2020	3.3	3.0
2022	3.4	2.8
2025	3.6	2.6
2035	4.2	2.0
2040	4.5	1.9

11 APPENDIX: HEAVY DUTY TRUCK EMISSION RATE UPDATES

The updates to heavy duty truck emission rates described in this section reflect updates to emission rates that were first integrated into the Statewide Truck and Bus Rule emissions inventory as external adjustments to emission rates developed using EMFAC2007. Those external adjustments in the rulemaking inventory have now been integrated into the EMFAC2011-HD calculation methodology and made consistent with EMFAC modeling methods on a regional basis.

There are four major updates that are covered in this document. The first is an update to medium-heavy duty diesel truck (MHDDT) running emission rates based on new test data. The second is improved assumptions about how manufacturers are complying with 2004, 2007, and 2010 emissions standards, and how that affects MHDDT and heavy heavy-duty diesel truck (HHDDT) emission rates. The third is carbon dioxide emission rate improvements using assumptions developed for the ARB's Statewide Truck and Bus Rule. Finally, idling emission rates are updated for both MHDDT and HHDDT.

In EMFAC2007 staff updated emission factors for heavy-heavy duty trucks based on emissions test data from the Coordinating Research Council (CRC) E55/59 project. The E55/59 project included testing on both heavy-heavy (HHDDT) and medium-heavy duty diesel trucks (MHDDT). After the release of EMFAC2007 the medium-heavy duty truck test data became available. Those data are used to update emission factors for medium-heavy duty trucks in EMFAC2011.

To revise the MHDDT emission factors, staff combined the E55/59 data into the data set that was used to develop MHDDT emission factors in EMFAC2002. The EMFAC2002 data set included emission test data from the New York State Department of Environmental Conservation and Energy, West Virginia University, and the Colorado Institute for Fuels, and High Altitude Engine Research. From the combined data set, staff then calculated zero-mile rates (ZMR) and deterioration rates (DR) of pollutants HC, CO, NOx, and PM.

The method of calculating MHDDT ZMR and DR is the same as that used for deriving emission factors of heavy heavy-duty trucks (HHDDT) in EMFAC2007. The method has been described in detail in an EMFAC2007 technical memo (ARB, 2006). Basically, the merged data set was divided into a number of model year groups by considering the general emission trends as well as changes in heavy-duty diesel engine emission standard and emission control technology. For each model year group, an average emission rate was calculated from the test data or projected based future emission standards, and a tampering and mal-maintenance (T&M) impact rate was also calculated. From the average emission rates and T&M impact rates, the ZMRs and DRs for HC, CO, NOx, and PM were then calculated for all model year groups using the Radian model. The revised MHDDT emission factors are given in Table 11-1. Note that in the table the NOx emission factors for 2006-2011 model years reflect the adjustments based on the latest engine certification data, and this will be discussed in the next section.

Table 11-1. Revised MHDDT ZMR (g/mi) and DR (g/mi/10,000mi) for MHDDT

Model Year Group	HC		CO		NOx		PM	
	ZMR	DR	ZMR	DR	ZMR	DR	ZMR	DR

2011	0.10	0.002	0.26	0.005	0.86	0.054	0.022	0.001
2012	0.10	0.002	0.26	0.005	0.67	0.041	0.022	0.001
2013+	0.10	0.002	0.26	0.005	0.67	0.041	0.022	0.001

Staff updated the 2006-2011 model year HHDDT and MHDDT emission factors in EMFAC2011 to reflect how engine manufacturers complied with the 2007 engine standards and how they comply with the 2010 engine standards between 2007 and 2011. A review of the certification data shows that some engine manufacturers introduced 1.2 g/bhp-hr NOx heavy-duty engines one year earlier than required and one manufacturer chooses to meet USEPA 2010 NOx standard without using selective catalytic reduction. For the earlier introduction of engines meeting 1.2 g/bhp-hr NOx and 0.01 g/bhp-hr PM standards, the current ZMR and DR for 2003-06 and 2007-09 model year groups were weighted by the sales fractions of 2007 standard compliant engines in 2006 model year.

For the introduction of 0.5 g/bhp-hr NOx engines in 2009 model year, staff estimated the ZMR by adjusting the current ZMR for 2006-2009 model year group (1.2 g/bhp-hr NOx engines) but assumed that the DR for 2006-09 model year would still apply to the 0.5 g/bhp-hr NOx engines. The assumption of unchanged DR is largely based on the fact that the engine manufacturers will achieve a 0.5 g/bhp-hr NOx level with an integrated technology solution based on their 2006-09 technologies.

Staff estimated the 2005-2008 model year sales fractions of heavy and medium heavy-duty diesel engines based on the sales fraction data reported by the manufacturers and projected the 2009-2012 model year sales fractions from the available information. The penetration rates for 2005 to 2012 model years are summarized in Table 11-2.

Table 11-2. Penetration Rates of 2005-2012 Model Year Engines

Model Year	Certified NOx (g/bhp-hr)				Certified PM (g/bhp-hr)	
	2.2	1.2	0.5	0.25/0.2*	0.1	0.01
HHDDT						
2005	100%					
2006	99%	1%			98%	2%
2007	14%	86%			1%	99%
2008	7%	93%				100%
2009		90%	10%			100%
2010			10%	90%		100%
2011			10%	95%		100%
2012				100%		100%
MHDDT						
2005	100%					
2006	100%				98%	2%
2007	23%	77%				100%
2008	12%	88%				100%
2009		90%	10%			100%
2010			10%	90%		100%
2011			10%	90%		100%
2012				100%		100%

* 0.25 g/bhp-hour applies to 2010 model year only.

Using the sales fractions in Table 11-2, staff calculated the NOx ZMR and DR of both HHDDT and MHDDT for 2006-2011 model years by weighting the ZMR and DR of the corresponding model year groups. Staff did not revise the PM emission factors for HHDDT and MHDDT. As seen in Table 11-2, the sales of PM filter-equipped engines in 2006 account for only about 2% for both HHDDT and MHDDT categories, and therefore the impact of DPF engines on the PM emission rates for the 2006 model year should be negligible. Table 11-3 shows the current and adjusted NOx ZMR and DR for 2006-2011 model year HHDDT and MHDDT.

Table 11-3. Before- and After-Adjustment NOx ZMR (g/mi) and DR (g/mi/10,000 mi) for 2006-2011 MY Heavy-Duty Diesel Trucks

Model Year	HHDDT				MHDDT			
	Before		After		Before		After*	
	ZMR	DR	ZMR	DR	ZMR	DR	ZMR	DR
2006	12.5	0.052	12.5	0.052	7.35	0.077	7.35	0.077
2007	6.84	0.047	7.66	0.057	4.01	0.062	4.78	0.065
2008			7.25	0.047			4.39	0.064
2009			6.44	0.046			3.78	0.062
2010	1.14	0.041	1.72	0.041	0.669	0.053	1.01	0.054
2011			1.46	0.041			0.859	0.054

*The adjusted ZMR and DR have been reflected in Table 1 (Revised MHDDT Emission Factors).

In addition to updating MHDDT emission factors for E55/59 test data, staff also updated carbon dioxide (CO2) emission rates using a similar methodology to that described in ARB (2008). In EMFAC2007, CO2 emission rates of diesel trucks were assumed to remain constant regardless of model year, technology, activity, and other factors. However, with the emphasis on greenhouse gas emissions control over the past few years, staff decided to update CO2 emission rates for individual model years in EMFAC2011. During the Board's In-Use On-Road Diesel Vehicle rulemaking, staff evaluated available data to determine how improvements in engine technology and increasingly stringent criteria pollutant emission control requirements have affected the fuel economy of trucks. Staff reviewed multiple data sources to characterize the variations in the fuel economy values of trucks in California. After fuel economy was estimated, fuel usage was then converted to CO2 emissions. The data and the method used for the CO2 emission rate update have been described in detail in Appendix G of the In-Use On-Road Diesel Vehicle rulemaking staff report (ARB, 2008). Table 11-4 gives the CO2 emission rates for both HHDDT and MHDDT.

Table 11-4. HHDDT and MHDDT CO2 Emission Rates (g/mi)

MY Group	HHDDT	MHDDT
Pre-1987	2,335	1,511
1987-1990	2,262	1,464
1991-1993	2,176	1,408
1994-1997	2,086	1,350
1998-2002	2,137	1,383
2003-2006	2,112	1,367
2007-2009	2,171	1,405
2010+	2,099	1,358
2010+/OBD	2,094	1,355

Staff also updated MHDDT idle emission rates. As with the revision of MHDDT running exhaust emission rates, the available CRC E55/59 idle emission test data allowed staff to revise the MHDDT idle emission rates in EMFAC2011. The method of analysis is the same as that used for calculating HHDDT idle emission rates in EMFAC2007 (see ARB, 2006). The high idle correction factors for HHDDT in EMFAC2007 are also applicable to MHDDT. Table 11-5 shows the revised MHDDT idle emission rates.

Table 11-5. Revised MHDDT Idle Emission Rates (g/hour)

	HC	CO	NOx	PM	CO2
Low Idle					
Pre-1987	20.0	38.7	59.4	5.65	3,802
1987-1990	8.08	23.7	64.6	2.47	4,029
1991-1993	5.56	19.3	71.9	1.75	4,246
1994-1997	3.86	15.7	82.1	1.25	4,532
1998-2002	2.41	12.1	99.3	0.810	4,995
2003-2006	1.73	10.1	113	0.599	5,357
2007-2009	1.73	10.1	30.0	0.0599	5,357
EPA2007	1.73	10.1	30.0	0.0599	5,357
High Idle for Summer					
Pre-1987	33.9	120	125	14.1	8,744
1987-1990	13.7	73.6	136	6.17	9,266
1991-1993	9.46	59.8	151	4.38	9,766
1994-1997	6.56	48.7	172	3.13	10,424
1998-2002	4.09	37.5	208	2.02	11,489
2003-2006	2.95	31.3	237	1.50	12,322
2007-2009	2.95	31.3	63.0	0.150	12,322
EPA2007	2.95	31.3	63.0	0.150	12,322
High Idle for Winter					
1987-1990	17.8	173	116	10.6	7,252
1991-1993	12.2	141	129	7.53	7,643
1994-1997	8.49	115	148	5.38	8,158
1998-2002	5.30	88.2	179	3.48	8,991
2003-2006	3.81	73.7	203	2.58	9,643
2007-2009	3.81	73.7	54.0	0.258	9,643
EPA2007	3.81	73.7	54.0	0.258	9,643

Finally, staff updated HHDDT idle emission rates for NOx and CO2. The EMFAC2007 NOx idle emission rates for HHDDT for 2007 and subsequent model years were projected based on the then prevailing assumption that engine manufacturers would adopt a 5-minute shut-off mechanism to comply with ARB's anti-idle rules. However, ARB certification data demonstrate that all engine manufacturers have instead chosen to meet the ARB requirements with the 30 g/hour NOx idle emission rate option. As a result, staff revised the NOx idle emission rates of 2008+ model year trucks in EMFAC2011 to reflect the engine certification data.

The HHDDT CO2 idle emission rates were also updated in EMFAC2011. In EMFAC2007, an average CO2 idle emission rate was used for all model years. To be consistent with the revision to the CO2 exhaust emission rates of HHDDT, in EMFAC2011 idle emission rates of CO2 were calculated for individual model year groups. Table 11-6 gives the updated NOx and CO2 idle emission rates of HHDDT.

Table 11-6. Updated HHDDT NOx and CO2 Idle Emission Rates (g/hour)

Model Year Group	NOx			CO2		
	Low Idle	High Idle for Summer	High Idle for Winter	Low Idle	High Idle for Summer	High Idle for Winter
Pre-1987	45.7	95.9	82.2	4,271	9,822	7,687
1987-1990	70.2	147	126	4,507	10,365	8,112
1991-1993	78.4	165	141	4,610	10,603	8,298
1994-1997	85.3	179	153	4,713	10,840	8,483
1998-2002	92.1	193	166	4,846	11,145	8,722

12 APPENDIX: DETAILED INCREMENTAL CHANGES

This section documents incremental changes made from EMFAC2007 to the final version of EMFAC2011-SG. Each major change is referenced in each section, and incremental changes are provided for each change for Statewide emissions as well as for the Sacramento Valley, San Francisco Bay Area, San Diego, San Joaquin Valley, and South Coast air basins. Model version names and version numbers are listed in each change.

12.1 REVISE CO_2 EMISSIONS DUE TO AIR CONDITIONING

The following pages give a breakdown and discussion of the emissions changes of the items discussed in Section 3.3.3.2. This update had the effect of reducing CO2 emissions by approximately 5%. This will vary by region depending upon temperature and humidity and age of the fleet.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.
PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.
Fuel[3] - VMT Matching by Fuel Type Using Populations

12.2 REVISE EVAPORATIVE DIURNAL BASIC EMISSION RATE COEFFICIENTS

Please refer to Section 3.3.3.3. This change only affects evaporative diurnal emissions, and has less than a 1% effect on emissions. It will vary by area based upon temperature, but for most areas this effect is insignificant.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.

PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.

Fuel[3] - VMT Matching by Fuel Type Using Populations

12.3 FIX RESTING TIME IN HOT SOAK ALGORITHM

Please refer to Section 3.3.3.4. This change resulted in a general increase in hot soak evaporative emissions by less than 2%. This factor does not very significantly by area.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.
PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.
Fuel[3] - VMT Matching by Fuel Type Using Populations

12.4 REVISE BRAKE WEAR PM EMISSION FACTOR

Please refer to Section 3.3.3.5. This update significantly increases PM10 emissions by 40 to 50%. The largest part of the change is due to moving the fleet away asbestos brakes which is independent of area. There is some regional variation largely because of fleet mix differences in heavy-duty trucks. It should be noted that brake ware tends to be larger particles, so the PM 2.5 disbenefit would be approximately 60% less.

12.5 HEAVY DUTY DIESEL TRUCK EMISSION FACTOR UPDATE

As described in Section 4.6, heavy duty diesel truck emission factors have been updated in accordance with new assumptions developed through the Statewide Truck and Bus Rule development process.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.

PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.

Fuel[3] - VMT Matching by Fuel Type Using Populations

12.7 NEW SURVIVAL RATES AND LIFETIME MILEAGE CALCULATIONS FOR MOTOR VEHICLES

Please refer to Section 3.3.4.3. This update includes two distinct changes, only one of which made its way into the final model. There are two separate effects. First, originally staff had planned to update survival rates for all vehicle categories, and this change was made here. The survival rates tend to make the fleet younger into the future. Ultimately, these survival rates were removed and only two were updated as described in Section 3.3.4.2. That change is discussed later in this section. Second, the new lifetime mileage calculation tends to reduce the odometer and therefore reduces the emissions. The first effect can be seen in the VMT. There is a slight increase because newer vehicles travel more. CO2 follows the VMT because there is not a strong age dependency, and there are no deterioration rates. The second effect is much more difficult to observe. The lower odometer values will reduce emissions, but the amount of production is dependent upon the smog check program in place and the area-specific accrual rates.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.

PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.

Fuel[3] - VMT Matching by Fuel Type Using Populations

12.8 REVISE GREENHOUSE GAS EMISSION FACTORS AND GASOLINE PM

Please refer to Section 3.3.3.1. and Section 3.3.3.6. These components were added to the model and the incremental emissions are discussed here together. The change in CO2 emissions are small, generally reducing by 0 to 2% independent of region. PM generally went down significantly, as much as 20% in the future. This is due to lower emission factors for newer vehicles and LEV. There was some increase in the past as older vehicles were found to be higher emitting in the Kansas City study.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.
PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.
Fuel[3] - VMT Matching by Fuel Type Using Populations

12.9 VMT AND SPEED DISTRIBUTIONS (FIRST ROUND)

Please refer to Section 3.3.2. This change is complex and highly regional specific. In general, the future VMT projections are lower. Intuitively, one would expect the future emissions to be lower. However, the slowdown in growth means fewer new vehicle sales, so the fleet actually gets older and new technologies are not introduced as quickly.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.

PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.

Fuel[3] - VMT Matching by Fuel Type Using Populations

12.10 TEMPERATURE AND RELATIVE HUMIDITY PROFILES

Please refer to Section 3.3.4.4. These changes are regionally dependent as well as seasonal. The incremental changes shown below are for summer. There would be other differences for winter or monthly. In general, where emissions increase the temperatures have gotten warmer and/or more humid. This results in more air conditioning usage. NOx is more complex in that higher humidity lowers NOx formation, but simultaneously increases air conditioning usage. This update also includes a change to the fleet mix update for 2000-2008 relative to connecting current and historical fleet mix estimates using multiple DMV analysis methods as described in Section 3.3.1**.**

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.

PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.

Fuel[3] - VMT Matching by Fuel Type Using Populations

12.11 UPDATES TO SPEED DISTRIBUTIONS

Please refer to Section 3.3.2. This updated the latest speed profiles provided by the local transportation planning agencies. The incremental changes vary by region but tend to be small.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.

PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.

Fuel[3] - VMT Matching by Fuel Type Using Populations

12.12 2004 - 2010 LEV 2 AND DIESEL BASELINE UPDATES

During the development of the LEV3 regulation it became apparent that many of the assumptions regarding the LEV2 program were obsolete and should be adjusted. Additionally, new registration data pointed out that many of our assumptions regarding light duty diesel technology were also obsolete. We updated EMFAC for what was actually sold. This generally reduced emissions, regardless of region.

Fuel[3] - VMT Matching by Fuel Type Using Populations

12.14 MISCELLANEOUS SURVIVAL RATE AND NEW VEHICLE SALES ADJUSTMENT

Please refer to Section 3.3.2. In addition to the survival rate adjustments, a cap was removed limiting the rate of new vehicle sales. That is, new vehicle sales were limited to no more than a 10% increase from the previous year. Because the base year, 2009 was a very low sales year, this limit was causing anomalies in the age distributions. This generally reduces emissions by allowing more new vehicles to enter the fleet, which generally have lower emission rates.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from evaporative processes.

PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear

Fuel[3] - VMT Matching by Fuel Type Using Populations

12.15 REMOVAL OF HEAVY DUTY TRUCKS

Please refer to Section 4. These incremental emissions document how the EMFAC model responds as the heavy duty fleet is removed from EMFAC to the truck model. As expected, this significantly reduces the NOx and PM inventories. Areas with higher truck VMT are disproportionately affected.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.

PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.

Fuel[3] - VMT Matching by Fuel Type Using Populations

12.16 LIFETIME MILEAGE CALCULATIONS AND EVAPORATIVE I/M

Please refer to Section 3.3.4.3. Staff inadvertently left out the adjustment for evaporative I/M. This had the effect of overestimating the benefit for smog check areas. In general this change increases ROG emissions on the order of a couple percent.

PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.							
Fuel[3] - VMT Matching by Fuel Type Using Populations							

12.17 REDUCTION IN LIGHT-HEAVY TRUCK STARTS

Please refer to Section 3.3.4.5. Reducing the number of starts reduces ROG and NOx, especially in the future. This effect is more pronounced in future years because of the large contribution of light heavy trucks to the hot soak and starts inventory in future calendar years.

Fuel[3] - VMT Matching by Fuel Type Using Populations							

12.18 DEFAULT ZEV IMPLEMENTATION ASSUMPTIONS

Please refer to Section 3.3.4.6. The change in the number of ZEVs had no measurable impact on the emissions inventory. EMFAC2011-LDV was finalized based on the working inventory *EMFAC2010-2.50.53*.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.							
PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.							
Fuel[3] - VMT Matching by Fuel Type Using Populations							

12.19 FINAL EMFAC2011

The final change to the EMFAC2011 emissions inventory is the addition of the diesel fueled truck and bus categories calculated using EMFAC2011-HD to the emissions inventory generated using EMFAC2011-LDV. The combined total from the LDV and HD modules is used as input to EMFAC2011-SG. The impact on emissions is shown below.

ROG_Tot[1] - This includes running, starting, idle exhaust emissions and emissions from all evaporative processes.							
PM10_Tot[2] - Total emissions from running, starting, idle processes, and from tire wear and brake wear.							
Fuel[3] - VMT Matching by Fuel Type							

12.20 JULY 2012 UPDATE TO SANTA CLARA COUNTY VEHICLE STARTS

The impact on emissions of fixing the bug described in Section 3.3.4.7 is shown below.

- ▶ The Clean Air Act

U.S. EPA 2007/2010 Heavy-Duty Engine and Vehicle Standards and Highway Diesel Fuel Sulfur Control Requirements

In December 2000, EPA adopted a rulemaking to establish stringent standards designed to reduce emissions from on-road heavy-duty trucks and buses by up to 95 percent and to cut the allowable levels of sulfur in diesel fuel by 97 percent. The EPA rule is the most significant and far-reaching mobile source initiative since Congress adopted the 1970 Clean Air Act Amendments establishing the U.S. Mobile Source Emission Control Program.

Beginning with the 2007 model year, 100 percent of the on-road diesel HDEs will require the use of a diesel particulate filter and 50 percent of the engines will require NOx exhaust control technology; beginning with the 2010 model year, 100 percent of the on-road heavy-duty diesel engines will require NOx exhaust control technology.

Key Elements of the Regulation

The rule has several key elements:

- A sulfur cap of 15 ppm beginning June 1, 2006 for 80 percent of the diesel fuel sold by major refiners for use in highway vehicles, becoming 100 percent after December 31, 2009. (ULSD became available at retail outlets on October 15, 2006.) In addition, small refiners, who produce approximately five percent of the on-road diesel fuel, are eligible to sell diesel fuel with 500 ppm sulfur until 2010.
- 0.01 g/bhp-hr PM standard that takes effect with the 2007 model year for all on-road diesel HDEs
- 0.2 g/bhp-hr NOx standard, a 0.14 g/bhp-hr NMHC standard, and a 0.016 g/bhp-hr formaldehyde (HCHO) standard for HDEs to be phased in beginning with the 2007 model year (diesel HDEs -- 50% for MYs 2007-2009 and 100% beginning with the 2010 MY; gasoline HDEs – 100% in 2007)
- New requirements for crankcase emissions on turbocharged diesel engines
- Tighter standards for heavy-duty vehicles certified as complete vehicles
- Standards requiring reduced evaporative emissions

Emission Standards

The emission standards for HDEs are shown in Table 1 below. Under the final rule, 50% of the engines must meet the 0.2 NOx standard for model years 2007-2009.

Manufacturers who sell diesel HDEs meeting the 0.2 g/bhp-hr NOx and 0.01 g/bhp-hr PM standards before the 2007 MY deadline will receive a credit of 1.5 for each engine sold (i.e., for every two low emitting engines sold before 2007, a manufacture will receive a credit for three engines sold beginning in 2007).

Table 1. Full Useful Life Heavy-Duty Engine Emission Standards and Phase-Ins

Engine Type	Pollutant	Standard (g/bhp-hr)	2007	2008	2009	2010
Diesel	NOx	0.20	50%	50%	50%	100%
Diesel	NMHC	0.14	50%	50%	50%	100%
Diesel	HCHO	0.016	50%	50%	50%	100%
Gasoline	NOx	0.20	0%	50%	100%	100%
Gasoline	NMHC	0.14	0%	50%	100%	100%
Gasoline	HCHO	0.016	0%	50%	100%	100%
Diesel	PM	0.01	100%	100%	100%	100%
Gasoline	PM	0.01	0%	50%	100%	100%

For vehicles between 10,000 and 14,000 pounds, the standards are 0.4 g/mi for NOx, 0.02 g/mi for PM, and 0.230 g/mi for NMHC. EPA believes these standards are roughly comparable to the engine-based standards in these size ranges.

Note that these standards would not apply to vehicles above 8500 pounds that we classify as medium-duty passenger vehicles as part of our Tier 2 program because of their primary use as passenger vehicles (the final standards for these vehicles are in 65 FR 6698, February 10, 2000). The standards for HDVs are shown in Table 2.

Table 2. Emission Standards for HDVs

GVWR (lbs)	PM (g/mi)	NOx (g/mi)	NMHC (g/mi)
8,500-10,000	0.02	0.2	0.195
>10,000-14,000	0.02	0.4	0.230

EPA also revised the evaporative emissions standards for heavy-duty engines and vehicles, effective in the 2007 model year. The evaporative emission standards are shown in Table 3.

Table 3. Evaporative Emission Standards

GVWR (lbs)	3-Day Diurnal Test	Supplemental 2-Day Diurnal Test
8,500-14,000	1.4 g/test	1.75 g/test
>14,000	1.9 g/test	2.3 g/test

Diesel Sulfur Limits

EPA had originally proposed a 15 ppm sulfur cap for all diesel fuel sold for on-road vehicles beginning in 2006. To address concerns expressed by the U.S. Department of Energy regarding possible fuel shortages and price spikes, and in recognition of the special burden placed by the rule on small refiners, EPA in the final rule called for a phase-in of the 15 ppm low sulfur diesel fuel requirement. From June 1, 2006 to December 31, 2009, a minimum of 80% of the diesel fuel sold by large refiners (on a pad-by-pad) basis must meet the 15 ppm sulfur limit, with the remaining diesel fuel meeting a 500 ppm limit. Credit trading between refiners is allowed on a regional (i.e., pad-by-pad) basis. Small

refiners, who produce approximately five percent of the on-road diesel fuel, are given until 2010 to meet the 15 ppm sulfur limit.

Small refiners who elect to produce diesel fuel meeting the 15 ppm sulfur limit are also given the option of receiving an additional three years or until 2011 to meet the gasoline sulfur limit.

Less than 100 percent availability of 15 ppm sulfur diesel does raise the issues of a duel fuel distribution system and the possibility of fuel contamination, but EPA is confident these issues can be addressed. Also, EPA anticipates that the amount of low sulfur diesel fuel actually sold in the 2006-2009 timeframe will approach 90 percent.

Costs

EPA estimates that the proposed standards will add about $1200 to $1900 per new vehicle, depending on the vehicle size. To put these costs in perspective, a truck can costs as much as $150,000 and a bus can cost as much as $250,000.

The agency estimates that cutting sulfur levels from the current 500 ppm level to 15 ppm will add about 4-5 cents per gallon to produce and distribute diesel fuel, but there will be a cost off-set of 1 cent per gallon from vehicle maintenance savings resulting from the use of cleaner diesel fuel.

Air Quality Benefits

EPA estimates that the new standards will reduce smog-forming NOx emission by 2.6 million tons annually when the program is fully implemented in 2030. Emissions of PM will be reduced by 110,000 tons each year, hydrocarbons by 115,000 tons each year, and toxic air pollutants such as benzene by 17,000 tons annually. EPA estimates that the emission reduction benefits of the rule is equivalent to removing 13 million of today's trucks out of service.

December 2014

Table of Contents

1 Introduction

The mobile source particulate matter inventory includes exhaust emissions and non-exhaust emissions. Exhaust emissions include particulate matter attributable to engine related processes such as fuel combustion, burnt oil, and other particles that exit the tailpipe. Non-exhaust processes include brake wear, tire wear, suspension or resuspension of road dust, and other sources. Particulate matter from brakes and tires is defined as the airborne portion of the "wear" that can be created by abrasion, corrosion, and turbulence. These wear processes can result in particles being suspended in the atmosphere. The size, chemical composition, and emission rate of particles arising from such sources contributes to atmospheric particle concentrations. However, these particles are composed of different species and size than exhaust particulate matter.[1]

The literature review for the development of the brake and tire wear emission models was conducted in 2006 and 2007, the models were developed for MOVES2010, and this report was written in 2008. However this documentation was not revised until the peer review complete in 2014 and no revisions to the model were made. As of 2007, the references in this report were recent, yet there were likely a few publications on particulate matter from brake and tire wear which were not included in the original literature review. In the sections below we present the studies from the literature conducted at the time, as well as the models that were developed based on the best data presented in the papers cited. A more recent literature search and a potential model update will be conducted in the future.

2 Brakewear

2.1 Literature Review

There are two main types of brakes used in conventional (or non-hybrid electric) vehicles: disc brakes and drum brakes. In a drum brake the components are housed in a round drum that rotates with the wheel. Inside the drum are shoes that, when the brake pedal is pressed, force the shoes against the drum and slow the wheel. By contrast, disc brakes use an external rotor and caliper to halt wheel movement. Within the caliper are brake pads on each side of the rotor that clamp together when the brake pedal is pressed.[2]

The definition of wear versus airborne PM seems to have slightly different definitions in the literature. In this paper it is generally the mass of material lost, whether in the brake pads or the tires. A fraction of that wear is airborne PM. Some studies look at both wear and airborne PM, others look at one or the other. In brakes, the composition of the brakeliner has an influence on the quantity and makeup of the released particles. Disc brakes are lined with brake pads while drum brakes use brake-shoes or friction linings. These materials differ in their rate of wear, their portion of wear particles that become airborne, and the size as well as composition of those particles. Both types of brakes use frictional processes to resist inertial vehicle motion. The action of braking results in wear and consequent release of a wide variety of materials (elemental, organic and inorganic compounds) into the environment.

The overall size or mass of the brake pads also varies with vehicle type. Typically trucks use larger brakes than passenger vehicles because the mass of vehicle that requires slowing down or stopping is greater. In 2004, most light duty vehicles used disc brakes in the front and drum

brakes in the rear. Disc brakes tend to have improved braking performance compared to drum brakes and have correspondingly higher cost. Disc brakes are sometimes used on rear wheels as well for higher performance (sportier) vehicles.

As a complicating issue, the particulate matter from brakes is dependent on the geometry of the brakes, wheels and rims. The air flow through the rims to cool the brakes and rotors play a key role in determining the wear characteristics. The emissions are also sensitive to driver activity patterns, where more aggressive stop and go driving will naturally cause greater wear and emissions.

There are only a very limited number of publications on brake wear PM emissions. There are even fewer publications discussing size distributions and speciation, and none quantifying emissions modally on which to directly base a model. This section summarizes the limited literature as of 2006. More details of the literature on brake and tire wear can be found in Appendix D. One of the earliest studies on brake wear emissions was done in 1983.[3] Particulate emissions from asbestos-based brakes from automobiles were measured under conditions simulating downtown city driving. The report presented a systematic approach to simulating brake applications and defining particulate emissions, and was used in the development of the EPA PART5 model.[4] For PART5, EPA calculated PM_{10} emission factors for light-duty gasoline vehicles of 12.5 mg/mi for brake wear. Since 1985, the asbestos in brakes has been replaced by other materials, and newer studies have been conducted. These factors suggest the need for this update of the emission factors applicable to more modern vehicles.

Garg et al. (2000) conducted a study in which a brake dynamometer was used to generate wear particles under four wear conditions (much of the background information provided in the previous paragraphs are from this paper).[5] The study was performed using seven brake pad formulations that were in high volume use in 1998. Measurements were taken on both front disc as well as rear drum brakes. The study measured mass, size distribution, elemental composition, as well as fiber concentration at four temperature intervals. The report also estimated $PM_{2.5}$ and PM_{10} emissions for light-duty vehicles of 3.4 and 4.6 mg/mile, respectively for small vehicles, and $PM_{2.5}$ and PM_{10} emissions of 8.9 and 12.1 mg/mile, respectively for pickup trucks.

Sanders et al (2003)[6] looked at three more current (as of ~2003) classes of lining materials: low metallic, semi-metallic and non-asbestos organic (NAO) representing about 90% of automotive brakes at that time. Three kinds of tests were conducted: a dynamometer test, a wind tunnel test and a track test at the Ford Dearborn proving grounds. Three sets of brake conditions were used: (a) the first set of tests evaluated all three materials on a brake dynamometer under mild and aggressive driving conditions, the urban driving program (UDP) with a set of 24 stops and a -7.9 m/s^2 deceleration called the Auto Motor und Sport magazine (AMS) test; (b) a series of high speed 1.8 m/s^2 stops of a mid-size sedan with low metallic brakes were conducted in a wind tunnel; and c) measurements of the same vehicle on a test track where collected where decelerations were made from 60 mph at 0.15, 0.25 and 0.35 g-forces, the latter corresponding to the AMS test to compare to the brake dynamometer. The latter test included low metallic as well as NAO materials. The authors found that the mean particle size and the shape of the mass distribution are very similar for each of the three linings, however they found that the low metallic linings generate 2-3 times the number of wear particles compared to semi-metallic and NAO linings. They also found that wear (and portion of wear that is airborne PM emissions) increased non-linearly with higher levels of deceleration. Wear debris composition was found to

have the most abundant elements consisting of Fe, Cu, Si, Ba, K and Ti, although the relative composition varied significantly by brake type. The authors further found that 50-70% of the total wear material was released in the form of airborne particles.

Table 2-1 contains the emission rates derived from the literature review conducted in support of MOVES2009. While there are emission rates presented from other papers, this paper largely relies on the Sanders et al. paper as it includes the widest array of materials currently in use, measurement techniques, and deceleration ranges in a scientifically designed study. It is the only paper from which modal rates can be derived. It is also the most recent of the papers listed and improves on the measurement methods introduced in its predecessors. The other papers results are provided as a source of comparison. Note that the range of rates from Sanders et al. (2003) largely covers the range presented in the other papers as well. When determining the rates below, the values from Garg et al. (2000), are also used.

Table 2-1 Non-Exhaust PM Emissions (per vehicle) from Mobile Sources Literature Values of emission factors from brake lining wear (largely cited in Luhana et al. (2004)'s literature review

Literature Source	Vehicle Type	$PM_{2.5}$ [mg/km]	PM_{10} [mg/km]
Luhana et al.(2004)	Light Duty		0-79
	Heavy Duty		0-610
Sanders et al. (2003)	Light Duty		1.5 -7.0
Abu- Allaban et al.(2003)	Light Duty	0 - 5	0-80
	Heavy Duty	0-15	0-610
Westurland (2001)	Light Duty		6.9
	Heavy Duty		41.2
Garg et al(2000)	Passenger Cars*	3.4	4.6
	Large Pickup Trucks	8.9	12.1
Rauterberg-Wulff (1999)	Passenger Cars		1.0
	Heavy Duty Vehicles		24.5
Carbotech (1999)	Light Duty		1.8-4.9
	Heavy Duty		3.5
Cha et al.(1983) used in PART5	Cars and Trucks		7.8

* In this table, "passenger cars" are equivalent to light duty cars. "Light Duty" on their own includes all Light-duty vehicles, including trucks though the studies are not all equivalent in their definitions.

2.2 Developing Rates for MOVES

2.2.1 Emissions during braking

The MOVES2009 braking emission rate is based on the average of:

(1) Composition of brake pad
(2) Number (and type) of brakes
(3) Front vs rear braking
(4) Airborne fraction

and explicitly accounts for:

(1) Particle mass size distribution ($PM_{2.5}$ vs PM_{10})
(2) Braking intensity
(3) Vehicle class: Light-Duty vs Heavy-Duty

As discussed in Sanders et al. (2003), most brake pads (at the time of the publication of that paper) are either low-metallic, semi-metallic (full-truck), or non-asbestos organic (full-size car). Using the results from this study, we make the following assumptions which are consistent with those used in the paper.

- equal mix of the three brake types,
- four brakes per light duty vehicle, including 2 front disc brakes, and 2 rear drum brakes
- 2/3 of braking power (and thus emissions) in front brakes (1/3 rear)[a]
- the fraction of total PM below 2.5um is ~ 10% (+/-5%)[b]
- 60% of brake wear is airborne PM (+/- 10%).

We also do not compensate for the different average weights of the vehicles (though the MOVES VSP bins scale emissions with mass). We assume there is an equal mix of the three brake types because the market share penetration is not known.

For each test cycle from Sanders et al. (2003) and Garg et al. (2000), the following figures show how we went from the measured results to emission rates of g/hour (for deceleration times only) at various deceleration speeds. Sanders et al. (2003) used three measurement techniques, a filter, an Electrical Low Pressure Impactor (ELPI), and a Micro-Orifice Uniform Deposition Impactor (MOUDI). While all three measurement techniques produced similar results, we show all here. Test results are shown for the UDP and wind tunnel tests from Sanders et al. (2003), as well as the Garg et al. (2000) analysis. The latter paper adds another deceleration point for comparison. The AMS results are not presented in the Sanders paper, however, the authors provided the data for the purposes of this study.

[a] Based on discussions with author of paper Matti Mariq at Ford Motor Company and consistent with the Garg et al. (2000) paper, who used 70%. Some of the other assumptions in this list is also from these discussions

[b] More will be discussed below.

Table 2-2 – UDP results[c]

Test	brake lining	PM_{10} emiss. (mg/stop/brake) filter	ELPI	
UDP				
	low metallic	6.9[d]	7.0	
	semi-metallic	1.7	1.7	
	Non-asbestos	1.1	1.5	
Average/stop/brake		3.2	3.4	
Avg. /veh		9.7	10.2	
deceleration =			**0.0012**	**km/s^2**
avg. brake time in secs =			13.5	secs
avg. emissions in mg/stop =			9.95	Mg/stop
emission rate for the UDP test =			**2.65**	**g/hr**

Table 2-3 – Wind Tunnel results

Test	brake lining	PM_{10} emiss. (mg/stop/brake) filter*	ELPI	MOUDI	
Tunnel					
	low metallic	44	45	40	
deceleration=			**0.0018**	**in km/s^2**	
Initial Velocity V(0) =			0.0267	in km/s	
avg. brake time in sec =V(0)/dec			14.8	secs	
avg. emissions in mg/stop =			129.0	mg/stop	
emision rate for the wind tunnel test=			**31.4**	**g/hr**	

[c] As these are intermediate values, the number of significant digits may exceed the precision known, however they are kept in this presentation, and rounded for the final results. The UDP decelerations are the average decelerations from those measured in the Sanders paper. The average brake times were determined with the assistance of one of the original authors of the paper (Matti Mariq) who supplied the second by second trace. The filter PM10 were determined by multiplying the total PM reported in Table 5 of the paper with the PM10 to total PM ratio determined from the ELPI measurement.

[d] Sanders et al, reports the total filter PM to be 8.2 mg/brake/stop. In order to get PM10 equivalent, we applied the ELPI ratio from table 5 in the reference. So 6.9 = 8.2* (7/8.3). The other numbers were calculated in a similar fashion. Also, the avg per vehicle emissions is the avg stop/veh/brake emissions multiplied by 3. This is based on the assumption made earlier that 2/3 of braking comes from the front brakes and 1/3 from the rear brakes.

Table 2-4 – AMS results

Test	brake lining	PM_{10} emiss.	(mg/stop/brake)
AMS		filter	ELPI
	low metallic	800	70
	semi-metallic	510	63
	Non-asbestos	550	92
	Average=	620	75
	Avg/veh rate =	1116	135

deceleration =	0.0079	in km/s^2
Initial Velocity V(0) =	0.0278	in km/s
avg. break time in sec =V(0)/dec	3.5	secs
avg. emissions in mg/stop for PM_{10}=	1116	mg/stop
emision rate for PM_{10} for the AMS test=	**1143**	**g/hr**
avg. emissions in mg/stop for $PM_{2.5}$=	135.0	mg/stop
emision rate for $PM_{2.5}$ for the AMS test=	**138.2**	**g/hr**

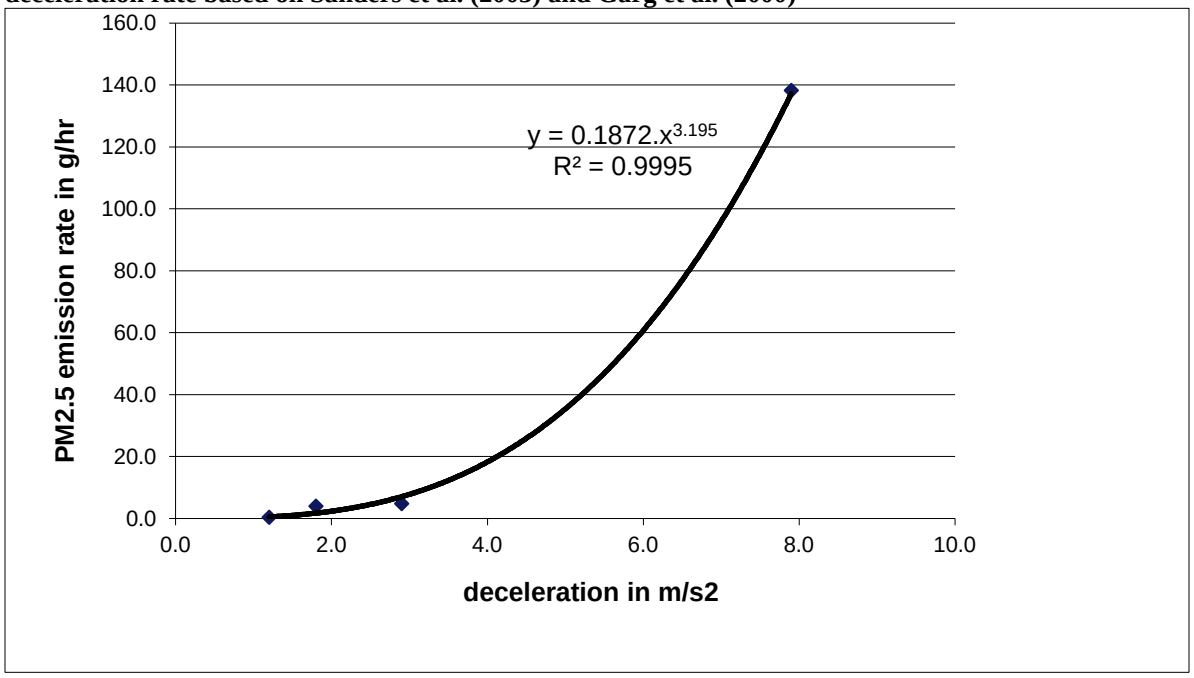
Table 2-5 – Garg et al. (2000) results

Test	brake lining	PM_{10} emiss.*	$PM_{2.5}$**	(mg/stop/brake)
avg. over all temp.	semi-metallic #1	1.85	1.35	
	semi-metallic #5	0.82	0.60	
	NAOS #2	2.14	1.57	
	NAOS #3	0.89	0.66	
	NAOS#7	1.41	1.03	
	Grand Avg. =	1.42	1.04	mg/stop

deceleration =	0.00294	in km/s^2
Initial Velocity V(0) =	0.0139	in km/s
avg. break time in sec =V(0)/dec	4.7	secs
avg. emissions in mg/stop for PM_{10} =	1.42	mg/stop
emision rate for PM_{10} for the GM test=	**1.08**	**g/hr**
avg. emissions in mg/stop for $PM_{2.5}$ =	1.04	mg/stop
emision rate for $PM_{2.5}$ for the test=	**0.79**	g/hr

We used these four data points to fit a power function to determine the emission rate at different deceleration levels shown in the following figure. The AMS test, at higher decelerations, clearly has a significant influence on results of the curve fit. Additional high speed tests could be used for future refinement of this data.

Figure 2-1- Brake wear $PM_{2.5}$ emission rates in units of grams per hour for light duty vehicles as a function of deceleration rate based on Sanders et al. (2003) and Garg et al. (2000)



2.2.2 Activity

In the previous section, we determined the rate of particulate matter emissions during braking in units of grams per hour (per vehicle) as a function of deceleration level for a light-duty vehicle. However, for MOVES, we also need to determine the frequency of different levels of braking. The MOVES vehicle specific power (VSP) bins are relatively coarse for braking.[e,7] There is a large braking bin (operating mode 0) that contains a large fraction of driving activity, however there are also a number of "coasting" bins that also contain braking events in each speed category (Table 2-6). Each of these deceleration operating modes include some braking as well as cruise and coasting operation (where the throttle is closed or nearly closed, but the brakes are not applied). Therefore, the emission rate assigned to these bins need to contain the appropriate average rates including the mix of driving and deceleration frequencies, and including decelerations that do not include braking.

[e] While this document does not provide a detailed discussion of vehicle specific power, the light duty emission rate report have an extensive discussion

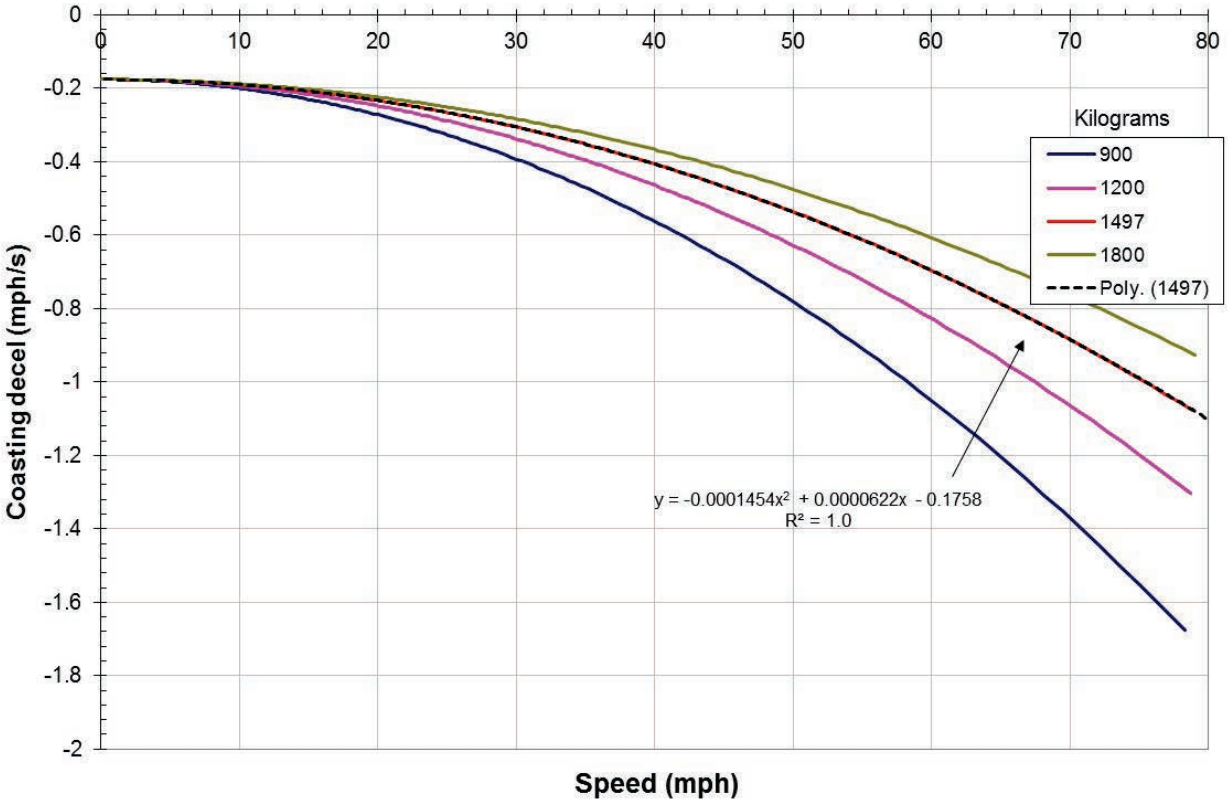
Table 2-6. VSP Operating Mode Bins by VSP and speed. Operating mode 0 and 1 (not listed) are braking and idle respectively

VSP Class (kW/tonne)	Speed Class (MPH)		
	1-25	25-50	50+
30+	16	30	40
27-30		29	39
24-27			
21-24		28	38
18-21			
15-18		27	37
12-15			
9-12	15	25	35
6-9	14	24	
3-6	13	23	33
0-3	12	22	
<0	11	21	
Operating mode where braking is assumed			

We estimated the fraction of activity that is braking within each of the "coasting" bins by first determining the coast down curve, then combining that with the activity fraction as seen in real-world driving surveys.

The coastdown curves were generated using the Physical Emission Rate Estimator (PERE).[8] This was done by using the coastdown equations from PERE, and calculating the deceleration at each speed when the forward tractive power is zero. We assumed all activity below coastdown is braking and all activity above the curve is low throttle deceleration. Figure 2-2 shows coastdown curves for cars of a variety of weights (and coastdown coefficients). The dotted curve is a typical coast down curve for this class of vehicle, where 1,497 kg is the typical mass of a light duty vehicle. The average weight for passenger cars used in MOVES is 1,497 kg.

Figure 2-2- Modeled Coastdown curves using the PERE model for a variety of light-duty vehicles masses



The deceleration activity was determined from two real world instrumented vehicle studies: one from Kansas City and the other in Los Angeles. The Kansas City study was conducted by EPA and Eastern Research Group (ERG) in 2005 to study real world driving activity and fuel economy on conventional as well as hybrid electric vehicles.[9] Over 200 vehicles were recruited, though for the current analysis, only the activity data from the conventional, or non-hybrid, population were examined. The Los Angeles activity data was conducted by Sierra Research for the California Department of Transportation with both instrumented vehicles as well as chase car data[10,11,12]. The deceleration data was analyzed for both of these studies.

Table 2-7 shows the distribution of braking activity across deceleration levels from both of these studies. As expected, the vast majority of braking occurs during mild decelerations rather than full (high decel) stops. More information about the PERE coastdown calculation process is described in Appendix A.

Table 2-7 – Activity Distribution of braking activity in the LA and Kansas City studies for each deceleration bin.

Decel (mph/s)	LA urban	LA rural	KC	AVG
1	37.1%	27.1%	54.5%	39.5%
2	26.3%	27.9%	26.3%	26.9%
3	17.9%	20.2%	12.8%	17.0%
4	10.2%	12.2%	4.6%	9.0%
5	5.6%	8.2%	1.3%	5.0%
6	1.6%	2.4%	0.30%	1.4%
7	0.64%	0.98%	0.07%	0.6%
8	0.28%	0.41%	0.02%	0.2%
9	0.17%	0.26%	0.02%	0.2%
10	0.10%	0.13%	0.01%	0.08%
11	0.05%	0.09%	0.01%	0.05%
12	0.03%	0.05%	0%	0.03%
13	0.01%	0.01%	0%	0.01%
14	0%	0.01%	0%	0%

2.2.3 Emission Rate for Light Duty vehicles

The emission rate curve from Figure 2-1 was combined with the average activity in Table 2-7 discussed above (using a sum of the product) to calculate MOVES rates for light duty vehicles. This gives an average $PM_{2.5}$ braking emission rate of 0.557 g/hr.

However, as mentioned earlier, MOVES has brake emissions in not only VSP op-mode bin 0 (defined as the braking bin), but also in modes 1,11,21,33. Idle (zero speed, op-mode bin 0) braking occurs in the transition (deceleration) from non-zero speed to zero speed which is a small amount of activity in this bin. Bins 12 and 22 also contain a very small amount of braking, which are ignored – i.e, the rates in these bins are set to zero. The brake emission rate in the other bins were reduced by the amount of braking activity in each bin.[f] These braking fractions were derived by combining the amount of average activity from Kansas City and LA above and the coast down curves from PERE discussed earlier. The results are shown in Table 2-8 below.

[f] For example, the $PM_{2.5}$ emission rate in VSP bin 11 for light-duty vehicles is 0.557 * 0.978 = 0.546 g/hr

Table 2-8 – Vehicle Specification (top) and Fraction of Activity in VSP bin that is braking (last 5 rows) for a variety of vehicle types (motorcycle and bus activity fractions were copied from Light-duty and heavy-duty trucks respectively).

	Mid-size car (LDV)	SUV (LDT)	LHDT (<=14k)	LHDT (>14k)	MHDT	HHDT
wgt (kg)	1497	1800	5602	9333	13517	22680
Cr0 (rolling resistance)	0.008	0.008	0.008	0.008	0.01	0.01
Cd (drag coeff)	0.32	0.36	0.37	0.44	0.44	0.44
A (frontal area m^2)	2.25	2.5	2.75	6.7	6.7	8.64
vsp bin						
0	1	1	1	1	1	1
1	0.0437	0.0437	0.0316	0.0316	0.0316	0.016
11	0.975	0.975	0.913	0.906	0.91	1
21	0.641	0.661	0.743	0.685	0.725	0.641
33	0.115	0.122	0.126	0.116	0.121	0.068

2.2.4 $PM_{10}/PM_{2.5}$ Brake Wear Ratio

MOVES stores $PM_{2.5}$ brake wear emission rates by operating mode bin, then estimates PM_{10} emission rates by applying a $PM_{10}/PM_{2.5}$ ratio. The $PM_{10}/PM_{2.5}$ ratio is based on the assumptions that the mass fraction of particles below PM_{10} is 0.8, and the mass fraction of particles below $PM_{2.5}$ is 0.1. More specifically, Sanders et al. (2003), report PM "fractions and cutoffs of 0.8 at 10 µm, 0.6 at 7 µm, 0.35 at 4.7 µm, 0.02 at 1.1 µm, and <0.01 at 0.43 µm for the UDP stops typical of urban driving". These assumptions result in a $PM_{10}/PM_{2.5}$ ratio of 8. Where no $PM_{2.5}$ values were reported, we calculated $PM_{2.5}$ from PM_{10} emission rates using this fraction. This estimate widely varies in the literature. Abu- Allaban et al. (2003) reports that only 5-17% of PM_{10} is $PM_{2.5}$, which is consistent with Sanders. Garg et al. (2000), report 72% of PM_{10} is $PM_{2.5}$, which is disputed by Sanders et al. (2003). The current study does use the $PM_{2.5}$ measurement reported by Garg et al. (2000), however in reality, this single value has little impact on the curve fit in Figure 2-1, which is dominated by the more recent data from Sanders et al. (2003).

The emission rates in g/hr $PM_{2.5}$ and PM_{10} by operating mode and regulatory class are included in Appendix B. The rates are calculated per the methodology described above and is independent of model year and environmental conditions. The average $PM_{2.5}$ and PM_{10} brake wear emission rates for passenger cars and trucks from three urban county inventories, using MOVES2014 are displayed in Table 2-9. MOVES brake wear emission rates by source type will vary according to the inputs of average speed, and VMT by road type, which impacts the distribution of operating modes within each source type in MOVES.

Table 2-9 Average PM2.5 and PM10 brake wear emission rates (mg/mile) for passenger cars and trucks from 3 urban county inventories using MOVES2014

	$PM_{2.5}$	PM_{10}
Passenger Cars (21)	3.7	29.8
Passenger Trucks (31)	6.2	49.8

The average passenger car MOVES PM_{10} emission rates of 29.8 mg/mi (output from the model) is compared to the previous studies (in the literature) in Table 2-1. Carbotech (1999), Sanders et al. (2003) , Garg et al. (2000), are all laboratory measurements and have significantly smaller reported emission rates than the present study. On the other hand Luhana et al. (2004), Abu-Allaban et al. (2003), Westurland (2001), and Rauteberg-Wulff (1999) are roadside measurement or tunnel measurements. These studies generally have higher emissions than laboratory measurements. The MOVES rates largely generated from Sanders et al. (2003), are also considerably larger than the publication cites. This is largely due to the fact that Sanders et al. (2003), cites results primarily from the UDP braking events which are significantly milder than the AMS decelerations. Through the modeling described in this paper, the AMS deceleration rates are weighted in to the milder deceleration emission rates to give higher rates comparable now to some of the results achieved from the tunnel and roadside studies. The light duty rates are thus calibrated to laboratory measurements adjusted to real-world factors, and "validated" to be within the range of roadside and tunnel measurements.

2.2.5 Brake Wear Emissions for Heavy-Duty Vehicles and Other Vehicle Types

There is very little literature on direct heavy-duty brake emissions measurements. To decelerate, heavy-duty vehicles employ technologies such as disc and drum as well as other braking methods including downshifting and engine (or "jake") braking. A scientific study comparing the emissions and relative activity of each of these methods of braking is beyond the scope of this report. In order to estimate brake wear emission factors for heavy-duty vehicles an engineering analysis was combined with results from a top-down study performed by Mahmoud Abu-Allaban et al. (2003).[13] The authors collected particulate matter on filters near roadways and apportioned them to sources utilizing Chemical Mass Balance, CMB, receptor modeling along with Scanning Electron Microscopy. The study was performed at roadside locations in Reno, Nevada and Durham, North Carolina where intensive mass and chemical measurements were taken. The authors of the paper attempted to collect and differentiate between PM measurements from tailpipe, tire, road dust, and brake from light- and heavy-duty vehicle types. Compared to the other papers described in the previous section (on light-duty braking) that include heavy-duty rates, the Abu-Allaban paper is one of the most recent studies of its kind performed at the time of the writing of this paper. The results are consistent with the heavy-duty rates measured from Luhana et al. (2004) as well as Westurland (2001), but is the only paper to measure $PM_{2.5}$. The paper's light-duty rates are also aligned with the rates determined above.

In this study, $PM_{2.5}$ brake wear emission rates for heavy duty vehicles ranged from 0 to 15 mg/km (0 to 24 mg/mi). For this analysis we have assumed the emission rate was the midpoint of the range of emission factors, or 12 mg/mi. For the purposes of populating MOVES rates, we

do not employ the measured emission rate directly from this study due to the extreme uncertainty and variability of measurement and locations selected. Rather, we rely on the paper's comparison of light-duty to heavy-duty emission factors. On table 5 of the paper, the emission rates for the exit ramps are reproduced below. Only the exit lanes were included of the many roads where measurements were collected. The remainder of the roads are represented by the average and the (min to max) range reported in the table.

Table 2-10 Brake Wear Emission Rates reproduced from Abu-Allaban et al. (2003)

Location	Vehicle Type	PM_{10} (mg/km)	$PM_{2.5}$ (mg/km)
J. Motley Exit	Heavy-Duty	610 ± 170	0 ± 0
	Light-Duty	79 ± 23	0 ± 0
Moana Lane Exit	Heavy-Duty	120 ± 33	0 ± 0
	Light-Duty	10 ± 3	0 ± 0
Average over all roads	Heavy-Duty	124 ± 71	2 ± 2
	Light-Duty	12 ± 8	1 ± 0
Range (min to max) of measurements on all roads	Heavy-Duty	0 to 610	0 to 15
	Light-Duty	0 to 80	0 to 5

Due to the difficulty of differentiating a small brake emissions signal from the much larger signal coming from tailpipe, tire wear and road dust combined, there is much uncertainty in these measurements – yet another reason why adjusted laboratory measurements were favored above. Clearly $PM_{2.5}$ was difficult to measure from most sites. Interestingly, the heavy-duty measurements were highest on the exit lanes for PM_{10}, however (rather inexplicably), the other road types had higher emissions than the exit lanes for $PM_{2.5}$. For these reasons, we rely more on averages to determine our ratio of heavy-duty to light-duty brake emission factors. From these measurements, we can determine that the average ratio of HD to LD brake emissions is 10 and 2 for PM_{10} and $PM_{2.5}$ respectively.[g] On average, based on Table 2-10, the ratio is 7.6 for PM10. The following table compares the ratio for the remaining studies for comparison.

Table 2-11- Ratio of Heavy-Duty to Light-Duty PM from the literature.

Study	**$PM_{2.5}$**	**PM10**
Luhana et al. (2004)		7.7
Abu-Allaban et al. (2003)	3	7.6
Westurland (2001)		6.0
Rauterburg-Wulff (1999)		24.5
Carbotech (1999)		0.7

For the purposes of MOVES, a simpler model requiring a single ratio of HD to LD brake emissions and another ratio of PM_{10} to $PM_{2.5}$ brake emissions is attractive – particularly since the data to populate the model is sparse. Also the broad range of uncertainties in the literature can support such simplification. Based on the range in the table, above, the value of the ratio chosen is 7.5, very close to the ratio as measured by Abu-Alaban et al. (2003), and consistent with the range of studies.

[g] Though it is not shown in the table here, according to Abu-Alaban, based on the highest sampling sites (maximum measurements from the table), the ratio of HD to LD brake emissions is 41 and 16 for PM_{10} and $PM_{2.5}$ respectively.

The estimated emission factors for all other categories of vehicles (between light and heavy-duty) were derived by linearly interpolating the rates between light-duty and combination heavy-duty vehicle classes by their respective weights as shown in the figure below. This is based on a rather simple engineering (and unproven in this study) hypothesis that the relative brake emissions is proportional to the weight of the vehicle classes relative to (and bounded by) light and heavy-duty vehicles. The hypothesis is based on the assumption that relative mass of the vehicles is proportional to the relative energy required to stop the vehicles. Figure 2-3 below shows the relative mass of light- and heavy-duty vehicles. The corresponding emission rates are in Table 2-12.

Figure 2-3 – Interpolated Brake $PM_{2.5}$ Emission Rates by Regulatory Class Weight. Passenger Cars and Combination Heavy duty Trucks Define the Slope.

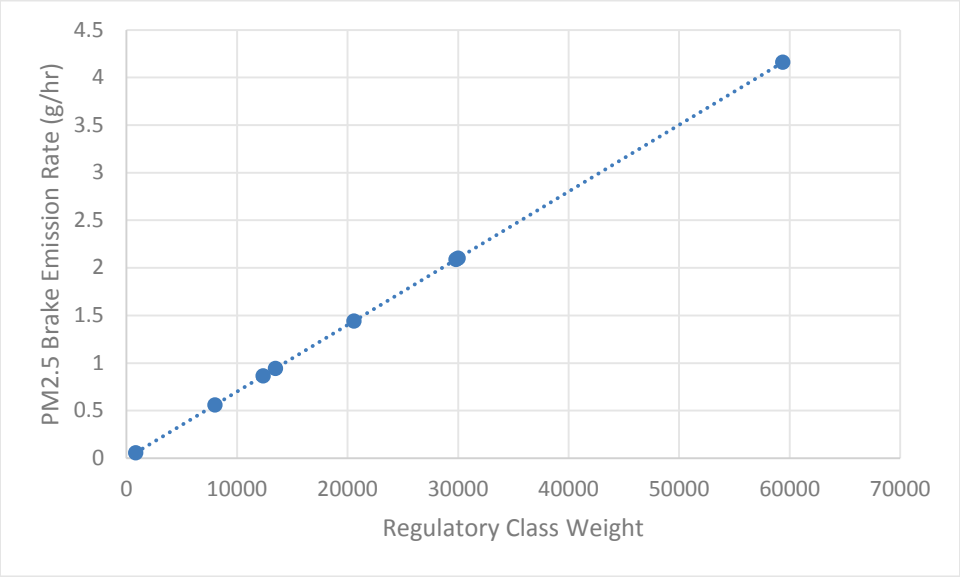


Table 2-12contains average brakewear PM emission rates from three MOVES runs for urban counties using MOVES2014, for each source types. As mentioned earlier, average emission rates by source type will vary for local users according to inputs that impact the operating mode distribution of vehicle operation

3 Tirewear

3.1 Introduction

Tires are an essential part of any vehicle and the number and size of tires increase with the size of the vehicle. Contact between tires and the road surface causes the tires to wear, with the rate dependent on a variety of factors.

EPA's previous estimates of tire wear are contained in the PART5 model, and are emission rates of 0.002 grams per mile per wheel. Two LDV studies from the 1970s are the basis for these emission rates. The PART5 emissions factors are based on tests of older bias-ply tires rather than more modern radial tire technologies The National Resource Council report on the MOBILE model, suggested that the PART5 rates may be out of date.[14]

Tire wear occurs through frictional contact between the tire and the road surface. Friction causes small and larger particles to wear from tire, which are then either released as airborne particulates, deposited onto the road surface or retained in the wheel hub temporarily or permanently until washed off. The road surface causes friction and abrasion and therefore the roughness of the surface affects the wear rate by a factor of 2-3.[15]

In addition to road surface roughness, tires wear is dependent upon a combination of activity factors such as route and style of driving, and seasonal influences. Heavy braking and accelerating (including turning and road grade) especially increases tire wear. The route and style of driving determine the amount of acceleration. Highway geometry is a key factor with rise and fall in roads also resulting in increased tread wear. The acceleration of the vehicle determines the forces applied to the tire, and includes turning. Tire wear due to tire/road interface is determined by and is directly proportional to these forces.[16] The season results in temperature, humidity and water contact variations. Wear rates are lower in wet compared to dry conditions.

Finally vehicle characteristics also influence tire wear. Key factors are the weight, suspension, steering geometry, and tire material and design. Axle geometry changes result in uneven wear across the tire width. The type of tire influences the wear significantly. In particular, the physical characteristics like the shape of the tire (determined by stiffness), the rubber volume (tread pattern), and the characteristic of the tire (rubber type etc.). As a consequence of different manufacturing specifications, different brands of tires wear at different rates. Retreads are also considered to wear more than new tires. Wear rate studies on tire fleets reported in Bennett & Greenwood (2001) also indicated that retreads had only about 75% of the tire tread volume that new tires had. Cenek et al. (1993) reported that 20% of New Zealand passenger tire sales were retreads and that retreads made up 75% of the tire tread in a sample of buses in the New Zealand fleet.[17] However, modeling emissions from retreads was deemed beyond the scope of the report

According to the literature, the most straightforward method for determining tire wear is the periodic measurement of tread depth. However, variations in the extent of wear across the tire and irregularities in tire shape could lead to inaccurate measurements. Determining tire weight loss is a more sensitive approach than the measurement of tire depth, though care must be taken to avoid errors due to damage to tires as a result of their removal from the vehicle and hubs, and material embedded in the tire. To minimize damage to the tire, Lowne (1970) weighed both the wheel and tire simultaneously after the wheel was brushed and stones embedded in the tire were

removed.[18] Table 3-1shows a summary of the literature search conducted as of 2006 on the mass of tire wear.

Wear rates for tires have typically been calculated based on tire lifetime (in kilometers traveled), initial weight and tread surface depth. Tire wear occurs constantly for moving vehicles, but may be significantly higher for cars which tend to brake suddenly or accelerate rapidly. Tire wear rates have been found to vary significantly between a wide range of studies.[19]

Speed variation is an important factor as well. Carpenter & Cenek (1999) have shown that the effect of speed variation is highest at low speeds as a result of inertial effects and effective mass.[20] They also examined lateral force effects on tires and assessed tire wear on routes of different amounts of horizontal curvature and found that there was little variation.

Tire abrasion is difficult to simulate in the laboratory, since the varied nature of the road and driving conditions influence wear rates in urban environments. Hildemann et al. (1991) determined the chemical composition of tire wear particles using a rolling resistance testing machine at a tire testing laboratory over a period of several days.[21] Rauterberg-Wulff (1999) determined particle emission factors for tire wear using modeling in combination with measurements conducted in the Berlin-Tegel tunnel.[22]

Tire wear rates have been measured and estimated for a range of vehicles from passenger cars to light and heavy duty trucks with results reported either as emission per tire or per vehicle. Most of the studies report only wear, not airborne PM. The wear rates found in the literature are summarized in Table 3-1 below and are converted to a per vehicle rate (units are in per vehicle kilometer). A range of light-duty tire wear rates from 64-360 mg/vehicle/km has been reported in the literature. Much of the variability in these wear rates can probably be explained by the factors mentioned above. These studies made no distinction between front and rear tires, even though they can wear at different rates.[23]

Table 3-1 - Tire wear rates found in the literature. Rates are per vehicle. Estimated number of tires is described later.

Source	Remarks	rate in mg/vkm
Kupiainen,K.J. et al(2005)[24]	Measured tire wear rate	9 mg/km - PM_{10} 2 mg/km -$PM_{2.5}$

Dannis (1974)[39]		90

While there is significant literature on tear wear, there is relatively little published on airborne particulate matter from tires. In this report, a model for tire wear rates are first determined, and then a discussion of the modeling of airborne $PM_{2.5}$ and PM_{10} follows building off the wear model.

3.2 Methodology

This report begins by estimating the tire wear from light-duty vehicles, then based on the per tire wear, extrapolates to other vehicle types. Then the emission rates are derived from the wear rates. The method primarily depends on the data from work published by Luhana et al. (2004) wherein wear loss rates for tires have been determined gravimetrically for in-service cars.[40] At the time of this analysis, this paper was both a recent and comprehensive study. The authors weighed car tires at two-month intervals, and asked drivers to note the details of each trip undertaken. Five test vehicles (labeled A-E) were selected for the tests. Of these vehicles A (1998 Audi A3), B (1994 Ford Mondeo), C (1990 Peugeot 205) and E (1992 Vauxhall Cavalier) were front-wheel drive vehicles (FWD). According to the driver surveys, the predominant road type used by vehicles A and B were motorways, for vehicle D (1990 Ford Sierra) it was rural roads and motorways for vehicle C it was suburban roads, and for vehicle E, it was rural roads. Vehicle D was excluded from this study since it was a rear-wheel drive (RWD) vehicle. RWD vehicles are relatively uncommon amongst passenger vehicles in the United States, and the wear from this particular vehicle was more than double the other FWD vehicles. It is uncertain whether the discrepancy from this vehicle was because it was a rear-wheel drive or for some other reason. The selection of vehicles was based primarily on driving conditions, as defined by the main type of road used by the owner and annual distance driven.

Results from the Luhana et al. (2004) study indicated that the lowest tire wear rates (56 mg/vkm and 67 mg/vkm respectively[h]) were for vehicles A and B that were driven predominantly on motorways. Vehicles C and E had very similar wear rates (around 85 mg/vkm) although these vehicles tended to be driven on different roads. Based on the wear rates from the four front-wheel drive cars alone, the study concluded that the average wear rate is around 74 mg/vkm. This value seems to lean towards the lower end of the range of wear rates reported in the literature.

The data presented in Table 3-2 includes calculations for the distances completed by each vehicle between successive tests, the estimated average trip speeds and predominant road types for the equivalent periods. It was assumed that the weight of the wheels remained constant during the tests, and any weight loss was due solely to the loss of tire rubber during driving.

[h] vkm is “vehicle kilometer” and assumes four times a per tire rate for light-duty vehicles.

Table 3-2: Data from Luhana et al. (2004) with measurements of tire wear for a variety of trips

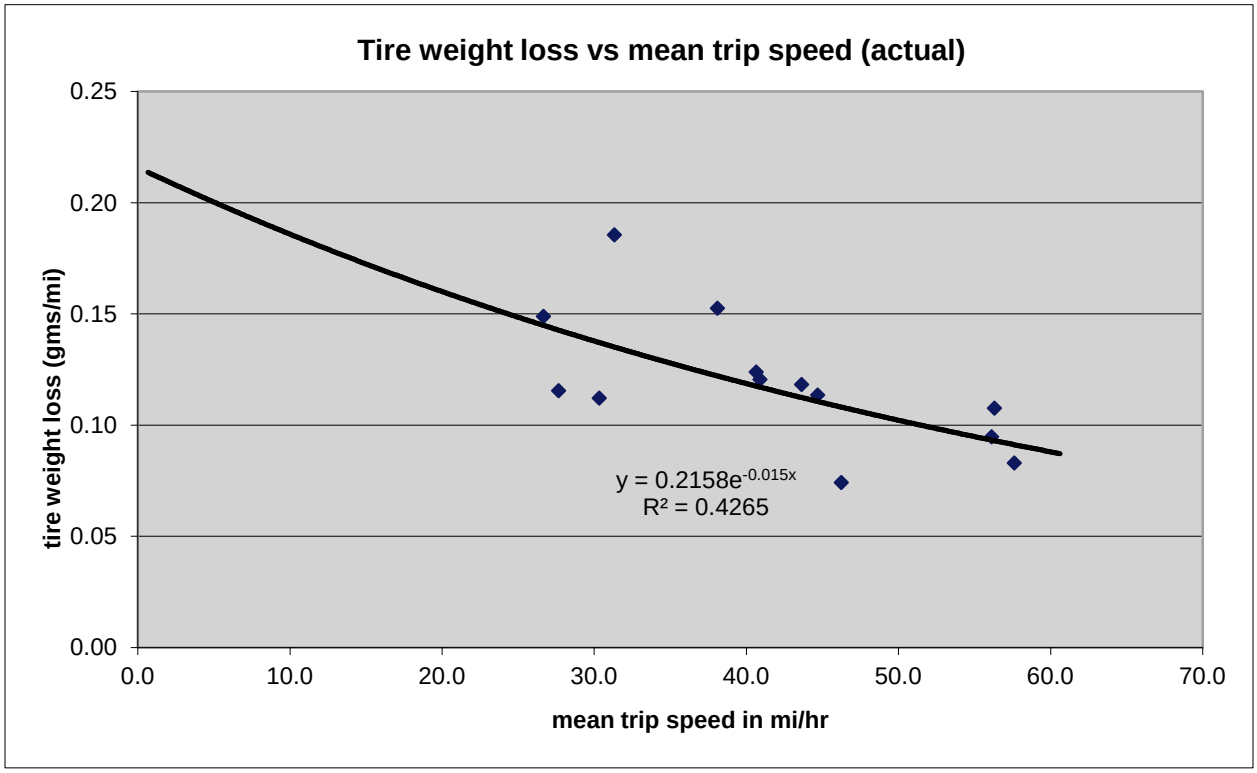
	Avg. trip speed	Tire Wt. Loss (per axle)		total wt. loss (per vehicle)	total wt. loss (per vehicle)	avg. speed
vehicle tests	km/hr	Front mean (g/km)	Rear Mean (g/km)	g/km	g/mi	mi/hr
test1-A	90.3	0.0202	0.0092	0.0589	0.0947	56.1
test2-A	90.6	0.0209	0.0126	0.0669	0.1076	56.3
test3-A	93.9	-	0.0069	-	-	58.4
test4-A	92.7	0.0172	0.0086	0.0516	0.083	57.6
test1-B	65.4	0.0298	0.0087	0.077	0.1239	40.6
test2-B	71.9	0.0262	0.0091	0.0705	0.1135	44.7
test3-B	74.4	0.019	0.004	0.0461	0.0742	46.2
test4-B	70.2	0.0297	0.007	0.0735	0.1183	43.6
test1-C	44.5	0.0312	0.0047	0.0718	0.1155	27.7
test2-C	42.9	0.0331	0.0132	0.0925	0.1489	26.7
test3-C	48.8	0.0284	0.0064	0.0697	0.1121	30.3
test4-C	50.4	0.0532	0.0045	0.1153	0.1855	31.3
test3-E	61.3	0.037	0.0104	0.0948	0.1525	38.1
test4-E	65.8	0.0265	0.0109	0.0749	0.1205	40.9

Note: Vehicles A and B were driven mainly on motorways (freeways)
Vehicle C was driven on Suburban Roads and
Vehicle E was driven mostly on Rural roads

Using the above data on average speed and total weight loss an exponential regression curve was fitted which was characterized by an R^2 value of 0.43. The actual and predicted values are presented in Figure 3-1.

A weak negative correlation is shown between tire wear and average trip speed, with wear being around 50% higher at an average speed of 40 km/h (dominated by urban driving) than at an average speed of 90 km/h (dominated by motorway driving).

Figure 3-1 Relationship between light-duty tire weight loss (per vehicle) and mean trip speed between tests



The shape of the curve in Figure 3-1 deserves some discussion. It can be seen from the curve that the wear is maximum at zero speed and goes down as the speed goes up. This is based on the extrapolation of the fitted curve. It may seem counter-intuitive that emissions is highest when speed equals zero, however, it is important to note that the relationship does not take accelerations (and turning) into account. Much of the tirewear occurs when the magnitude of a vehicle's acceleration/deceleration is at its greatest, e.g. at low speeds when the vehicle is accelerating from rest, or when the vehicle is braking hard to stop. A more improved relationship would be by VSP bin, however there is insufficient data to characterize tire wear on a second-by-second basis to enable binning by operating mode bins. The model has been simplified to be based on speed at this time. However, for MOVES, the emission rate at zero speed is set to zero to avoid anomalous results in project level analyses where increased idling would result in an over prediction of tire emissions.

The predicted values as determined above are for passenger cars (LDVs). To determine tire wear loss rates for other regulatory classes it was assumed that total tire wear per vehicle is dependent upon the number of tires on the vehicle which in turn is a function of the number of axles per vehicle by vehicle class. The latter data were found to be available in the Vehicle Inventory and Use Survey (VIUS 2002) data base. This data enabled the calculation of tires per vehicle for each of the six truck classes and thereby tire-wear losses for the different truck categories (regulatory classes) were determined. The average number of tires per truck is given in Table 3-3 below.

Table 3-3 - Average Number of Tires per Truck – Calculated from 2002 VIUS Survey of axle count.

RegClassID	RegClass name	Average Tires Per Vehicle
10	MC	2.0
20	LDV	4.0
30	LDT	4.0
41	LHD<=14K	5.5
42	LHD45	6.0
46	MHDD	7.0
47	HHDD	14.9
48	Urban Bus	8.0

* Note: Tires per vehicle for LDT is the same as that for LDV

In a future study, another literature search should be conducted to search for differences in (per tire) wear and emission rates from heavy-duty tires compared to those from the light-duty market. There is another assumption made for the sake of simplicity, which is to keep the emission rates of the tractive wheels identical to those of the wheels disconnected from the drivetrain axles. A more recent literature search may also help determine whether another approach is warranted.

Now that the average tire wear is quantified, it is critical to determine the fraction of that wear that becomes airborne PM. The literature indicates that probably less than 10% of car tire wear is emitted as PM_{10} under 'typical' driving conditions but the proportion could be as high as 30% (Boulter2005a). According to Luhana et al. (2004), PM_{10} appears to be released from (all 4) tires at a rate of between 4 and 6 mg/vkm for passenger cars. This suggests that generally between around 1% and 15% by mass of passenger car tire wear material is emitted as PM_{10} (though much higher proportions have been reported in some studies). For this study, it is assumed that 8% of tire wear is emitted as PM_{10} (average of 1% and 16%. According to Kupiainen et al (2005), $PM_{2.5}$ fractions were on average 15% of PM_{10}.[24] Based on this study, it is assumed that 1.2% of the total tire wear is emitted as $PM_{2.5}$ to develop our brakeweare emission rate. The 1.2% is derived from assuming that 8% of tire wear to be emitted as PM_{10} and 15% of PM_{10} is $PM_{2.5}$.

We then convert the g/vehicle/mile brakewear emission rates to g/hr by multiplying by the average speed of each MOVES speed bin. The g/hour brakewear emission rate for all regulatory classes used in MOVES can be found in Appendix B. MOVES applies the same brake wear emission rate for all vehicle fuel types (gasoline, diesel, flex-fuel, and CNG) within a MOVES regulatory class. The average $PM_{2.5}$ tire wear emission rates in (mg/mile) for each regulatory class, from three urban county inventories in MOVES2014 is shown in Table 3-4.

Table 3-4 Average $PM_{2.5}$ and PM_{10} tire wear PM emission rates (mg/veh-mile) for the MOVES regulatory classes from three urban county inventories using MOVES2014

sourceTypeID	sourcetypename	$PM_{2.5}$	PM_{10}
11	Motorcycle	0.7	4.9
21	Passenger Car	1.5	9.8
31	Passenger Truck	1.5	10.0
32	Light Commercial Truck	1.5	10.2
41	Intercity Bus	4.4	29.3
42	Transit Bus	2.9	19.7
43	School Bus	2.7	17.8
51	Refuse Truck	5.1	34.3
52	Single Unit Short-haul Truck	2.7	17.7
53	Single Unit Long-haul Truck	3.1	20.6
54	Motor Home	2.4	15.8
61	Combination Short-haul Truck	4.7	31.6
62	Combination Long-haul Truck	5.2	34.9

3.2.1 $PM_{10}/PM_{2.5}$ Tire Wear Ratio

MOVES stores $PM_{2.5}$ tire wear emission rates by operating mode bin (in this case, speed bins), then estimates PM_{10} emission rates by applying a $PM_{10}/PM_{2.5}$ ratio. Thus MOVES applies a $PM_{10}/PM_{2.5}$ ratio of 6.667, which is based on the particle size distribution of tire wear measured by Kupianen et al. (2005)[i]. The average PM_{10} emission rates from three urban county inventories using MOVES2014 are displayed in Table 3-4.

4 Next Steps

As mentioned in the earlier section, this report underwent revisions since the previous version, but these changes were largely editorial in nature in response to the peer review. There were no changes made to the model or the rates since MOVES2010. There are a number of updates that can be made to both this report and the model.

As a number of years have passed, it is possible that there are more publications in the literature or airborne brake and tire emissions from mobile sources. These papers may shed light on emission rates, size distributions, activity or speciation of PM. There is especially little information in the literature on the latter. These newer papers can either be used to modify the model, or validate the current rates.

The MOVES model has undergone changes since MOVES2010b. MOVES2014 includes some changes to the vehicle specifications described in this report. For example, the default

[i] The $PM_{10}/PM_{2.5}$ ratio is derived from dividing the PM_{10} fraction of total PM, by the $PM_{2.5}$ fraction of total PM, : .08/.012 = 6.667 from values reported by Kupianen et al. (2005).

assumptions regarding axle count (and thus number of wheels per vehicle), average weights, aerodynamics, and rolling resistance, of certain regulatory classes have changed. The weights will have a more significant impact on the brake rates (in particular) than the latter coefficients.

For brakes, the analysis from this study also only looked at front wheel drive brakes and primarily from vehicles equipped with disc brakes in the front and drum brakes in the rear (the most common light duty configuration). It was beyond the scope of this study to modify the rates the fraction of vehicles with four disc brakes, or to update the speciation profile for brake emissions, or to capture more advanced technology vehicles with electric regenerative braking. Vehicles with four disc brakes should presumably have higher, while hybrids and electric vehicles should have lower brake emissions. Moreover, the incident rate of other forms of decelerating a truck such as downshifting and engine (or jake) braking are also not considered in this study due to a lack of data.

Since the writing of this report, the only change that was made to the brake wear model in MOVES2014 was that for project level analysis, the emission rates in the idle bin was set to zero. This was done to avoid results where users may get increasing brake emissions in particular cases where idle rates are high. As mentioned above, the idle operating mode bin does contain a small amount of deceleration when a vehicle transitions from motion to non-motion (stop). However, if a user is increasing idle rates based on local knowledge compared to the MOVES default, it is logical to assume that they should not get higher brake emissions. Therefore, for inventory mode, the emission rates were maintained as described above in the idle bin and the change was made only to project level analysis.

The idling tire wear emission rate is set to zero in the default emission rate table (Appendix B). Thus, for idling tire wear emission rate is zero for both project level and inventory mode.

For tire emissions, it was beyond the scope of this study to quantify the differences in emissions (per tire) between light duty and heavy duty tires (and everything in between). It was also beyond the scope of this study to look at how trends in rolling resistance improvement may increase or decrease tire wear emissions. Finally a more complete model including speciation of tire and break PM, was beyond the scope of this study. Some of the references employed did include some of these measurements, however brake material has been known to evolve over time. These are all subjects for future study.

Appendix A Deceleration from PERE

This appendix briefly describes some of analytical methods used to determine the deceleration point at which coasting becomes braking. A full description of the PERE model is provided in a separate EPA report as cited earlier. This section, provides additional information beyond what can be found in the PERE documentation.

The basis for the tractive load equations in there PERE model are found in the A, B, C coastdown coefficients described in the report. The author of this report conducted coastdown testing on a ~2001 Nissan Altima on relatively "flat" roads in Southeast Michigan. The A, B, C coefficients for this vehicle can be found in the EPA database. The A,B,C tractive load equations in PERE were converted to a coastdown curve and plotted compared to the data below. The area above the curve is throttle and the area below the curve is braking. The curve itself is "coasting" on neutral gear.

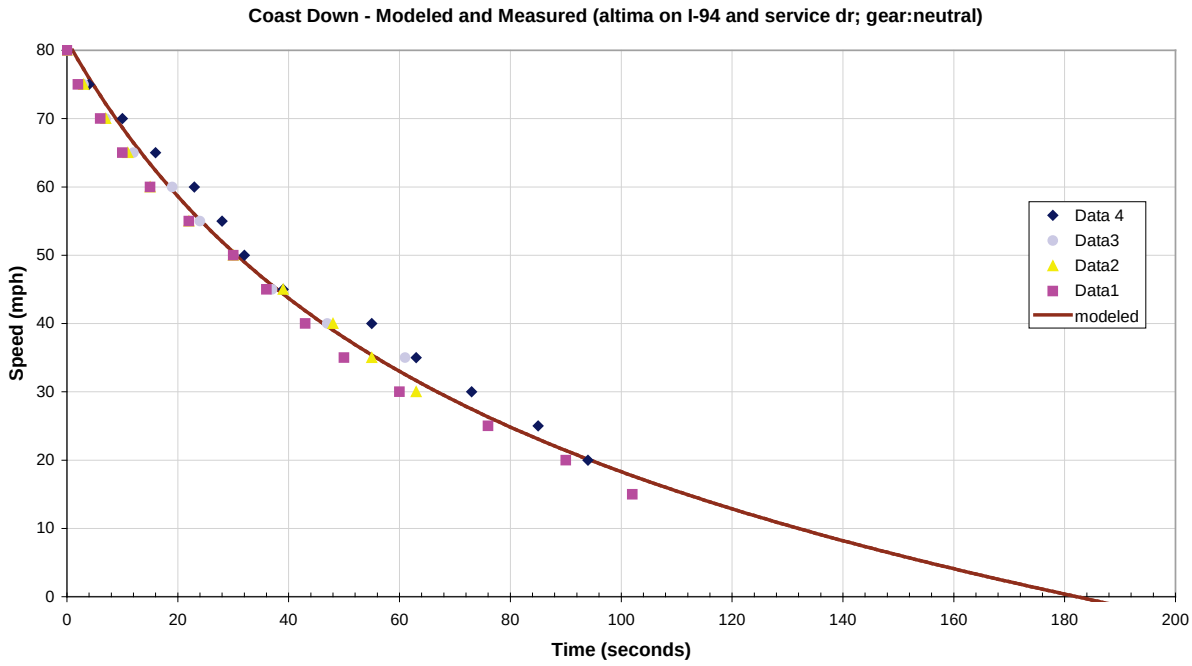


Figure A-1 Coast Down- Modeled and Measured (Altima on I-94 and Service Drive; Gear: neutral)

Based on these coastdown equations, a series of coastdown curves are generated as a function of vehicle mass. As in the previous plot, the area under the curve is braking and the area above the curve is throttling.

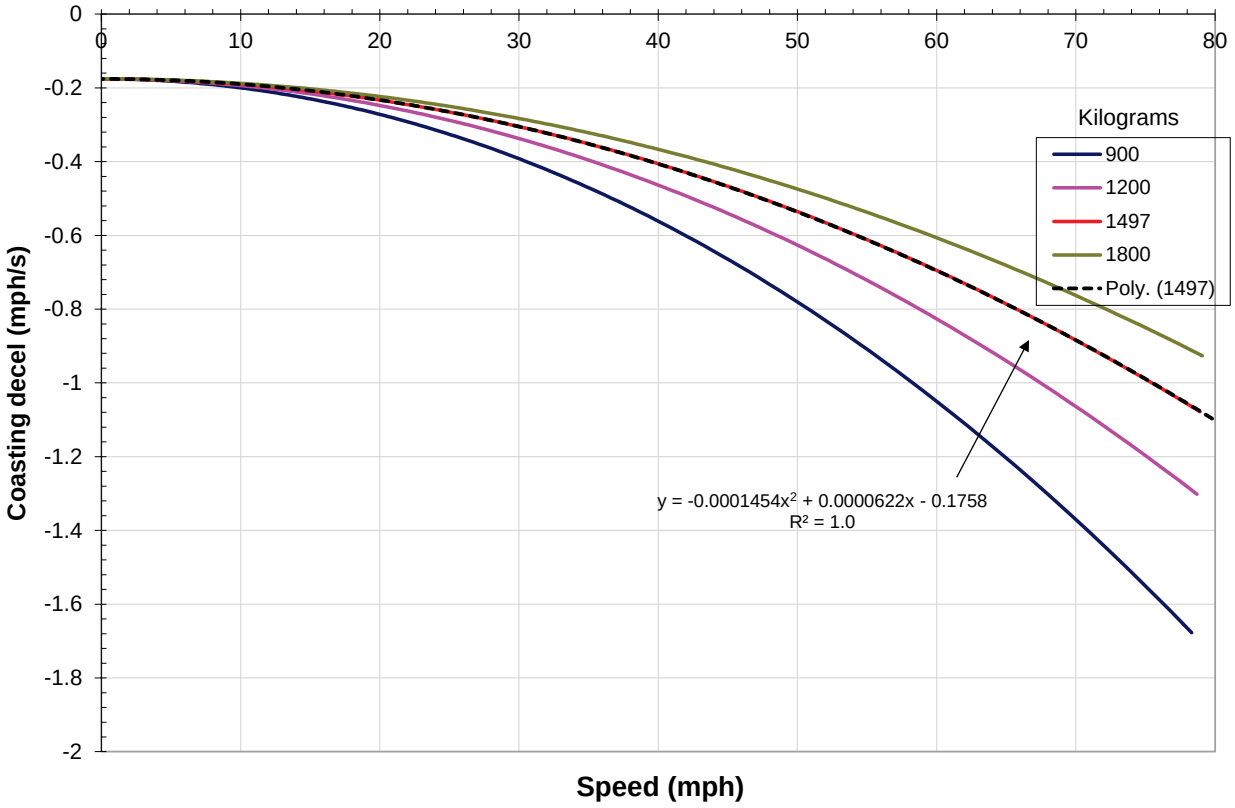

Figure A-2. Coast down Curves as a Function of Vehicle Mass

A PERE simulation is run on the FTP cycle and the braking episodes are flagged in the figure below (for a typical 1497kg LDV).

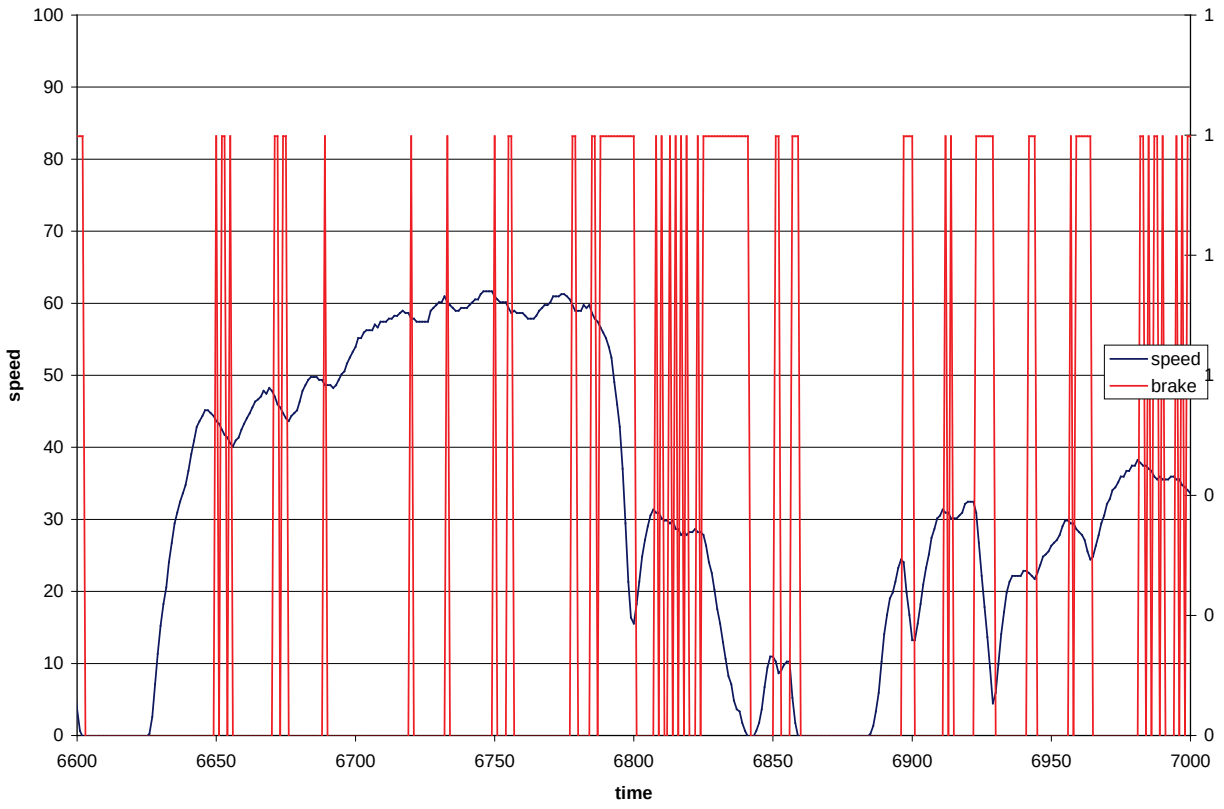

Figure A-3 Braking Episodes over the FTP cycle

Appendix B Brake and Tire Wear Emission Rates

This Appendix includes the brake and tire emission rates as a function of regulatory class and operating mode which are stored in the MOVES emissionrate table.

Table B-1 PM2.5 Brake Emission Rates by Regulatory Class and Operating Mode (g/hr)

regclassID	regClassName	opModeID	opModeName	MeanBaseRate (g/hr)
10	MC	0	Braking	0.055664
10	MC	1	Idling	0.0024472
10	MC	11	Low Speed Coasting; VSP< 0; 1<=Speed<25	0.054488

Appendix C Literature Review

Table C-1 Brief review of literature on brake and tire wear

Luhana,L.;Sokhi,R.;Warner,L.;Mao,H; Boulter,P;McCrae,I.S.;Wright,J and Osborn,D,"Non-exhaust particulate measurements:results," *Deliverable 8 of the European Commission DG TrEn, 5th Framework PARTICULATES project , Contract No.* 2000 -RD.11091, Version 2.0 , October 2004.	2004	Non-exhaust particle research was conducted in the Hatfield road tunnel. Combined tire and break wear emissions for PM_{10} from LDVs and HDVs in the tunnel were found to be 6.9mg/vkm and 49.7mg/vkm respectively. These emission factors from the Hatfield Tunnel Study appears to be at the lower end of the range of values reported elsewhere. The report also includes a literature review which examines the state of the art in the field. Tire wear and brake wear rates are listed below.
Sanders, Paul G.;Xu, Ning ;Dalka, Tom M.; and Maricq, M. Matti, "Airborne Brake Wear Debris: Size Distributions, Composition, and a Comparison of Dynamometer and Vehicle Tests",*Environ. Sci. Technol.*, 37,4060-4069,2003	2003	A brake wear study was performed using seven brake pad formulations that were in high volume use in 1998. Included were low-metallic,semi-metallic and non-asbestos organic (NAO) brakes.The quantity of airborne PM generated by automotive disk brakes was measured on a brake dynamometer that simulated : urban driving (low velocity,low g) and the Auto Motor und Sport (AMS,high velocity, high g). Airborne fractions from the low-metallic and semi-matallic linings were 5 and 1.5 times higher than the NAO lining.
L.R.Warner; R.S. Sokhi; L.Luhana ; P.G. Boulter; and I. McCrae,"Non-exhaust particle Emisions from Road Transport", *Proceedings of the 11th International Symposium on Transport and Air Pollution*, Graz, 2002.	2002	The paper presents preliminary results of gravimetric determination of tire and brake wear for cars, and chemical analysis of ambient particle samples for source identification using Inductively Coupled Plasma (ICP) spectrometry. Results suggest that the average loss rates of tire and brake material are 97 and 9 mg/vkm respectively. The ICP analysis shows a high relative abundance of Ba,Sb,Zr and Sr for brake and Zn for tire material. The chemical analysis also suggests that for tire wear it is much more difficult to use metal concentrations as tracers.
Abu-Allaban, M.;Gillies, J.A.;Gertler,A.W.;Clayton ,R.; and Proffitt,D., "Tailpipe, re-suspended road dust, and brake wear emission factors from on-road vehicles," *Atmospheric Environment*, 37(1),5283-5293,2002.	2002	Intensive mass and chemical measurements were performed at roadside locations to derive brake-wear emission factors from in-use vehicles. PM_{10} emission rates for LDSI vehicles ranged from 0 to 80 mg/vkm and for HDVs from 0 to 610 mg/vkm. The $PM_{2.5}$ emissions ranged from 0 to 5mg/vkm for LDSI vehicles and from 0 to 15mg/vkm for HDVs. Emissions from brake wear were highest near motorway exits.

Westerlund ,K.G.," Metal emissions from Stockholm traffic –wear of brake linings ",*The Stockholm Environment and Health Protection Administration*, 100,64,Stockholm,Sweden,2001.	2001	Westerlund estimated the amount of material lost due to brake wear from passenger cars and heavy goods vehicles. The PM_{10} emission factors were determined to be 6.9 and 41.2mg/vkm for LDVs and HDVs respectively.
Garg, B.D.; Cadle, S.H.; Mulawa,P.A.; Groblicki, P.J.;Laroo,C.; and Parr,G.A., "Brake wear particulate matter emissions", *Environmental Science & Technology*, 34(21),4463,2000b.	2000	A brake wear study was performed using seven brake pad formulations (non-asbestos) that were in high volume use in 1998. Brakes were tested on a brake dynamometer under four wear conditions. The brake application was designed to simulate real world events by braking from 50km/h to 0km/h at a deceleration of 2.94 m/s^2. The estimated range of PM emission rates for small vehicles to large pickup trucks are 2.9 -7.5 mg/vkm and 2.1 – 5.5 mg/vkm for PM_{10} and $PM_{2.5}$ respectively.
Annette Rauterberg-Wulff , "Determination of emission factors for tire wear particles up to 10um by tunnel measurements", *Proceedings of 8th International Symposium on Transport and Air Pollution*, Graz, 1999.	1999	PM_{10} emission factors were determined for tire and brake wear using receptor modeling in combination with measurements conducted in the Berlin-Tegel tunnel. Tire wear emission factors for LDVs and HGVs in the tunnel was calculated to be 6.1 mg/vkm and 31 mg/vkm. For brake wear it was 1.0 and 24.5 mg/vkm respectively.
Carbotech, "PM_{10} Emissionsfaktoren:Mechanischer …….",*Arbeitsunterlage,* ,17,1999	1999	Cited in Lukewille et al.(2001). The PM_{10} brake wear emission factor for LDVs was determined to be 1.8 mg/km and for HDVs it was 3.5 mg/vkm.
Cha,S.; Carter,P.; and Bradow, R.L., "Simulation of automobile brake wear dynamics and estimation of emissions,"*SAE Transactions Paper,*831036, Society of Automotive Engineers, Warrendale, Pennsylvania,1983	1983	Particulate emissions from asbestos-based brakes from automobiles were measured under conditions simulating downtown city driving. The report presents a systematic approach to simulating brake applications and defining particulate emissions. Based on the 1.6:1.1 wear ratio between disc and drum brakes,the estimated airborne particulate (PM_{10}) emission rate was estimated to be 12.8mg/vmi or 7.9 mg/vkm.

Appendix D Responses to Peer-Review Comments

This section provides a verbatim list of peer reviewer comments submitted in response to the charge questions for the Brake and Tire Wear Emissions/Temperature Effects Report.

D.1 Adequacy of Selected Data Sources

Does the presentation give a description of selected data sources sufficient to allow the reader to form a general view of the quantity, quality and representativeness of data used in the development of emission rates? Are you able to recommend alternate data sources might better allow the model to estimate national or regional default values?

D.1.1 Dr. Chris Frey

Table 2-1 of the report is a helpful summary of data sources that were reviewed by EPA as a possible basis for estimating brake wear emission rates. EPA chose to base the brake wear emission rates for light duty vehicles mostly on a study by Sanders et al. (2003). The brake wear emission rates for heavy duty vehicles are based mostly on a study by Moahmoud Abu-Allabah et al. (2003). The tire wear emission rates are based mostly on a study by Lahuna et al. (2004).

There is a need for more critical discussion of the representativeness of the data from these studies for the U.S. onroad fleet. Since all three of these key studies are approximately a decade old, a question naturally emerges in the reader's mind as to whether the brake lining, brake shoe, or tire materials that were the basis of these studies are representative of materials currently in use. Furthermore, are the vehicles measured representative of vehicles currently in use in terms of the most relevant characteristics, such as vehicle weight, and factors such as the ratio of brake pad or brake shoe area to vehicle weight, and tire tread dimensions to vehicle weight, and so on. If these questions are not answerable, then explain why they cannot be answered. However, it is important to indicate that these issues were at least considered, even if there is not a quantitative basis upon which to make a judgment.

> *RESPONSE: An explanation was added to the paper, which describes that the paper was originally drafted in 2006, and the literature review was current at the time. The MOVES team had not the resources to update this paper in time for MOVES2014 due to the many other updates required. A Next Steps section was also added to the report describing what a future study could update. As to whether the papers are representative, this is a difficult question to answer, as these are the only papers that could be found at the time, there simply is not a large amount of research conducted on airborne tire and brake wear particulate matter emissions. The author of the report attempted to analytically adjust the data to be as representative as practicable.*

D.1.2 Dr. Joe Zietsman

The literature used as the basis for this work is sufficient. I am not aware of any other literature that has been overlooked. The only concern is that the literature is quite old (newest study is from 2004 for brake wear and 2005 for tire wear).

On Table 2-1, the vehicle type classification for the Warner et al study refers to both "passenger cars" as well as "light duty". I am not sure what the distinction is or whether it is a typo. In the Sanders work, UDS, UDP, and AMS should be defined. On looking at the source reference looks like UDS may be a typo. It seems as though the description of the Sanders study on page 3 needs to be corrected – for example, -7.9m/s should be -7.9m/s2; specify what g is in the context of the decelerations, etc.

RESPONSE: These issues have been addressed in the report. The table has also been shortened to only include papers with measurements; the papers with brake emissions estimates based on models and literature reviews have been omitted.

On page 7 – first sentence should refer to accelerations if referring to Figure 2.5.

RESPONSE: This has been clarified in the report.

On page 15, effect of horizontal curvature is discussed. It is assumed vertical curvature or grade could have an effect on tire wear, but it was not mentioned in this work.

RESPONSE: Agreed: thank you for the suggestion, this has been added to the report.

In Table 3-1 – there is no mention of the Luhana study

RESPONSE: We added the Luhana et al. (2003) study to Table 3-1.

In Table 3-3 and related text– it should be better clarified how total weight loss is calculated.

RESPONSE: the table description now includes the information that the tires were weighed.

On Page 20, Table 5 is referred to as "above", and it is actually below; Table 6 is referred to, but it doesn't exist.

RESPONSE: this has been corrected.

D.2 Clarity of Analytical Methods and Procedures

Is the description of analytic methods and procedures clear and detailed enough to allow the reader to develop an adequate understanding of the steps taken and assumptions made by EPA

to develop the model inputs? Are examples selected for tables and figures well chosen and designed to assist the reader in understanding approaches and methods?

D.2.1 Dr. Chris Frey

No.

Consider Figure 2-1. This is apparently an excel worksheet that was copied into the report. The figure is labeled as "UDP results." What is UDP? Spell it out. Results for what, exactly? The table reports "PM10 emiss." for "filter" and "ELPI" (again, always make tables and figures self-documenting – what is ELPI?). I looked in Sanders et al. (2003) to try to figure out where these reported numbers come from. For UDP, low metallic, I find in Table 5 that "filter" results are reported for "total mass" in mg/stop/brake. However, the numbers in the draft report are not the same as from Sanders et al. (2003). For example, the low metallic filter PM10 emiss. is reported as 6.9 (are the units mg/stop-brake? – not very clear given that units are not given for each column of data). Let's assume that this is 6.9 mg/stop-brake. In Table 5 of Sanders et al. (2003), I find that the individual tests range from 6.2 mg/stop-brake to 11.7 mg/stop-brake, with an average of 8.3 mg/stop-brake. Thus, as a reader, I cannot figure out either why did EPA choose one test from among the multiple reported by Sanders et al. (2003), or what adjustment did EPA make from the average of 8.3 mg/stop-brake to arrive at 6.9 mg/stop-brake? On the other hand, for the ELPI results, EPA seems to be reporting the same values as shown by Sanders et al. (2003) for the average of all reported tests for each of the three types of brake pad linings.

> *RESPONSE: All of these have been clarified in the section 2.1. For example, the acronyms have been spelled out and the units are more clear. Describing what exactly these instruments do is beyond the scope of this report. We also removed UDP from the heading of Figure 2-1. As for the reason why the paper's UDP number doesn't match Sanders et al.: We calculated 6.9 mg/stop/brake from the 8.2 mg/stop/brake. The filter number reported in Sanders is TOTAL PM Mass. In order to get the PM10 mass, the ELPI ratios were used, thus 8.2 * (7/8.3). Likewise, 1.7 was determined from 1.7 * (1.7/2) etc. A footnote was added with an example calculation.*

Also unclear: how does EPA go from average/stop/brake (what is this… isn't this average emission rate in mg/stop-brake) to "Avg./veh" (again, what is this – always report units). It would help to show an example calculation. The ratio of avg./veh to 'average/stop/brake" is approximately 3, which may be based on an assumption that the non-drive wheels have ½ the brake wear of the drive wheels. This could be more clear.

> *RESPONSE: The avg per vehicle emissions is the avg stop/veh/brake emissions multiplied by 3. This is based on the assumption made earlier that 2/3 of braking comes from the front brakes and 1/3 from the rear brakes. Footnote has been added.*

As far as the deceleration in Figure 2-1, where does this come from? Is this an average of all decelerations from all stops during the UDP? This could be more clear. Is the value of 0.0012 km/s2 reported by Sanders et al. (2003) or was this inferred by EPA. If the latter, how?Similarly, what is the basis for the "average brake time in secs" that is reported in Figure 2-1?

Similarly, what is the basis for the "avg . emissions in mg/ stop" that is reported in Figure 2-1?

> *RESPONSE: The following footnote was added below the table (f). The UDP decelerations are the average decelerations from those measured in the Sanders paper. The average brake times were determined with the assistance of one of the original authors of the paper (Matti Mariq) who supplied the second by second trace.*

The bottom of Figure 2-1 includes "emission rate for the UDP test" of 2.65 gms/hr. Since the previous lines indicate that time is for braking or per stop, clarification is needed as to the time basis for 2.65 g/hr. Is this based only on braking time? Is this based on total travel or trip time?

> RESPONSE: Yes, the emission rate is only during braking events and times as clarified in the text near the figure.

Similar comments apply to Figures 2-2, 2-3, and 2-4.

Without clear documentation of how the emission rates were estimated, it is not possible to comment on whether the curve fit in Figure 2-5 is reasonable. The fit shown is reasonable given the numbers used in fitting the curve, but the basis for, and meaning of, the numbers is unclear.

Additional comments regarding needs for improved communication of the data and methods are given in detail in a section on "Specific Comments"

D.2.2 Dr. Joe Zietsman

The methods and approaches are adequate. It is not clear in this report how the exact measurement (of the PM emissions) was conducted in the source studies, as well as the basis for assumptions/measurements regarding apportionment (of what gets emitted into the air as PM10) and what percentage of PM10 is PM2.5. For example, on Page 20 (last sentence) – 8% of tire wear as PM10 assumption is not referenced.

RESPONSE: these have been addressed throughout the document. For example the 8% text is made more clear on page 22.

D.3 Appropriateness of Technical Approach

Are the methods and procedures employed technically appropriate and reasonable, with respect to the relevant disciplines, including physics, chemistry, engineering, mathematics and statistics?

Are you able to suggest or recommend alternate approaches that might better achieve the goal of developing accurate and representative model inputs? In making recommendations please distinguish between cases involving reasonable disagreement in adoption of methods as opposed to cases where you conclude that current methods involve specific technical errors.

D.3.1 Dr. Chris Frey

EPA is making use of data collected by others and reported in the literature. The selected references generally seem to be reasonable.

The methods and procedures employed by EPA include judgments about the representativeness and appropriateness of the selected data sets for use as a basis for developing MOVES inputs, and regarding the statistical analyses conducted based on the selected data. Given lack of sufficient data from which to develop more detailed models, EPA has developed relatively simply models. The general approach is reasonable. However, the communication of what was done could and should be more clear and complete. Ideally, sufficient information should be communicated regarding the underlying data and inference approaches such that an independent investigator can reproduce the results and obtain the same answer. Many of the detailed comments given below under "specific comments" are aimed at this objective.

> *RESPONSE: These comments have been addressed throughout the report as described in greater detail in the more detailed comments.*

D.3.2 Dr. Joe Zietsman

No response.

D.4 Appropriateness of Assumptions

In areas where EPA has concluded that applicable data is meager or unavailable, and consequently has made assumptions to frame approaches and arrive at solutions, do you agree that the assumptions made are appropriate and reasonable? If not, and you are so able, please suggest alternative sets of assumptions that might lead to more reasonable or accurate model inputs while allowing a reasonable margin of environmental protection.

D.4.1 Dr. Chris Frey

In general, I agree that EPA has done a reasonable job with a very limited data set to make inferences and develop data and fitted models for use with MOVES.

D.4.2 Dr. Joe Zietsman

No response.

D.5 Consistency with Existing Body of Data and Literature

Are the resulting model inputs appropriate, and to the best of your knowledge and experience, reasonably consistent with physical and chemical processes involved in exhaust emissions

formation and control? Are the resulting model inputs empirically consistent with the body of data and literature that has come to your attention?

D.5.1 Dr. Chris Frey

Yes.

D.5.2 Dr. Joe Zietsman

With regard to the above three questions, based on the available data the methods are appropriate and reasonable. I concur with what is noted in the report regarding improvements with more data, for example allocating tire wear by VSP bin, etc. I am not aware of any current datasets or methods that can enhance this work.

D.6 Tire and Brakewear PM2.5 and PM10 Emission Rates and Speciation

MOVES2014 estimates total PM2.5 and PM10 emission rates from brake and tire wear. Additional PM2.5 speciation capabilities have been incorporated in MOVES2014 for exhaust emission processes. What recommendations do you have for EPA for incorporating the PM2.5 and PM10 speciation of tire and brakewear for future versions of MOVES?

D.6.1 Dr. Chris Frey

Clearly, it will be desirable to include speciation of PM10 and PM2.5 into future versions of MOVES for brake and tire where when sufficient data are available to support such estimates. In the current report, EPA could provide at least a paragraph summarizing what is known about the PM composition of brake wear debris, to expand upon some text on page 3. To the extent that there is or isn't information on PM composition of tire wear, EPA should add at least a paragraph to discuss this and, if applicable, summarize available information. Of particular interest is what are the key indicator species or components of brake wear and of tire wear, and are these sensitive to the materials used, or is there insufficient information to address these points? There is no information offered in the section on tire wear regarding the chemical composition of tear wear debris or emissions. Is this because no information is available?

> *RESPONSE: The literature had very limited discussion of PM speciation. There were some measurements of this, however, it was beyond the scope of this current modeling exercise. We added discussion in Section 4 Next Steps, that we would like to do more work on PM speciation of brake and tire wear.*

D.6.2 Dr. Joe Zietsman

While the additional PM2.5 speciation capabilities in MOVES 2013/2014 (in terms of added species, as relevant) will be useful, a first step for brake and tire wear emissions would be to better estimate and justify the following factors: a) PM-10 to PM2.5 ratio; b) percentage of brake and tire wear that is actually emitted as PM-10 and PM2.5.

RESPONSE: We hope to improve on these emission factors as we become aware of new literature and data. We have added a statement that we would like to improve the information on size distributions in the Next Steps Section.

D.7 General/Catch-All Review

Please provide any additional thoughts or review of the material you feel important to note that is not captured by the preceding questions.

D.7.1 Dr. Chris Frey

This is a significant report that documents an important part of the MOVES emission factor model, which is used nationally for a wide variety of regulatory and other analyses. As such, it is critically important that the report be well written and very clear. While the current draft of the report is good in many respects, it comes across as a draft and is not in final form in terms of the critical thinking needed to make sure that it clearly communicates information to the reader.

For each of the major sections on brake and tire wear, it will help the reader to have clearly labeled sections that deal with light duty vehicles and with all other vehicle source categories. It will also help to clearly define and consistently use terms and concepts. For example, it is critically important to have a clear quantitative definition of break wear and of tire wear, and to be clear as to whether these are rates per wheel, per vehicle, or other (specify).

RESPONSE: We added Light- Duty to Section 2.23, and Heavy-duty and Other Vehicles to Section 2.2.5.

Since this is a formal technical report, the use of first person should be avoided. Statements regarding how an analysis was done, or regarding judgments that were made, can be made without self-reference.

In general, be careful about significant figures. It is pretty rare in this type of work that data are known with more than 3 significant figures. However, in various places, numbers are reported with 5 or 6 significant figures, and often with 4. Even if the original data might be known with many significant figures, its adoption for use in representing a national fleet introduces uncertainty, since the original data may not represent the U.S. national fleet as it exists today.

RESPONSE: Significant figures for intermediate numbers were largely maintained. The final numbers were appropriately adjusted. Some of the figures/tables have reduced sig figs now as well.

Many specific comments are given below that elaborate on responses given above in response to the charge questions.

Specific Comments (numbers refer to page/paragraph/line … e.g., 3/3/1 means page 3, paragraph 3, line 1)

RESPONSE: Unless otherwise noted, all minor comments have been addressed in the report in the relevant sections. Responses are provided to the major comments.

Given that this report will be finalized perhaps in 2013 or 2014, explanation is needed for the reader as why the literature review starts off with information from 2004. Is this because more recent data are not available?

Page 2, 3rd paragraph in Section 2.1, next to last line "is acceptable" does not fit here.

Page 2, 4th paragraph in Section 2.1: while these statements seem intuitively reasonable, they are stated as if they are known facts. However, no references are cited. How do the authors know that these are accepted facts? Or are these the author's hypotheses or opinions? If factual, then cite reference(s). If these are hypotheses, then say so.

RESPONSE: we believe that these statements in this particular paragraph are obvious to anyone with a basic knowledge of vehicle brakes. While not all readers of this paper may have knowledge of brakes, some of the text in this paper are meant to be include basic instructive material as well. As such, we do not believe that relatively "basic" statements like this require references. However, the subsequent statements in the following 2 paragraphs are more specific. We've added a parenthetical when the Garg paper is first mentioned that much of the basic PM information comes from this paper. This paper is very important in the list of this study's references.

Please carefully define what is meant by "wear" and then use the definition consistently. Does "wear" refer to a mass rate of emissions or loss per tire per braking episode, or is it a time-based rate for a tire (or a vehicle), or a mileage-based rate? If this is not defined, then readers will make their own assumptions as to what this means. Does "greater wear" mean greater rate of wear, or more accumulative lost mass regardless of time period?

RESPONSE: the definition of wear versus airborne PM has been differentiated in various points in the paper. Wear means slightly different things in the literature, but in this paper it is generally, the mass of material lost, whether in the brake pads or the tires. A fraction of that wear is airborne PM. Some studies look at both wear and airborne PM, others look at one or the other. We added discussion providing a definition of brake wear, and airborne PM in Section 2.1.

3/2/1: Page 3, 2nd paragraph, a 2000 study is not "recent" in 2013… delete "In recent studies,"

3/2/6: "ranged from 3.4 mg/mile to 4.6 mg/mile" is the correct way to write the range at the end of the same paragraph.

3/3/1: "currently used" – refers to 2003 or to now?

3/3/7: this list is hard to read because apparently not all brake linings were measured in all types of tests, but the reader has to reread this a few times to really figure this out.

3/3/9: -7.9 m/s is not an acceleration. Is this supposed to be -7.9 m/s2?

3/3 – near end of paragraph… it would help to give a summary of how the PM composition varies by brake type.

RESPONSE: We added as much information as we could, but we do not have perfect information.

End of page 3 – why is there no discussion of other references, particular ones published shortly before or after Sanders et al. (2003), such as Warner et al. (2002), Abu-Allaban et al. (2002), and others. From Table 2-1, the reader infers that some of these could also be useful. If EPA judged that they are not useful, a rationale should be given.

RESPONSE: a paragraph was added to the paper here.

Related to page 3 – is the current market share of each brake lining type known? If so, please summarize. If not, then say so.

RESPONSE: We added a sentence saying that this is not known in this section.

4/1/1: "is based on the average of the" is better than "averages"

4/3: why are only results from Sanders et al. (2003) used here… give an explanation.

5/1/1: how sensitive are results to the assumption regarding equal mix of brake types?

RESPONSE: this is answered indirectly earlier in the report where there is a summary provided from the paper regarding the differing results from the varying materials.

5/1/2: is there some basis for the assumption that 2/3 of braking power is in the front brakes? Actually, the assumption made here is that the rate of brake lining wear is twice that for front drive wheels than for rear nondrive wheels. Is the assumption really based on "power"?

RESPONSE: this information was provided by Matti Mariq from Ford who is a co-author on the Sanders paper and helped us with the data and information like this in this report. This is a "rule of thumb" in the industry. It is also consistent with what is written in Garg and that is now added to the footnote.

5/1/4: what is meant by "total PM"? is this total suspended particulate matter?

Page 8 – include definitions of opmode bins 0 and 1.

8/1: to reader it is unclear as to why 1,497 kg is used. Explain that this is a typical weight of a sedan passenger car. Is this the only selected weight? Why not others? What about larger vehicles?

RESPONSE: this is the average weight of passenger cars in MOVES. Other vehicle type weights are provided elsewhere in the report. We added this to the report.

Page 9, figure 2-7: "coastdown curves" for what, based on what data sources? Figure and table captions generally need to be more specific throughout the report. Also, the number of significant figures given for the equation borders on the absurd.

RESPONSE: PERE is a vehicle simulation model, that has undergone separate peer review. A complete description of how these plots were developed would be lengthy and distract from the focus of the report. We do not believe that it is required for what is a minor part of the quantification of the braking emissions. However, more detail was added with three figures on the PERE coast down and braking estimates in Appendix A.

9/1/3: "Eastern" not "Easter"

9/2/2: it is very unclear as to how the distribution of braking activity across speed and deceleration can be determined from the numbers given in Table 2-7.

9/2/2: "vast majority of braking" – how is this known? What is a "minor slowdown"? (give quantitative criteria for this).

RESPONSE: The following table quantitatively shows deceleration frequencies drop as braking becomes more severe. We disagree that an actual quantitative definition of mild and full decelerations is required here. This is not a distinction that is made in the MOVES model.

11: Table 2-8: in text or footnote, show the equations that define or use the constants given such as "wgt", "Cr0", "Cd", "A"… and preferably use mathematical nomenclature. Also, do not report "m^2". This should be "m2" Please use source bin terminology and please define what the columns are in this table… i.e. the last 5 columns should have a superheader of "Vehicle Type." Does MOVES have source ids for "Compact," "Mid-size," "SUV," "mddt," and "tractor"?. If these are assumptions that are meant to apply to source bin ids in MOVES, then use proper MOVES terminology to avoid confusion.

RESPONSE: MOVES does not have source types for compact, mid-size or SUV. These source type definitions are typical for vehicle simulation models like PERE. These models are capable of greater precision than MOVES, and an attempt is made here to model greater detail first, then aggregate the results up to MOVES source bins.

Table 2-8 has some definition problems, in that the first four rows of numbers are not fractions and thus should not be defined as such, and yet the last 7 rows are in a sense undefined, because there is no header in the table that defines what they are. There is inconsistency in the number of decimal places given. Also, the basis for these numbers is unclear – where do they come from and how exactly where they derived?

RESPONSE: The table has been cleaned up. Also more information has been included in the text near this table as well as appendix.

11/1: it would help to have an example calculation showing how these emission rates were estimated.

13/1: please give some rationale as to why this study was used and/or why others were not. Was this the only relevant study? The most recent study? The best study? Just stating that it was used is not sufficient to explain to the reader why it was used. Also, please indicate what type of instruments were used and at least some summary of how the sampling was done, and how it was possible to associate the measurements with a per vehicle emission rate specific to brake wear.

RESPONSE: a lengthy description has been added on page 13 and following.

13/1/7: "by ratioing"… ratio is not a verb. "by taking the ratio of…" More importantly, please explain the empirical basis for these ratios. Upon what measurements are they based, and how was it possible to distinguish among the vehicle categories – e.g., how was it possible to apportion measurements to vehicle types?

Table 2-2: the caption "scaling to other vehicle class" may mean something to the author, but lacks sufficient detail and specificity to mean much to the reader. What exactly is contained in this table and what is the source or basis of the information? Tables and figures should be self-documented to the extent possible, to make very clear as to what is the content. Please define or explain specialized terms – e.g., "regclasswt" and "regclassid" are variables used in MOVES (define them). What is the basis of the weight ratio? Is this based on weights given in MOVES (for clarity, report the weights so that the basis of the weight ratios is more clear). What is the source of the "mg/mi" and why is there no description of what this is in the column header? Similarly, "gms/hr**" has no explanatory title nor is there any explanation of whether "**" is meant to be a footnote. This type of sloppy and incomplete documentation of tables leads to long-term confusion as to the basis of data contained in MOVES, and causes a lot of problems for MOVES users for many years to come. Thus, it is essential that these reports be well documented.

RESPONSE: A paragraph has been added before Figure 2-4 in addition to a Figure 2-4 and additional tables (Tables 2-12, 2-13) to help clarify.

13/2/2: "a PM10/PM2.5 ratio" – is one ratio used regardless of opmode bin? Source category? Etc.? Needs to be more clear.

RESPONSE: this has been clarified in the report that there is one ratio used for simplification.

13/2: The PM10/PM2.5 ratio is "based on the assumption that the mass fraction of particles below PM10 is 0.80, and that the mass fraction of particles below PM2.5 is 0.1" ☐ this is suggested revised text. I do not think that the authors really mean to refer to the fraction of

particle number, but rather mean to refer to fraction of particle mass, yet the text implies that these ratios are by particle number. There is a big difference. Also, explain the basis of these assumptions. Are these mass fractions of 0.8 (why 0.80 – 2 sig figs) and 0.1 (why only 1 sig fig) based on measurements, a wild guess?

RESPONSE: Additional clarification on the size distribution used to derive the PM10/PM2.5 fraction from Sanders et al. (2003) is provided in Section 2.2.4.

13/2/6: what are examples of cases either in which the PM2.5 values are known, or are not known, so that the reader has some idea of how extensive is the reliance on the assumption?

13/3: could delete "Tires are an essential part of any vehicle and"

RESPONSE: this is a matter of style. We disagree on this deletion.

14/2: this paragraph ("Tire wear occurs through…") needs references. Some of the points here are repetitive of previous text.

14/4 ("The key influences…") this text comes across as repetitive although it does more specifically refer to vehicle characteristics, whereas other lists given previously seem not be specifically about vehicle characteristics. However, in general, this material could be better and more clearly organized with less repetition and with citation to literature to support statements of apparent fact that presumably have an empirical basis.

14/5 "Retreads are considered…" "considered" is extremely vague. "estimated" would be better. However, the text that follows does not support this claim. It merely indicates that retreads have less tire volume than the original tread. Why does this imply more wear? And what does more wear really mean – a higher rate of wear in terms of mass per stop, mass per time, mass per mile?

RESPONSE: this is another issue that is commonly known. The references include some other interesting facts, however, the report now lists that modeling emissions from retreads is beyond the scope of the report in Section 3.1 .

14/6: any statement that starts with "According to the literature" must end with one or more cited references.

RESPONSE the subsequent paragraphs and table have many references on the technique that is introduced in this sentence.

Page 15: Table 3-1 appears but I cannot find anywhere in the text where it is mentioned or discussed. If it is not mentioned or discussed, why is it here, or if it is here, why isn't it mentioned or discussed? Also, clarify specifically what is meant by the tire wear rates – are these rates per vehicle and, if so, based on how many tires per vehicle? The mass reported here is for what PM size range? Why isn't Luhana et al. (2004) summarized in this table, since it is the only reference really used?

15/1/1-2: delete “that have been carried out”

15/2/2: “m9ass” should be “mass”

15/3/2: delete “That being said” (too colloquial for a formal technical report).

15/4/2: change to “with results reported either as”

16/1: there is a disconnect between stating that data are primarily from one reference and yet that reference is not included in the summary table just above.

16/1/middle – there are syntax problems here.

Table 3-2: caption is too vague. What type(s) of vehicles? What type(s) of tires? What is the source of these data? The table is not very clear either – e.g., mean tire weight loss “mg/km” – does this refer to per tire or per vehicle? The numbers reported in the table have inconsistent numbers of decimal places and/or significant figures.

17/1: does mg/vkm refer to all tires on a vehicle, or one tire? Clarify throughout.

17/2/1: “the tables below” – cite the specific table(s).

Table 3-3. The caption “Data used for the analysis” takes the prize for vagueness. I don’t think there could be a more meaningless caption. The caption should specifically indicate the content of the table. The lack of thought that went into this table is frustrating for the reader. These are some examples: “Front-wheel drive vehicles only” is not a valid column header, it should be part of the caption; “units” does not describe what is in the first column, yet why not use the same labels for both Tables 3-2 and 3-3 to denote the same tests (i.e. be consistent); the average trip speed of the first data row of 90.3 km/hr is not the same as the corresponding number in Table 3-2; is the tire weight loss per tire or the sum of both wheels on the axles? i.e. are the units g/km-axle or g/km-tire?; total weight loss for all tires (could be more clear) and could have one superheader over both of the columns that contain this information. Why is average speed given in the 2nd and 7th columns, rather than in adjacent columns if the only difference is a units conversion?; where do these data come from (what reference), and why not (in the footnote) specifically state the year, make, and model of each vehicle?

RESPONSE: This and other tables throughout the report have more descriptive captions now. The table has also been reformatted and redone so that the information is more clear to the reader.

Figure 3-1 and 3-2: the caption should indicate the vehicle type and whether the g/mi is per tire or per vehicle. If per vehicle, based on the assumption of how many tires/vehicle? Also, are mean trips speeds based on a particular time period of travel? One could divide a trip arbitrarily into short segments and obtain a wider range of mean trip speeds. However, if the averaging time is something like 60 seconds, 600 seconds, or 3000 seconds, that would affect the appropriate use of these rates.

RESPONSE: The paper does not specify the trip times.

Figure 3-2 – this figure seems unnecessary. The fitted curve is in Figure 3-2. If the purpose is to show the curve extrapolated beyond the range of the observed data, this could be done in figure 3-1 by using a dashed line for the fitted curve when it is outside the range of mean trip speeds.

RESPONSE: this figure has been removed.

19/1/1: rewrite as "Based on extrapolation of the fitted curve, wear is highest at zero speed and decreases as the speed increases." Why is this counter-intuitive? Lower mean trip speed might imply more variability in speed and, hence, more acceleration/deceleration(braking) that could increase tire wear. Thus, to me, this curve is intuitive. Delete "it is important to note" which is a passive phrase that has no content. The statement that "the relationship" does not take accelerations (and turning) into account is probably false. Aren't these data based on real-world driving? If so, then the observed wear rates implicitly take into account these factors, and the curve is fitted to these data – thus, the curve implicitly accounts for these.

RESPONSE: more text is included in this section to help clarify why the authors believe why some readers may believe this to be counterintuitive.

20/1/2: how is it known that the vehicle is "braking hard"?

RESPONSE: this is a descriptive term, not scientific. We do not feel that change to the text is required.

20/1/2-4: text here is a bit awkward… could say that there is insufficient data to characterize tire wear on a second by second basis to enable binning by operating mode bins.

20/2/1: this first sentence needs to be stated up front – i.e. that this section focuses on LDVs. Tire wear rates for other than LDVs should be in a new section. The assumption that tire wear is just based on the number of tires also presumes that tire wear for larger tires is the same as for LDV tires, and that tire wear is the same regardless of the ratio of weight/number of tires on a vehicle. These assumptions should be more clearly enumerated and discussed. Might it be the case that all else being equal (e.g., weight, acceleration, speed, road surface, etc.), tires with larger tread surface in contact with the ground would have less wear, but that more weight per tire would increase wear?

RESPONSE: We added a sentence at the beginning of Section 3.2 stating that the analysis starts with light-duty, and then is extended to other vehicle types. A number of engineering assumptions were required here. There is clearly a lack of information in the literature (as of when this study was completed) that would give emission rates for a variety of regulatory classes. A paragraph was added on future work.

20/2/4: Should say "The latter data were found in the …" s

Table 3-4: does the 2002 VIUS Survey report the number of tires per truck? Or the number of axles? If the latter, then it is not valid to imply that the number of tires is from the survey.

However, in either case, the survey can be cited with appropriate explanatory text in a footnote. The report is inconsistent in how vehicle categories are defined and described. If "regclass" is actually used here, which doesn't' seem quite right (aren't these source id?), then also give the MOVES code associated with each for complete clarity. There is no way that there are 519 billion LDVs in the U.S. – something is wrong with all of the numbers in the 3rd and 4th columns of this table. Some explanation is needed of the "Tires Per Vehicle" – this must be "Average Tires Per Vehicle," since no vehicle can have 5.5 or 14.9 tires, and 7 tires would also be quite unusual. Some explanation of the basis for the number of tires per vehicle for each vehicle type is needed. The assumption that the number of tires for LDT is the same as for LDV seems reasonable, but should be explained – i.e. LDT includes SUV, minivan, and pickup trucks which are typically 4 wheels. Larger pickup trucks that might have 6 wheels are not considered or do they fall into another category?

> *RESPONSE: We added clarification in the Table heading, that the tires were calculated from the 2002 VIUS Survey axle count. We also removed the survey weighting factors that were not helpful from for the reader. We also, specify that the Tires are calculated as the averages in the Table headings, which can yield the non-integer numbers. As discussed in the MOVES2014 Population and Activity Report, trucks with 6 wheels are classified in RegClassID 41, not as LDT.*

20/3/1: text refers to "Table 5" – should this be Table 3-5? (but Table 3-5 seems to be on a different topic).

20/4: This paragraph is unclear. It starts by stating that probably less than 10% of car tire wear is emitted as PM10 based on Boulter (2005a) and then goes on to say that results of Kupiainen et al. (2005) were used by Boulter. If Kupiainen is the original source of the data/information, then this could be more clear and conveyed consistently in the paragraph. Also, here and in general throughout the report, clarify if the mg/vkm values are per tire or per vehicle.

> *RESPONSE: this sentence was removed. Kupiainen and Boulter are research collaborators and co-authors, judging from their series of publications.*

20/5: what is the basis for assuming 8% of total tire wear is PM10 and that 15% of PM10 is PM2.5 For clarity, what happens to the other 92% of tire wear? Is it assumed that none of it ever re-emitted to the atmosphere?

> *RESPONSE: References and description of how the 8%, and 15% mass fractions were selected are added in Section 3.2. We also added a footnote (h) describing how the PM10/PM2.5 ratio is derived from the PM mass fractions in Section 3.2.1.*

Table 3-5: please clarify if the g/mi tire wear is per vehicle or per tire. What is "avgbinspeed" and "RegclassID" – should define/explain in footnotes. The last 8 columns need a superheader of "Regulatory Class" and it would help if each of the individual columns included descriptive

text in the header. Avebinspeed should have units. SpeedBinID and OpModeID also need to be defined/explained.

Response: The previous table is removed, and is replaced with Table 3-4, which includes output by MOVES2014 by sourcetypeID. We also specify that the tire wear emission rates are per/vehicle-mile. We also included information on the exact rates used in MOVES (g/hour), in Appendix B.

21/1: for clarity, insert information that 15% of the mass of PM10 is estimated to be emitted as PM2.5.

For the references, the reference format does not seem to follow any standard convention.

Response: We have provided information such that readers can find the sources.

D.7.2 Dr. Joe Zietsman

Overall, this report on brake and tire wear emissions in MOVES 2014 is well documented and satisfactory. Most of my comments are related to clarifications that are needed rather than methodological issues.
